The fourth and final phase of this work was the measurement of several alloys of special interest. Figure 15 shows a magnetostriction curve on the Ferroxcube specimen. The magnetostriction was less than 1×10^{-6} for all values of the field up to 600 oersteds. This result is in accordance with the theory of ferrites in which oxides are present in the proper proportion to obtain approximately zero magnetostriction.[15] Figure 15 also shows curves of magnetostriction obtained on tape specimens (0.002 in.×0.250 in.) of iron-cobalt alloys having 65, 70, and 75 percent cobalt. The tape was given 95 percent cold reduction, wound into a specimen form (2.0 in. I.D., 2.5 in. O.D.) and the turns consolidated by impregnating in Bakelite. Values of 120, 130, and 114×10^{-6} were obtained respectively. A value of 80×10^{-6} had previously been reported[16] on the alloy containing 65 percent cobalt. In our specimens, we have oriented the domains transversely by drastic cold work so that the maximum change in length is observed when the domains are oriented by the applied field. The value of 130×10^{-6} obtained on the 70 percent cobalt alloy is one of the highest values of magnetostriction reported in the literature.

CONCLUSIONS

The curves obtained on Alnico V show that its magnetostriction depends upon heat treatment, the values ranging from 22 to 35×10^{-6}. The highest value of 35×10^{-6} was for the cooling rate which gives optimum permanent magnet properties. If we include the magnetic field treatment, the magnetostrictive values of Alnico V vary from 2.5 to 43×10^{-6} or more than a tenfold variation. The low longitudinal value is due to the fact that most of the domains are oriented either parallel or antiparallel to the magnetization and a 180° reversal of the domains does not contribute to the change in length. The high transverse value is due to the fact that most of the domains are oriented at right angles to the magnetization and each domain contributes to a change in length. The behavior of magnetostrictive specimens of Alnico V which were treated in longitudinal and transverse fields was in accordance with domain theory, as has been pointed out by Hoselitz and McCaig.[17] They concluded from their measurements that the domain magnetization is along the easy crystallographic direction which makes the smallest angle with the axis of anisotropy. However, our data indicate that the domain magnetization is more closely aligned with the direction of the field applied during heat treatment (see Figs. 9 and 10).

The alloys in the immediate vicinity of Alnico V have yielded substantial but not quite as high values of magnetostriction as Alnico V. The alloy containing 6 percent aluminum had a maximum magnetostriction of 25.5×10^{-6}, the standard 8 percent aluminum alloy had a maximum magnetostriction of 35×10^{-6} while the 10 percent aluminum alloy had a maximum value of 19×10^{-6}.

As a result of the investigation of the magnetostriction of permanent magnets having various coercive forces it appears that for alloys hardened by carbon (tool steel, cobalt steels) there is a rough linear relationship between magnetostriction and coercive force for the alloys tested. When we include the carbon-free magnets in the comparison such as Alnico, Vicalloy, Remalloy, Cunico, and the iron-nickel-aluminum system, the linear relation no longer exists. For example Alnico V has over twice the coercive force of Honda steel but its magnetostriction is only 60 percent of that of Honda steel. Likewise the Remalloy and Vicalloy specimens measured had ap-

proximately the same coercive force but the magnetostriction of the Vicalloy was twice that of Remalloy. Cunico had a low magnetostriction and a low indentation hardness compared with its high coercive force of 445 oersteds. Finally many of the iron-nickel-aluminum alloys had a low magnetostriction combined with a high coercive force and for some of these alloys the magnetostriction actually became zero (Fig. 13).

On the basis of this experimental work one can say that the coercive force of some of the iron-nickel-aluminum alloys does not depend on the magnetostriction. Also, it may be concluded that in the other carbon-free alloys investigated, the magnetostriction is not the only factor operating in these systems to produce the high coercive force, especially in the case of Alnico V since this alloy is directly related to the iron-nickel-aluminum system. For the three carbon-hardening alloys investigated it appears that there may be a close relation between magnetostriction and coercive force.

Recent theories of coercive force have emphasized inhomogeneity of composition and fine particles as well as internal stress. The results obtained in this paper suggest that inhomogeneity of composition or the existence of fine particles is the controlling factor in the iron-nickel-aluminum system and that they may be a factor in the other carbon-free alloys investigated.

The use of a reservoir of liquid to collect ribbons of thin sections as they are cut enables serial sections to be obtained and provides means for detecting variations in thickness. Reducing the effects of static friction and of external vibrations makes it possible to cut long series of sections 0.2μ thick and uniform to better than five percent. Some observations which may throw some light on the mechanics of the cutting process are reported. Mounting the sections without any treatment is shown to be superior to any technique in which the embedding material is removed or replaced. It is shown that the technique provides sections in which a structural resolution of 200A is possible. The remaining artifacts introduced by the sectioning and mounting are easily recognized deformations which do not influence the interpretation.

I. INTRODUCTION

ANY analysis of the requirements for the widespread application of the electron microscope in the fields of biology and medicine leads directly to the necessity of sectioning tissue routinely at thicknesses of the order of 0.2μ, preferably serially. Its acceptance by the cytologists, who will ultimately be the users, will depend entirely on the ability of the technique to provide resolution of structure and freedom from artifacts considerably beyond those obtained by the conventional techniques of histology and cytology. Pease and Baker[1] made a major contribution to this work when they demonstrated that it is feasible to cut sufficiently thin sections by relatively simple modifications of conventional microtomes and techniques. Viewed in retrospect, their subsequent work and that of the workers who followed their technique shows rather large scale artifacts. A simple check with a light microscope shows that these artifacts are of considerably greater magnitude than would be expected from the fixation and imbedding used. It must be assumed therefore, that the artifacts were introduced by the sectioning technique or the subsequent manipulation of the sections. The research reported in this paper involves a careful analysis of the Pease and Baker technique with the result that many of the sources of artifacts have been identified and removed.

The complete problem of examining tissues with the electron microscope involves: (1) the selection and fixation of the tissue, (2) embedding, (3) sectioning, and (4) mounting of sections. The first two steps include a number of variables about which no information can be

obtained until the last two are developed to the point where routinely reproducible results are possible. Thus the work described in the following was all carried out on a set of specimen blocks obtained from osmium-perfused mouse liver. Actually the livers from only two mice were used and all the blocks from each liver were embedded simultaneously by the technique described in Pease and Baker's original work.[1]

II. SECTIONING: BLOCK ADVANCE

In spite of its multiplicity of moving parts, the Spencer rotary microtome (No. 820) has proved to be ideal for the cutting of thin sections. In this machine the knife is stationary and the block is moved vertically to make the cuts and advanced horizontally between cuts. In the mechanical design of the Spencer microtome, these two motions are intimately related and will be considered in the discussion concerning the advancing of the block. It was found that for very thin sections which require little cutting force the actual sectioning (that is, the action of the knife on the block) is not related to the advancing of the block except under some rather special conditions.

The reservoir for collecting and spreading the specimens serially, described by Gettner and Hillier[2,3] also proved very useful for testing the operation of the advance mechanism. It was found that for a given block, knife, cutting speed, and reservoir liquid the length of the floating section (in the direction of cutting) is a direct function of the thickness of the cut. The shortening of the sectioning is first appreciable at 0.3μ and increases rapidly with decreasing thickness, usually being greater than 50 percent for sections of 0.1μ thickness. Thus, the lengths of successive sections observed at a magnification of 27, as they appear, provides a sensitive criterion of the uniformity of thickness. By this means it has been possible to identify several sources of variations in the advance mechanism: (1) static friction, (2) vibrations of external origin, and (3) thermal expansion. In an unchanged Spencer microtome, operated by hand, these effects produce variations in thickness of the order of 0.2μ which while insignificant in normal sectioning are much too great for ultra-thin sectioning. *It is to be noted, from the discussion which follows, that modification of the method or magnitude of advance has no effect on these sources of variations (except possibly a slightly detrimental one).* Further refinements are necessary therefore, if sections of uniform thickness at the 0.1μ level are to be cut properly.

FIG. 4. Normal mouse liver cut at 0.2μ. Embedding was completely replaced with collodion. Micrographed with a double objective with limiting aperture set at 4×10^{-3} radian. This section demonstrates a uniform compression of approximately 40 percent which means that the actual specimen is more than 0.3μ thick. Destructive "knife marks" due to edge defects 8 and 2μ long are visible. All of the micrographs presented in this paper were with a standard RCA Model u.c. operating at 50 kv. Magnification approximately 900×.

The advance mechanism of the Spencer microtome consists of a series of mechanical reductions.[4] At the top of each cutting cycle, a pawl actuated by the drive wheel engages a toothed ratchet wheel and advances it one tooth for the unit advance. Coaxial with, and rigidly attached to the wheel is an accurately threaded rod which engages a threaded nut. The nut in turn is rigidly attached to a pointer which rides against an inclined plane, an integral part of the specimen block holding and moving system. The forward motion of this last unit is guided by a set of horizontal slides which also support it. A spring keeps the inclined plane in contact with the pointer. The cutting is accomplished by moving the block and its support, including the spring, inclined plane, and horizontal slides, in a set of vertical slides. The cutting motion is sinusoidal and has an amplitude of 5 cm. Since the pointer is stationary, it traces a line on the inclined plane approximately vertical and approximately perpendicular to the inclination. If the normal to the inclined plane were in the horizontal plane, or, more precisely, perpendicular to the direction defined by the vertical slides, the true motion of the specimen block would be parallel to the vertical slides. Under this condition there would be no motion of the block support relative to the horizontal slides during the cutting movement. Actually, it is an important feature of the Spencer microtome that the normal to the inclined plane usually makes a small angle to the horizontal. This means that, as the block makes its vertical excursion of 5 cm, it also makes a horizontal excursion of several microns (300 in our case). Thus, there is relative motion in the horizontal slides some time before and during the actual cutting. By this simple means, the large varia-

[4] O. W. Richards, *The Efficient Use and Proper Care of the Microtome* (American Optical Company, Buffalo, New York, 1949), second edition, p. 84.

tions in the advance of the block caused by static friction in the horizontal ways are almost completely eliminated. Some crude tests indicated that the force required to overcome the static friction in the horizontal slides was such as to produce a deformation of between 1 and 2μ in the inclined plane and block support. Thus if the horizontal excursion were eliminated and the advance set at 0.1μ, the specimen would still advance in 1 to 2μ steps and be cut only after every 10 to 20 cutting cycles. The horizontal excursion also means that any "play" in the vertical slides or any flexibility in any other associated parts is taken up by the same amount in each cycle.

It was found that for ultra-thin sections static friction in the horizontal slides still produced greater variations than were desirable. This was due to the fact that the relative motion in the horizontal slide stopped and reversed at the top and bottom of each cutting cycle allowing static friction to introduce variations which were not entirely removed by the time the block reached the knife. The addition of considerable extra weight in the modification of the inclined plane aggravated this situation. The variations in section thickness were then of the order of 0.05 to 0.1μ. In view of the reduced total advance in the modified system, it was possible to eliminate these variations by removing about 90 percent of the weight of the block support and modified inclined plane from the horizontal slides. To do this, a short coil spring of the proper tension was inserted between the rear point of attachment of the main spring and the lower brace for the inclined plane. While this was satisfactory, it was found more convenient to use a leaf spring mounted on the top of a new block which also serves to secure the back end of the main spring. The lifting force is applied to the block support by a bent rod which hooks under the lower brace of the inclined plane. The upper end of this rod is threaded and secured to the end of the leaf spring by a small nut. Thus the lifting force can be adjusted. The horizontal excursion of the block and the total advance are permitted by the fact that the leaf spring can twist and that neither end of the bent rod is rigidly attached.

The modification of the inclined plane used follows the principles described by Pease and Baker. There are, however, a number of specific points of difference. The modification consists of machined iron block which slips over the original inclined plane. It is held in place by eight pointed set screws which grip the original plane behind its top and bottom edges. There is close contact between the top and bottom edges of the original plane and the block but none in the central region. The new inclined plane is a selected piece of plate glass which is flat to within two fringes of sodium light. It is fastened to the iron block by embedding in Woods metal. Before embedding, the glass plate was adjusted to the proper position, by what amounts to three leveling screws threaded into the block.

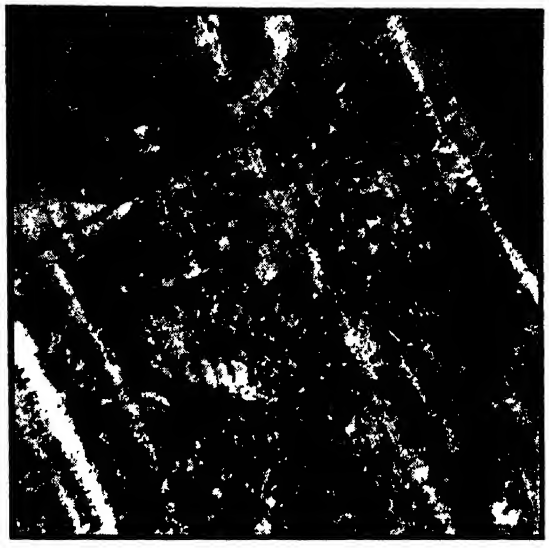

FIG. 2. Normal mouse liver cut at 0.2μ. Embedding was left intact. Micrographed with conventional objective but with focal length of approximately 8 mm and limiting aperture set at 3×10^{-3} radian. This shows a number of fine folds perpendicular to the direction of cutting caused, in this case, by the greater compression which occurred in the thinner strip which separates the two rows of folds. Note also that the "knife marks" are more evident than in Fig. 1. Magnification approximately 900×.

The unit of advance was set at 0.02μ. This low value was not chosen with any thought that sections of this thickness could be cut, but rather to overcome possible variations due to static friction in the slides that support and guide the pointer between the nut and the thread and in the end bearings of the thread and drive wheel. With this arrangement, sections of thickness 0.2μ which have been found most suitable require a rotation of the drive wheel and thread of 16.4° and a movement of the pointer of 20μ. Both of these movements are large enough to be accurately reproducible. This means also reduces the effects of inaccuracies in the threaded rod.

Variations of section thickness equal in magnitude to those put in by the effects of static friction are introduced by vibration of the microtome or of its support. The main trouble in this respect was traced to the irregularities of manual operation of the instrument. It was successfully overcome by adding a motor drive. A small 1/15 hp motor was used with a built-in reduction gear that gave 30 r.p.m. The motor was ballasted and shock mounted on sponge rubber separately from the microtome. In order to avoid transmission of vibrations through the coupling to the microtome and also to avoid difficulties of accurately aligning the drive shafts of the microtome and the motor, a special coupling was devised. The power is transmitted through a strip of Neoprene (approx. $\frac{1}{16}\times\frac{3}{8}\times1\frac{1}{2}$ in.) from the end of a 3-in. long bar clamped to the motor output shaft to a pin set in the microtome drive wheel, also 3 in. from the axis. The Neoprene seems to have the right degree of elasticity with the proper damping for the arrangement

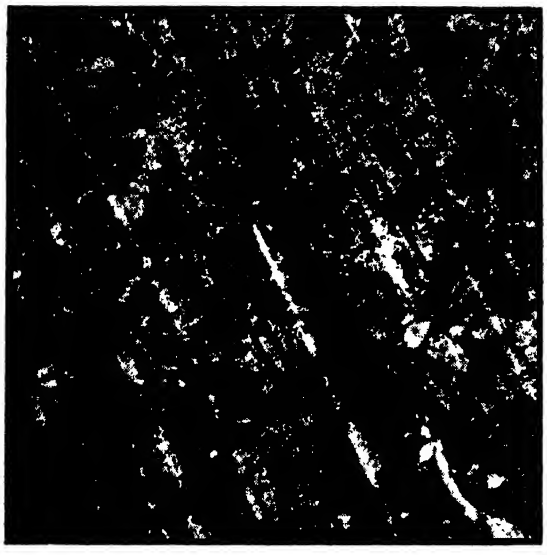

FIG. 3. All conditions identical with those of Fig. 2. Here a dense granule has been carried by the knife splitting the section until it was left on the section. Note that some of the denser "knife marks" appear to consist of a homogeneous material (paraffin?) which has been left on the specimen. Magnification approximately 900×.

used. Direct coupling by means of a wire loop or coupling through a coil spring under tension produced periodic variations in thickness.

A brass plate was added to the drive wheel of the microtome to counterbalance accurately the change in weight of the horizontal member caused by the addition of the modifications.

The instrument remains extremely sensitive to externally produced vibrations. In fact, resting a finger very lightly on any part of it will introduce variations in thickness amounting to 0.05 to 0.1μ. Building vibrations caused by nearby traffic also cause variations. Although it was not done in this work, it would be desirable to mount the instrument on a high inertia vibration-free support.

Thermal changes in the instrument are the only remaining major source of thickness variations. The time constant of these changes is so long, however, that with motor drive, the effect is more one of a disturbance of calibration. Thus, it cannot be detected directly by observation of the uniformity of compression as the sections appear on the liquid surface. It can be detected, however, by setting the advance to zero and observing the cutting through a low power microscope. A continuation of cutting or delay in returning to cutting when the advance is set to a finite value indicates the presence of thermal changes. More recently it has been found that an accurate estimate of the direction and amount of thermal drift can be obtained by the following procedure. The machine is allowed to cut a series of sections of desired thickness, say 0.2μ, then within one cycle the manual advance crank is turned backward one turn while the machine is allowed to continue operating. This represents a retraction of the block by 25 0.2μ sections. The knife is observed and the cutting cycles counted until the first new section is cut. This should happen on the 26th cycle. Any deviation will indicate the presence of thermal drifts. Furthermore, the amount and direction of the deviation will enable the true thickness of the cut to be calculated to within four percent in this example. More than one turn of the crank can be used if higher accuracy is desired. The method has the advantage that any disturbance introduced by touching the instrument is completely damped out by the time a new cut is made.

The most important source of thermal changes has been from the use of a focused light to illuminate the edge during observation. This practice has now been discontinued in favor of using a large fluorescent light placed some distance above the instrument. Ordinary changes in room temperature introduce little effect though it is essential that the instrument be placed in a location free from strong air currents.

A possible source of variations which has not yet been studied is in the thickness of the oil film which lubricates the vertical ways. Variations in the thickness of this film of 40A would be detectable under optimum conditions. Obviously such changes could occur. Furthermore, the "working in" of an oil film of different thickness could produce periodic variations. In practice, very little lubrication (Pike oil) has been used and the microtome is run at zero setting for several minutes before sections are cut. These are mainly precautionary measures and may prove unnecessary.

A final point which should be mentioned in connection with the function of the advance mechanism is in regard to the adjustment of the slides. This proved to be simpler than was expected because the cutting force required for the thin sections and very small blocks is very small. This force is never sufficient to lift the weight of the block supporting mechanism from the lower of the horizontal slides, nor to separate the rear of the vertical slides against the tension of the main spring. Thus, since a transference of the reactive force from one slide to the other never occurs in either set, there is no need to adjust the slides so that there would be no displacement of the block if such a transfer were to occur. In this work, the slides are adjusted so as to be very free running and are somewhat looser than would be considered good practice in ordinary microtomy.

III. SECTIONING: CUTTING

The interaction of the knife with the specimen which constitutes the cutting of sections is, as yet, a very poorly understood phenomenon. From this work it has become evident that defects in a knife-edge produce observable effects if they have dimensions of the same order as the thickness of the section cut. Thus it would appear that the cutting of ultra-thin sections will provide information regarding the nature of the edge at a level at least an order of magnitude below what was

previously possible and thus provide a very profitable approach to this fundamental problem.

It is apparent that the quality of the sections will be a complicated function of many variables, including in particular, the nature of the tissue, the fixation, the dehydration, the embedding, the sharpness and cleanliness of the edge, the bevel and clearance angles, the speed of cutting, the temperature, and the properties of the liquid in the reservoir. An attempt was made to reduce the number of variables by using only one specimen of fixed tissue cut into a number of pieces which were dehydrated and embedded simultaneously. Unfortunately, this leaves an uncomfortably large number of variables, at least two of which cannot be determined independently—namely, the sharpness and cleanliness of the edge. Nevertheless, some conclusions can be drawn from the observations already made.

For the work shown here, commercially sharpened knives were used throughout. It is recognized that such edges represent a compromise between quality and cost. More recently, hand-sharpened edges have been providing much superior results. The edges of the blades are examined at 400× by the scattered light technique described by Richards[2] and the facets by reflected light.

The fundamental defects in the sections obtained in this work consists of a uniform microscopic compression (Fig. 1), an accordian-like folding parallel to the cutting edge (Fig. 2) strips of partially destroyed tissue which run parallel to the direction of cutting (Fig. 1), and local distortions due to different cutting properties of different areas of the tissue. The last defect can vary in magnitude from the picking up by the blade of small hard granules which cut the sections until they are dropped (Fig. 3) to the folding of large areas. In passing, it should be mentioned that in material which is much harder than the embedding, there is a characteristic "chattering" phenomenon involving a rather uniform rearrangement of the tissue in 5 to 15μ steps.

The compression which appears as a microscopically uniform contraction in the direction of cutting is dependent on the nature of the tissue and the thickness of the section. It is definitely not dependent on the rake angle over the 6° range used in the tests. This is contrary to the experience of Baker and Pease.[5] This may be due to the presence of the liquid surface.

The accordion-like folding is peculiar to thin sections and does not appear in sections thicker than 0.3μ. It appears that the great flexibility of the sections permit them to fold whenever they encounter mechanical resistance beyond the cutting edge of the knife. As would be expected, the persistence of the folds is very sensitive to the cleanliness of the knife and to the surface tension and level of the liquid. It has been found necessary to adjust the surface tension and level of the liquid for many of the blocks. Observation of the sections at approximately 30× as they are cut provides a good criterion for these adjustments. It has been found that good sections appear suddenly and fully extended on the surface of the liquid. Moreover, they are transparent and nearly invisible. Poor sections appear to slide slowly on to the liquid from a folded condition near the edge of the blade and appear somewhat translucent.

A very special type of folding which cannot be removed is caused by a defect in the knife which cuts a thin track through the specimen without causing any destruction. The thinner line is more compressed with the result that the adjacent areas must fold to compensate for the change in length of the section (Fig. 2).

Large defects in the knife will simply split the section, but more often, a characteristic line of destruction is produced (Fig. 1). The latter occurs for nicks or other defects which are isolated and occupy more than 1μ of the length of the edge. Defects occupying a length of the edge approximately twice the thickness of the section appear to produce slight local deformations of the structure (Fig. 4).

Observations of long series of sections cut at one point of the knife indicate that the dulling is a step-by-step process involving an increase in the number of larger defects in the knife. A relationship has also been observed between the sharpness of the blade and the frequency with which it must be cleaned. A slow decrease in the lengths of successive sections and an immediate return to the original length upon cleaning is indicative of an edge that is in need of sharpening. Examination of sections produced by such an edge show a greatly in-

FIG. 4. A portion of the same section as shown in Fig. 1 taken at higher electronic magnification and with the same instrumental conditions. The nuclear membrane appears to be slightly deformed by a defect in the knife roughly estimated to be 0.5μ long. In comparing this with Fig. 6, note the thicknesses of the cell wall, the nuclear membrane, and the intracellular fibers. Note also that the granules in the cytoplasm appear hollow with dense walls. Magnification approximately 3,700×.

[5] R. F. Baker and D. C. Pease, J. App. Phys. 20, 480 (1949).

creased number of lines of destruction which are also somewhat wider than obtained with a sharp edge.

Another interesting observation on the nature of the edge can be made by retracting the block a few section thicknesses and moving the blade, parallel to itself, to a new position. If the first cuts are observed, it is found that they are invariably narrow strips, all parallel to the direction of cutting, which grow wider on each successive cut until a complete section is obtained. This usually requires a total advance of the block of something more than a micron. This clearly indicates that the cutting edge is not a straight line but is corrugated with an amplitude of approximately 1μ.

IV. MOUNTING AND MICROGRAPHY OF SECTIONS

The handling of the specimens after they have been cut depends to a certain extent on their thickness, the nature of the tissue, and the problem under investigation. From our work, it appears that earlier workers have grossly underestimated the delicacy of the cut sections and that it is in this stage of the work that most of their artifacts have been introduced.

A technique described by Pease and Baker[3] involved mounting the section on a glass slide, after it had been spread on dioxane, and allowing it to dry. It was then washed with benzene to dissolve out the paraffin. This was followed with 0.2 percent collodion in amyl acetate which washed out the collodion embedding but left in a thin layer to support the specimen. The section was then floated off the slide on to clean water and mounted on a 200-mesh screen for examination in the microscope.

This technique was found to introduce artifacts in two ways. While the dioxane is an excellent means of spreading and flattening the section at the concentrations used, it nevertheless introduces considerable distortions in a way that is not completely understood. The use of the dilute collodion solution meant that the final film was much thinner than the section and thus, in the final stages of drying, surface forces are allowed to act on the very fragile structures of the section. This produced gross distortion of all but the coarsest structures (Fig. 5). The technique was then modified to omit the dioxane and to use a two percent solution of collodion leaving enough of the solution on the section to dry down to a film that was slightly thicker than the section. This eliminated the distortions due to surface forces, but greatly reduced the contrast obtainable and introduced difficulties in making the sections adhere to the specimen screens.

FIG. 5. Section cut at 0.2μ from which the embedding was entirely removed and replaced with collodion in amyl acetate of such concentration and amount as to produce a dried film of approximately 400A thickness. That there are large scale distortions is obvious from comparison with 2, 3, and 6. No objective aperture. Magnification approximately 900×.

FIG. 6. A field selected for comparison with Fig. 4. The conditions of sectioning and micrography are the same with the exception that the embedding was not removed. Magnification approximately 3000×.

The contrast problem was overcome by raising the specimen to give an objective focal length of approximately 7 mm and by using a standard (50μ diam.) objective aperture resulting in an angular aperture of 3.5×10^{-3} radian.

This modified technique was finally abandoned when serial sections showed that merely dissolving the embedding material at any time after sectioning leaves many of the finer structures free to move. (Compare Figs. 4 and 6.)

The mounting technique now used involves no treatment of the section other than a mechanical mounting on a specimen screen (Figs. 6 and 7). A piece of 200-mesh copper screen (Elektromesh) 2×3 in. is etched in dilute nitric acid until it has at least 50 percent open area. A 300A thick collodion membrane is then mounted on this screen in the conventional way and dried. The sections

are mounted on suitable pieces of this screen by lifting them directly from the collecting reservoir. It is important that the prepared screen be lowered in to the liquid in a nearly vertical position but with the collodion membrane on the underside and that it be moved slowly through the liquid with film-side facing the direction of motion. After the sections are lifted from the liquid, the blank side of the screen is immediately blotted with hard dry filter paper and as much liquid as possible is drawn out from between the sections and the film.

The use of the extra film has successfully overcome the difficulty of anchoring the sections to the screen. In these sections there remains a problem of shrinkage under moderate electron bombardment. It can be avoided by raising the intensity quite slowly on each new field. Shrinkage of the section from around the screen openings can be avoided by placing the mount in the microscope with the sections facing the electron source, so that the whole area bombarded is seasoned uniformly.

The use of some dioxane (less than 50 percent) in the reservoir has been found to improve the flattening of the section in some cases, but requires that they be treated much more carefully under bombardment.

V. EXPERIMENTAL RESULTS AND DISCUSSION

Using the techniques described above, a large number of micrographs of the osmium-perfused liver have been obtained in which the structures have been consistent. The structure resolution is between 200 and 300A for the 0.2μ sections used. It is obvious that many new structures are being observed though their significance and even their reality are yet to be determined. Several artifacts introduced by the sectioning technique are still present. These include compression, folding, knife marks, shrinkage under bombardment, and occasional removal or shifting of material. However, all of these defects are quite obvious and do not interfere with the correct reading of the micrographs. It would be desirable, of course, to eliminate these as they detract from the esthetic value of the micrographs and can be annoying.

As indicated in the beginning, this investigation concerned only the factors involved in the cutting of uniformly thick sections and in the mounting for electron microscopic examination. The tissue, fixation, and

FIG. 7. A representative field of a 0.2μ section mounted with the embedding intact. Magnification approximately 1800×.

embedding was maintained as constant as is possible in biological preparations. A type of tissue and a technique which had already been shown to be quite favorable for the problem were chosen. It is to be noted, however, that the refinements introduced are only slightly dependent on the nature of the preparation. This is not true of the cutting properties which can vary widely according to the nature of the tissue of the fixative, or of the embedding.

A number of other preparations have now been sectioned with varying degrees of success. However, while experience in this respect has not suggested any modifications in the techniques described above, it has emphasized the necessity of adjusting the embedding very carefully to the properties of the specimen and the technique of fixation and the need for sharper knives.

ACKNOWLEDGMENTS

The authors wish to thank Drs. J. J. Biesele and J. A. Jacquez for providing carefully prepared specimens and for their valuable discussions of the resulting micrographs. Thanks are also due Miss G. Cohn for her assistance in the embedding and mounting of the blocks.

Reflection and Transmission of Electromagnetic Waves by Thin Curved Shells*

The scattering of an arbitrary electromagnetic field by a conducting or non-conducting obstacle is investigated. The differential equations and boundary conditions satisfied by the field are transformed into a pair of inhomogeneous linear integro-differential equations for E and H. For an obstacle which is a thin shell of constant thickness h, a formal procedure for obtaining a solution of these equations as power series in h is given. The lowest order term in this solution is the incident field. An explicit expression for the next term is found in the form of a surface integral. This integral is evaluated approximately by the method of stationary phase. The physical properties of the solution are examined in detail, and satisfactory agreement is found with many results previously obtained by other methods.

1. INTRODUCTION

WE wish to find the electromagnetic field which results when a given incident field strikes an obstacle—more precisely the field produced by a given source in the presence of an obstacle. For some special obstacles the problem has been solved exactly, and for arbitrary obstacles several approximate methods are available (geometrical optics,[1-3] Kirchhoff method,[3,4,5-7] Rayleigh scattering formula). Recently, Professor H. Primakoff and the author treated the corresponding acoustic problem for thin shell obstacles by a method which takes account of propagation within the obstacle and includes the results of the methods listed above.[3] In this paper the same method is applied to electromagnetic scattering by thin shells.

In Section 2 the problem is formulated and converted into an inhomogeneous integral equation. In Section 3 an approximate solution is obtained for an obstacle which is a thin shell. In Section 4 the integral representing the approximate solution is evaluated and in Section 5 the solution is examined and compared with other results. Many of the omitted details may be found elsewhere.[3,8]

2. DERIVATION OF THE INTEGRAL EQUATION

An obstacle (b) is immersed in an infinite medium (a), both being homogeneous and isotropic. A periodic source ($e^{-i\omega t}$) is located in (a). Outside the source the electric field $E(r)$ satisfies the reduced wave equation

$$(\nabla^2+k^2)E(r)=0. \tag{1}$$

Here $k^2=(\omega^2/c^2)\epsilon'\mu$; $\epsilon'=\epsilon+(4\pi i\sigma/\omega)$; $k\equiv k_a$ in (a); $k\equiv k_b$ in (b). (We shall write equations for E only; the corresponding equations for the magnetic field $H(r)$ are obtained by interchanging E with H and ϵ' with $-\mu$.) At the boundary between the two media the field satisfies the discontinuity conditions

$$E_t{}^a=E_t{}^b; \quad \epsilon_a'E_n{}^a=\epsilon_b'E_n{}^b. \tag{2}$$

Here n and t indicate normal and tangential components, and a, b indicate sides of the boundary, respectively. At infinity the scattered field $E-E_0$ satisfies a radiation condition. The source is characterized by $E_0(r)$, the field which would be produced in the absence of the obstacle. (We assume the obstacle does not affect the source.)

All these conditions and equations will be transformed into an integro-differential equation with the aid of a Green's function $G(r,r')$ which satisfies Eq. (1), with $k=k_a$ everywhere, with respect to the variable r'. At $r'=r$, G has a singularity of the form $1/(|r-r'|)$, and at infinity it satisfies a radiation condition. We apply Green's theorem to $G(r,r')$ and $E(r')-E_0(r')$, assuming $E-E_0$ has no singularities. We first integrate over the obstacle V bounded by S', then over the rest of space, and add, obtaining (r' is the integration variable)

$$E(r)-E_0(r)=\frac{1}{4\pi}\int_{S'}\left\{(E^a-E^b)\frac{\partial G}{\partial n}-G\left(\frac{\partial E^a}{\partial n}-\frac{\partial E^b}{\partial n}\right)\right\}ds+\frac{k_b{}^2-k_a{}^2}{4\pi}\int_V EG\,dv. \tag{3}$$

To evaluate the first difference occurring in the integrand in Eq. (3), we use Eq. (2). We find (n is the unit normal)

$$E^a-E^b=[(\epsilon_b'/\epsilon_a')-1]E_n{}^b n. \tag{4}$$

The evaluation of the second difference is more difficult and requires the use of Eq. (2), Maxwell's equations and the use of curvilinear coordinates. The lines of curvature on the boundary surface S', designated as $u_1=$const., $u_2=$const. are employed. We finally obtain (see reference 8 for details)

$$\frac{\partial E_n{}^b}{\partial n}-\frac{\partial E_n{}^a}{\partial n}=\left(\frac{\epsilon_b'}{\epsilon_a'}-1\right)E_n{}^b\cdot 2G_m, \tag{5}$$

$$\frac{\partial E_1{}^b}{\partial n}-\frac{\partial E_1{}^a}{\partial n}=\frac{i\omega}{c}(\mu_b-\mu_a)H_2{}^b+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\frac{\partial E_n{}^b}{\partial u_1}, \tag{6}$$

$$\frac{\partial E_2{}^b}{\partial n}-\frac{\partial E_2{}^a}{\partial n}=-\frac{i\omega}{c}(\mu_b-\mu_a)H_1{}^b+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\frac{\partial E_n{}^b}{\partial u_2}. \tag{7}$$

Here u_1 and u_2 represent arc length along the lines of curvature; E_1 and E_2 represent components along these lines and G_m is the mean curvature of the surface S'. (A curvature is positive if the center of curvature and positive normal are on opposite sides of S'.)

We now use Eqs. (4)–(7) in Eq. (3) and obtain (i_1, i_2 are unit vectors along the lines of curvature)

$$E(r)=E_0(r)+\frac{1}{4\pi}\int_{S'}\left\{\left(\frac{\epsilon_b'}{\epsilon_a'}-1\right)E_n{}^b\left(\frac{\partial G}{\partial n}+2GG_m\right)n+G\left[\frac{i\omega}{c}(\mu_b-\mu_a)(i_1H_2{}^b-i_2H_1{}^b)\right.\right.$$
$$\left.\left.+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\left(i_1\frac{\partial E_n{}^b}{\partial u_1}+i_2\frac{\partial E_n{}^b}{\partial u_2}\right)\right]\right\}dS+\frac{k_b{}^2-k_a{}^2}{4\pi}\int_V EG\,dV. \tag{8}$$

Equation (8) is the fundamental integro-differential equation for the field in the presence of an obstacle. The integrals represent the scattered field, and obviously vanish when the properties of the two media are the same.

3. SOLUTION FOR THIN SHELL OBSTACLES

Equation (8) may be simplified and solved if the obstacle is a thin shell of constant thickness h. Then S' consists of two parallel parts S_I and S_{II}, neglecting the edges. If r is exterior to the shell we may expand the integrands of Eq. (8) in Taylor series about points of S_I. Then Eq. (8) becomes approximately, for r in medium (a) (n is a unit normal to S_I pointing into the obstacle)

$$E(r)=E_0(r)+\frac{1}{4\pi}\int_{S_I}\sum_{m=0}^{\infty}\frac{h^{m+1}}{(m+1)!}\frac{\partial^m}{\partial n^m}\left[\frac{\partial}{\partial n}\left\{\left(\frac{\epsilon_b'}{\epsilon_a'}-1\right)\left(\frac{\partial G}{\partial n}+2GG_m\right)E_n{}^b n\right.\right.$$
$$\left.\left.+\frac{i\omega}{c}(\mu_b-\mu_a)G(i_1H_2{}^b-i_2H_1{}^b)+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)G\left(i_1\frac{\partial E_n{}^b}{\partial u_1}+i_2\frac{\partial E_n{}^b}{\partial u_2}\right)\right\}+(k_b{}^2-k_a{}^2)GE^b\right]dS. \tag{9}$$

If the edges are taken into account, we obtain another similar line integral over the curve bounding S_I in Eq. (9).

To solve Eq. (9) we represent the field in medium (a) as a power series in h,

$$E(r)=\sum_{\nu=0}^{\infty}h^\nu E_{(\nu)}(r); \tag{10}$$

insert this into Eq. (9) and equate coefficients of like powers of h. It is to be understood that all quantities in Eq. (9) evaluated on side b are to be replaced by appropriate quantities on side a. We then find that $E_{(0)}=E_0$, and that all succeeding terms can be determined successively as surface integrals.

For $E_{(1)}(r)$ we obtain

$$E_{(1)}(r)=\frac{1}{4\pi}\int_{S_I}\left\{n\left[\left(\frac{\epsilon_b'}{\epsilon_a'}-1\right)\left(\frac{\partial^2 G}{\partial n^2}+2G_m\frac{\partial G}{\partial n}\right)E_{n(0)}{}^b+\left(\frac{\epsilon_b'}{\epsilon_a'}-1\right)\left(\frac{\partial G}{\partial n}+2GG_m\right)\frac{\partial E_{n(0)}{}^b}{\partial n}+(k_b{}^2-k_a{}^2)GE_{n(0)}{}^b\right]\right.$$
$$+i_1\left[\frac{i\omega}{c}(\mu_b-\mu_a)\right)\left(\frac{\partial G}{\partial n}H_{2(0)}{}^b+G\frac{\partial H_{2(0)}{}^b}{\partial n}\right)+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\left(\frac{\partial G}{\partial n}\frac{\partial E_{n(0)}{}^b}{\partial u_1}+G\frac{\partial^2 E_{n(0)}{}^b}{\partial n\partial u_1}\right)+(k_b{}^2-k_a{}^2)GE_{1(0)}{}^b\Big]$$
$$\left.+i_2\left[-\frac{i\omega}{c}(\mu_b-\mu_a)\left(\frac{\partial G}{\partial n}H_{1(0)}{}^b+G\frac{\partial H_{1(0)}{}^b}{\partial n}\right)+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\left(\frac{\partial G}{\partial n}\frac{\partial E_{n(0)}{}^b}{\partial u_2}+G\frac{\partial^2 E_{n(0)}{}^b}{\partial n\partial u_2}\right)+(k_b{}^2-k_a{}^2)GE_{2(0)}{}^b\right]\right\}dS. \tag{11}$$

The integrand involves the field and its derivatives on the b side of S_I, and these must be replaced, using

Eqs. (4)–(7), by corresponding quantities on the a side. Equation (11) then becomes

$$E_{(1)}(r)=\frac{1}{4\pi}\int_{S_I}\Big\{n\Big[E_{n(0)^a}\Big(1-\frac{\epsilon_a'}{\epsilon_b'}\Big)\Big(\frac{\partial^2 G}{\partial n^2}+2G_m\frac{\partial G}{\partial n}\Big)+\Big(\frac{\epsilon_b'}{\epsilon_a'}-1\Big)\Big(\frac{\partial G}{\partial n}+2GG_m\Big)\Big(\frac{\partial E_{n(0)^a}}{\partial n}+2G_mE_{n(0)^a}$$
$$\times\Big[1-\frac{\epsilon_a'}{\epsilon_b'}\Big]\Big)+(k_b^2-k_a^2)\frac{\epsilon_a'}{\epsilon_b'}GE_{n(0)^a}\Big]+i_1\Big[\frac{i\omega}{c}(\mu_b-\mu_a)\Big(\frac{\partial G}{\partial n}H_{2(0)^a}+G\frac{\partial H_{2(0)^a}}{\partial n}$$
$$+\frac{i\omega}{c}G[\epsilon_b'-\epsilon_a']E_{1(0)^a}+G\Big[\frac{\mu_a}{\mu_b}-1\Big]\frac{\partial H_{n(0)^a}}{\partial u_2}+\Big(\frac{\epsilon_a'}{\epsilon_b'}-1\Big)\frac{\partial G}{\partial n}\frac{\partial E_{n(0)^a}}{\partial u_1}+G\Big(1-\frac{\epsilon_b'}{\epsilon_a'}\Big)$$
$$\times\Big(\frac{\partial^2 E_{n(0)^a}}{\partial u_1\partial n}+2G_m\Big[1-\frac{\epsilon_a'}{\epsilon_b'}\Big]\frac{\partial E_{n(0)^a}}{\partial u_1}\Big)+(k_b^2-k_a^2)GE_{1(0)^a}\Big]+i_2\Big[-\frac{i\omega}{c}(\mu_b-\mu_a)\Big(\frac{\partial G}{\partial n}H_{1(0)^a}$$
$$+G\frac{\partial H_{1(0)^a}}{\partial n}-\frac{i\omega}{c}G[\epsilon_b'-\epsilon_a']E_{2(0)^a}+G\Big[\frac{\mu_a}{\mu_b}-1\Big]\frac{\partial H_{n(0)^a}}{\partial u_1}\Big)+\Big(\frac{\epsilon_a'}{\epsilon_b'}-1\Big)\frac{\partial G}{\partial n}\frac{\partial E_{n(0)^a}}{\partial u_2}+G\Big(1-\frac{\epsilon_b'}{\epsilon_a'}\Big)$$
$$\times\Big(\frac{\partial^2 E_{n(0)^a}}{\partial u_2\partial n}+2G_m\Big[1-\frac{\epsilon_a'}{\epsilon_b'}\Big]\frac{\partial E_{n(0)^a}}{\partial u_2}\Big)+(k_b^2-k_a^2)GE_{2(0)^a}\Big]\Big\}dS. \quad (12)$$

Equation (12) represents the scattered field to first order in h in medium (a). Only the integral over the edges has been neglected in obtaining this result. In the same way, the higher order terms in the solution may be obtained.

4. EVALUATION OF $E_{(1)}(r)$

To evaluate the integral for $E_{(1)}(r)$ in Eq. (12) we select for $G(r, r')$ the Green's function for infinite space:

$$G(r,r')=\frac{\exp(ik_a|r-r'|)}{|r-r'|}. \quad (13)$$

We assume that the incident field is given by

$$E_0(r)=\mathcal{E}(r)\exp(ik_a|r-r_0|), \quad (14)$$

where $\mathcal{E}(r)$ is slowly varying compared to the exponential factor, in the vicinity of the obstacle. This is exactly true for a plane wave ($\mathcal{E}$=const.) and for other sources it becomes more accurate as the distance from the source increases. The position r_0 is an equivalent center of the source. We now insert Eqs. (13) and (14) into Eq. (12), and consider the variations of the exponential factors only. Before writing the resulting equation, it is convenient to introduce the following angles (n is normal to S_I into obstacle):

$$\gamma=\text{angle between } r'-r_0 \text{ and } n;\ \text{thus } \cos\gamma=\frac{\partial|r'-r_0|}{\partial n}, \qquad \beta=\ r'-r_0 \text{ and } i_1;\ \cos\beta=\frac{\partial|r'-r_0|}{\partial u_1},$$
$$\delta=\ r'-r_0 \text{ and } i_2;\ \cos\delta=\frac{\partial|r'-r_0|}{\partial u_2}, \qquad \alpha=\ r'-r \text{ and } n;\ \cos\alpha=\frac{\partial|r'-r|}{\partial n}. \quad (15)$$

Then Eq. (12) becomes

$$E_{(1)}(r)\approx\frac{1}{4\pi}\int_{S_I}\Big\{n\mathcal{E}_n\Big[\Big(1-\frac{\epsilon_a'}{\epsilon_b'}\Big)(-k_a^2\cos^2\alpha+2ik_aG_m\cos\alpha)+\Big(\frac{\epsilon_b'}{\epsilon_a'}-1\Big)(ik_a\cos\alpha+2G_m)$$
$$\times\Big(ik_a\cos\gamma+2G_m\Big[1-\frac{\epsilon_a'}{\epsilon_b'}\Big]\Big)+(k_b^2-k_a^2)\frac{\epsilon_a'}{\epsilon_b'}\Big]+i_1\Big[\frac{i\omega}{c}(\mu_b-\mu_a)\Big(ik_a\mathcal{H}_2\cos\alpha+ik_a\mathcal{H}_2\cos\gamma$$
$$+\frac{i\omega}{c}[\epsilon_b'-\epsilon_a']\mathcal{E}_1+ik_a\mathcal{H}_n\Big(\frac{\mu_a}{\mu_b}-1\Big)\cos\delta\Big)-\Big(\frac{\epsilon_a'}{\epsilon_b'}-1\Big)k_a^2\mathcal{E}_n\cos\alpha\cos\beta+\Big(1-\frac{\epsilon_b'}{\epsilon_a'}\Big)$$
$$\times\Big(-k_a^2\mathcal{E}_n\cos\alpha\cos\beta+2ik_aG_m\mathcal{E}_n\Big(1-\frac{\epsilon_a'}{\epsilon_b'}\Big)\cos\beta\Big)+(k_b^2-k_a^2)\mathcal{E}_1\Big]$$
$$+i_2\Big[-\frac{i\omega}{c}(\mu_b-\mu_a)\Big(ik_a\mathcal{H}_1\cos\alpha+ik_a\mathcal{H}_1\cos\gamma-\frac{i\omega}{c}[\epsilon_b'-\epsilon_a']\mathcal{E}_2+ik_a\mathcal{H}_n\Big[\frac{\mu_a}{\mu_b}-1\Big]\cos\beta\Big)$$
$$-\Big(\frac{\epsilon_a'}{\epsilon_b'}-1\Big)k_a^2\mathcal{E}_n\cos\alpha\cos\delta+\Big(1-\frac{\epsilon_b'}{\epsilon_a'}\Big)\Big(-k_a^2\mathcal{E}_n\cos\gamma\cos\delta+2ik_aG_m\mathcal{E}_n\Big[1-\frac{\epsilon_a'}{\epsilon_b'}\Big]\cos\delta\Big)$$
$$+(k_b^2-k_a^2)\mathcal{E}_2\Big]\Big\}\frac{\exp[ik_a(|r-r'|+|r'-r_0|)]}{|r-r'|}dS. \quad (16)$$

The integral in Eq. (16) can be evaluated approximately by the method of stationary phase. The result is (the factors P and $\mathcal{G}$ are given in Eqs. (19) and (18), respectively):

$$hE_{(1)}(r)=P\cdot\mathcal{G}\cdot\left[\frac{k_a h}{2}\right]\Bigg[n\mathcal{E}_n\Bigg\{\left(1-\frac{\epsilon_a'}{\epsilon_b'}\right)\left(\frac{2iG_m}{k_a}-\cos\alpha\right)+\left(\frac{\epsilon_b'}{\epsilon_a'}-1\right)\left(i+\frac{2G_m}{k_a\cos\alpha}\right)\left(i\cos\gamma+\frac{2G_m}{k_a}\left[1-\frac{\epsilon_a'}{\epsilon_b'}\right]\right)$$
$$+\left(\frac{k_b^2}{k_a^2}-1\right)\frac{\epsilon_a'}{\epsilon_b'\cos\alpha}\Bigg\}+i_1\Bigg\{\frac{i\omega}{k_a c}(\mu_b-\mu_a)\left(i\mathfrak{IC}_2\left[1+\frac{\cos\gamma}{\cos\alpha}\right]+\frac{i\omega}{k_a c\cos\alpha}[\epsilon_b'-\epsilon_a']\mathcal{E}_1\right.$$
$$+i\frac{\cos\delta}{\cos\alpha}\mathfrak{IC}_n\left[\frac{\mu_a}{\mu_b}-1\right]\Bigg)-\left(\frac{\epsilon_a'}{\epsilon_b'}-1\right)\cos\beta\mathcal{E}_n+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\left(-\frac{\cos\gamma}{\cos\alpha}+\frac{2iG_m}{k_a\cos\alpha}\left[1-\frac{\epsilon_a'}{\epsilon_b'}\right]\mathcal{E}_n\cos\beta\right)$$
$$+\left(\frac{k_b^2}{k_a^2}-1\right)\frac{\mathcal{E}_1}{\cos\alpha}\Bigg\}+i_2\Bigg\{-\frac{i\omega}{k_a c}(\mu_b-\mu_a)\left(i\mathfrak{IC}_1\left[1+\frac{\cos\gamma}{\cos\alpha}\right]-\frac{i\omega}{k_a c\cos\alpha}[\epsilon_b'-\epsilon_a']\mathcal{E}_2+i\frac{\cos\beta}{\cos\alpha}\mathfrak{IC}_n\left[\frac{\mu_a}{\mu_b}-1\right]\right)$$
$$\left.-\left(\frac{\epsilon_a'}{\epsilon_b'}-1\right)\cos\delta\mathcal{E}_n+\left(1-\frac{\epsilon_b'}{\epsilon_a'}\right)\left(-\frac{\cos\gamma}{\cos\alpha}+\frac{2iG_m}{k_a\cos\alpha}\left[1-\frac{\epsilon_a'}{\epsilon_b'}\right]\right)\mathcal{E}_n\cos\delta+\left(\frac{k_b^2}{k_a^2}-1\right)\frac{\mathcal{E}_2}{\cos\alpha}\Bigg\}\right]. \quad (17)$$

5. PROPERTIES OF THE SOLUTION

In Eq. (17) the first-order scattered (reflected, transmitted, or diffracted) field has been written as a product of three factors, each of which has special physical significance. It is interesting to observe that the solution of the corresponding acoustic problem has a similar form, the first two factors being identical with those found here.[3] We shall now discuss each of the factors in turn.

Geometrical Factor

The factor $\mathcal{G}$ in Eq. (17) depends upon geometrical quantities only and is given by

$$\mathcal{G}=\Bigg\{1+D_2\left(\frac{1}{D_1}\left[\frac{2-\sin^2\gamma}{\cos^2\alpha}-\tan^2\alpha+2\tan^2\alpha\sin^2\alpha\sin^2(\theta-\varphi)\right]-(\cos\alpha+\cos\gamma)[2G_m+G_{||}(\theta)\tan^2\alpha]\right)$$
$$+\left(\frac{\cos\gamma}{\cos\alpha}\frac{D_2}{D_1}\right)^2+D_2^2G_g\left(1+\frac{\cos\gamma}{\cos\alpha}\right)^2-\frac{D_2}{D_1}\frac{\cos\alpha+\cos\gamma}{\cos^2\alpha}(2G_m\cos^2\gamma+G_{||}(\varphi)\sin^2\gamma)\Bigg\}^{-\frac{1}{2}}\frac{\cos\alpha}{|\cos\alpha|}. \quad (18)$$

The various symbols in Eq. (18) are defined as follows, at the point on S_I where the phase in Eq. (16) is stationary: θ=angle between u_1 and the plane containing the normal and r_1, φ=angle between u_1 and the plane containing the normal and r_2, G_m=mean curvature, G_g=Gaussian curvature, $G_{||}(\theta)$=curvature of the normal section of surface S determined by the plane making angle θ with u_1, $D_1=|r'-r_0|$, $D_2=|r'-r|$.

We say that this factor accounts for the geometrical spreading or focusing of the scattered field because it also occurs in the purely geometrical optical solution of the reflection problem. In fact, the ratio of the field amplitude reflected from an interface to the incident amplitude has been computed by geometrical optics[2,3] and found to be precisely the above quantity $\mathcal{G}$ in directions of specular reflection ($\alpha=\gamma$, $\theta=\varphi$) and zero in other directions (except for a reflectivity factor.) This factor has been investigated in references 2 and 3 and shown to yield the positions of caustics, foci, point images, focal length, and the mirror law. $\mathcal{G}$ becomes infinite on caustics and at foci, but a more careful evaluation of the integral in Eq. (16) at such places, employing Airy integrals instead of Fresnel integrals, yields finite but large values of the field.

Phase Factor

The factor P in Eq. (17) depends upon the incident wave-length and the obstacle dimensions, as well as the distances from source and observation point to the surface. It is given by

$$P=\frac{e^{iM'}}{2}[F_\pm(\xi_0'')-F_\pm(\xi_1'')][F_\pm(\eta_0'')-F_\pm(\eta_1'')]. \quad (19)$$

The symbols in Eq. (19) are defined as follows (see reference 3 for further details):

$F_\pm(x)=\int_0^x \exp[\pm i(\pi/2)u^2]du$=Fresnel integral; plus or minus sign chosen in accordance with the rule given in reference 3.

$$M'=k_a(D_1+D_2)+\cdots.$$

P oscillates as the wave-length varies, with its absolute value ranging between zero and about two. It generally has a maximum in the direction of specular reflection, and approaches one in this direction, and zero in all other directions, as the wave-length approaches

zero, thus yielding the optical "law of reflection." In addition it yields a 180° phase change on crossing a point image or focus. Reflection from an interface has been treated by the Kirchhoff method[3,4] and the reflected field found to equal the incident field multiplied by $\mathcal{G}P$. The arguments of the Fresnel integrals in Eq. (19) are given by

$$\xi_0''=\frac{\sqrt{2}\xi_0'}{\left(\frac{\pi}{|A'|}\right)^{\frac{1}{2}}},\quad \eta_0''=\frac{\sqrt{2}\eta_0'}{\left(\frac{\pi}{|C'|}\right)^{\frac{1}{2}}} \tag{20}$$

with similar expressions for ξ_1'', η_1''. The quantities $\xi_0'\xi_1'\eta_0'\eta_1'$ determine the boundaries of a rectangle equivalent to the "illuminated" part of the surface, referred to the point of specular reflection as origin. The denominators in Eq. (20) are just the half-dimensions of the first Fresnel zone on the surface around the specular reflection point. If the dimensions of the surface are large compared to those of the first Fresnel zone, the Fresnel integrals have their asymptotic values and the phase factor has absolute value one (provided medium a has zero conductivity, i.e., k_a is real). This is usually the case unless the dimensions of the surface are small compared to a wave-length or it is cylindrical or plane.

When the surface is small compared to the first Fresnel zone the arguments of the Fresnel integrals are small, and these integrals may be approximated by the first terms in their Taylor expansions, which yield $F_{\pm}(x)\approx x$. Then

$$P=e^{iM'}\frac{(\xi_0'-\xi_1')(\eta_0'-\eta_1')}{\pi/(|A'C'|)^{\frac{1}{2}}}. \tag{21}$$

From Eq. (21) we see that, apart from the exponential factor, P is equal to the ratio of the area of the obstacle surface to the area of the first Fresnel zone.

Since both A' and C' have the factor k_a, which is equal to $2\pi/\lambda_a$, where λ_a is the wave-length in medium (a), if the conductivity of medium (a) is zero, P is inversely proportional to λ_a. The reflectivity factor also has the factor $k_a h$, and hence one sees that the scattered field is proportional to the obstacle volume (=area$\times h$) and inversely proportional to λ_a^2. This is the Rayleigh scattering law for electromagnetic waves. In particular, it is valid if $\lambda_a \gg$ obstacle dimensions, since then the first Fresnel zone is larger than the obstacle.

Reflectivity Factor

The scattered field is expressed in Eq. (17) in terms of components in the n, i_1, i_2 directions, where n, i_1, i_2 are mutually orthogonal unit vectors at the point of stationary phase on the surface S. Each of these components is the product of the geometrical and phase factors and a third factor which is called the reflectivity factor. Since this factor is not the same for all components, it is appropriate to speak of three reflectivity factors, one for each component. The factors are the coefficients of n, i_1, and i_2 in Eq. (17).

The reflectivity factors are linear and homogeneous in the components of the incident field. They depend upon the physical properties of both media, the thickness and curvature of the shell, and the angles of incidence and reflection. Thus it can be seen that these factors take account of the propagation within the shell. From an examination of the form of these factors it is seen that they are proportional to the amplitude of the incident field, and increase in absolute value as $|\epsilon_a'-\epsilon_b'|$ and/or $|\mu_a-\mu_b|$ increase. Moreover, they are proportional to $k_a h$ which, in the case when medium (a) has zero conductivity, is $2\pi h/\lambda_a$. Thus the scattered field increases with the ratio of the thickness to the wave-length. This inverse dependence upon λ_a, in conjunction with the phase factor, leads to the electromagnetic analog of the Rayleigh scattering law, as has been pointed out above. When reflection and diffraction problems are treated by the Kirchhoff method no reflectivity factor is obtained, and hence the Rayleigh scattering law cannot be deduced.

If the reflectivity factors are divided respectively by the corresponding field components, they agree with the exact coefficients[9] for the reflection of plane waves from a thin, infinite, plane plate, except for additional terms proportional to the mean curvature of the surface. The polarization effects are therefore practically the same as for the plane case above. If Eq. (17) is specialized to the case of plane waves incident on a plane shell, the geometrical factor and the phase factor both become unity, and the reflected and transmitted fields agree exactly with those obtained by Luneberg[9] when his results are applied to a thin plate.

The presence of the quantity $\cos\alpha$ in the denominator of some terms of the reflectivity factors appears to indicate that the scattered field becomes infinite as $\alpha\rightarrow\pi/2$. In this case, however, the method used to evaluate the integral is not valid (see above).

CONCLUSION

The solution seems to yield a rather satisfactory quantitative as well as qualitative understanding of reflection and transmission by thin shells, as well as agreement with various special results previously obtained by other methods. For thick shells additional terms in the series solution would probably be needed. Since the calculations required would be quite complicated, an alternative method which was useful in acoustics seems preferable. We merely assume that the reflected field still contains three factors, the geometrical and phase factors being the same as those given here and the reflectivity factor being that obtained for a thick

plate. The physical interpretation of the various factors makes this procedure at least plausible. Calculations based on these assumptions seemed to agree with experimental results in acoustics.

A further test of the result of this paper is provided by an exact solution for the reflection and transmission of spherical waves by a spherical shell with a dipole source at its center.[10] This solution was specialized to the case of a thin shell and compared to the result of the present paper when applied to this case. The agreement between the two solutions was satisfactory for all components except E_r, the radial component of electric field, and except near the source (see reference 10 for further details).

ACKNOWLEDGMENT

I wish to express my appreciation to Professor Henry Primakoff for his excellent instruction, advice and direction in the solution of the corresponding acoustic problem.

A Technique for Taking Motion Pictures of Electron Microscope Images*

LUTHER E. PREUSS AND JOHN H. L. WATSON
Edsel B. Ford Institute for Medical Research, Detroit 2, Michigan
(Received April 12, 1950)

Lately, for the first time, a technique for taking motion pictures of electron microscope images has been developed which is proving useful in the study of some of the effects of electrons upon matter and particularly upon colloidal crystals. Resolution of 150 to 300A is achieved and is suitable for a host of practical electron microscopical problems. Pictures are taken from outside the instrument, utilizing the radiation emitted by the fluorescent screen. Some instrument adaptation is required for adequate illumination, and precautions must be exercised against toxic x-ray dosages.

THE feasibility of taking motion pictures of electron microscope images has been considered on occasion, but a lack of informative, moving subjects made the project impractical. Lately, the technique has been developed successfully in these laboratories for studying the effects of electrons, and indirectly of heat upon colloidal crystals. The effects of electrons upon a variety of other crystalline and non-crystalline materials are also being studied in the same way, and many specimen changes are observed in a much more positive manner than heretofore. Some reactions which escape detection entirely or which occur too rapidly for satisfactory observation to be made at all by the orthodox procedures are registered on motion picture films. Pronounced reactions have been recorded in one frame intervals in as short a time as 0.03 sec.

The motion pictures are taken by photographing the image on the fluorescent screen with the camera set up outside the microscope. Figure 1 shows the relative positions of camera and microscope with the final viewing screen tilted so as to have its plane normal to the optical axis of the camera and to give a maximum field of view. The angle is about 30 degrees. Some distortion is introduced by the tilt, and this has to be kept in mind when interpreting the images, but it is not found to be bothersome. The camera is a 16-mm Cine Kodak Special with a 4-in., $f/2.7$ telephoto lens mounted upon a conventional tripod. This tripod is a source of error due to vibration and a more rigid camera support is recommended. Practical operating speeds are from 8 to 32 frames per second, depending upon screen intensity. Above 32 frames per second the contrast deteriorates. Super XX negative panchromatic safety film has been found to produce the best contrast and Super XX and Kinolux positive emulsions are used with moderate success. The complete processing time with *D*-19, exclusive of drying, is at least two hours per 100-ft. roll of 16-mm negative. To reduce the amount of manual work required in the processing and to shorten the time, a motor-driven tank has been built, Fig. 2.

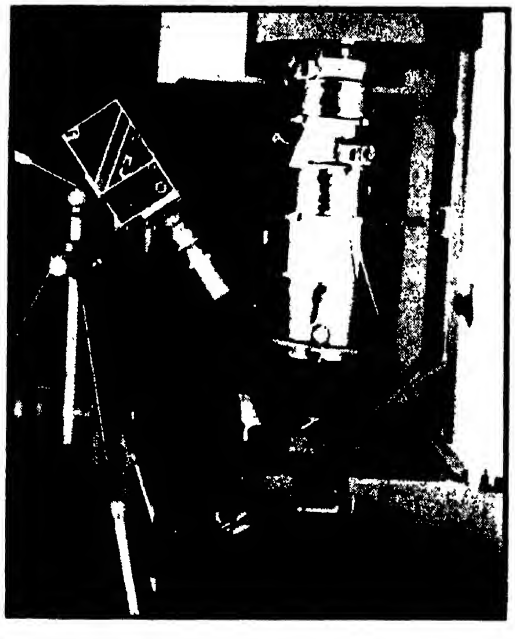

FIG. 1. Experimental arrangement of camera and microscope, showing angle of final viewing screen.

The intensity of the light emitted from the final viewing screen has to be of a relatively high order. A self-biasing electron gun[1] is the first requirement, both for sufficient intensity and for noticeable effects of bombardment upon samples. It is necessary to replace the fluorescent materials on the screens periodically because they become contaminated and lose their brilliance. Since much of the work has to be done in the lowest portion of the linear section of the Hurter-Driffield curve, the image brightness has to be increased to its maximum without provoking premature or undesirable specimen changes. In general, although the contrast would be desirable, no objective aperture can be used except with materials which react very slowly under the beam. Objective apertures were used in taking moving micrographs of colloidal crystals[2] of β-FeOOH under bombardment, but none were usable with NaCl or WO_3 crystals where the desired effects occurred more rapidly.

In order to increase the possible intensity still further, the diameter of the condenser aperture is opened from 25 to 50 mils. This, plus the tilting of the final viewing

screen, results in the production of a considerable amount of x-radiation and makes it imperative that the instrument be surveyed. Some remarkably high dosage rates were measured for the experimental conditions. Figure 3 shows rough isodose curves at the position of the final viewing screen.

The electron microscope, which has inherent in it both a source of heat from electron bombardment in vacuum and a means of photography from the same radiation, offers a convenient means of conducting studies of solid-liquid transformations. The application of the moving picture technique provides a method for investigating the crystalline properties of such transformations by observation of Bragg electron reflections in specimens under bombardment. In normal electron microscopy Bragg reflections are seen to best advantage in dark field,[3] but in bright or dark field are most easily and definitely detectable when caused to move by variations of objective lens current. When the object itself is crystallizing or melting, or is in some other unstable condition, the images of the reflections move on the screen and are detectable without an objective current variation. They may be recorded effectively, therefore, by the motion picture technique. From direct observation, the bombarded samples are seen to emit a profusion of such reflections which originate from what appear from characteristics of shape alone to be melted areas as well as from those regions which are judged to be composed of well-formed crystals. Presumably, some of the ostensibly melted areas must often retain some oriented forms.

The motion picture technique for electron microscopes should also be useful for studying samples which are under the influence of factors other than electron bombardment in the microscope. For example, observations could be recorded to advantage upon film, if heat effects were studied, where the heating was done by a direct furnace source rather than by the beam. Ideal objects for study would also be provided during the deposition of thin metal films within the vacuum of the electron microscope, as reported[4] by Sennett of the Toronto group. The method is promising for a detailed study of the effects of electron bombardment upon bacteriological and biological specimens, and whenever a method is

devised for studying live or wet specimens satisfactorily by electron microscopy the advantages of recording the observations on movie film will be obvious.

There are a number of other incidental advantages to be gained from taking motion pictures of electron microscope images. Non-electron microscopists, who are not as familiar with the appearance of images in the microscope but who are collaborating on a problem, find

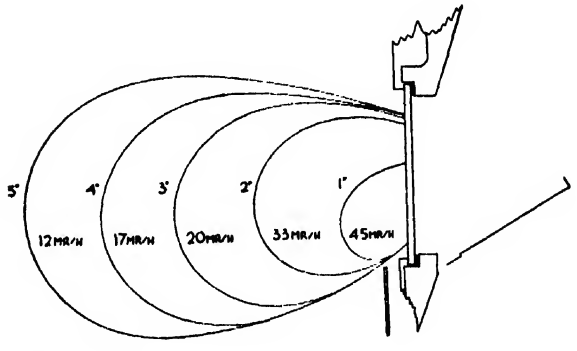

FIG. 3. Rough isodose curves drawn in location of tilted final viewing screen, with a 50-mil condenser aperture and sufficient intensity for taking motion pictures. Values would be much higher from intermediate screen.

the films very instructive. The same is true in lectures on electron microscopy where an audience is given an improved impression if a movie sequence is shown as illustration, even when the motions recorded are themselves not particularly informative for new things. The ability to reverse or retard a film is very useful, especially when observing the extremely fast reactions which occur during the earliest stages of a bombardment series.

Motion Picture Studies of Electron Bombardment of Colloidal Crystals

JOHN H. L. WATSON AND LUTHER E. PREUSS
Edsel B. Ford Institute for Medical Research, Detroit 2, Michigan

(Received April 12, 1950)

Phenomena not seen or recorded by orthodox methods are observed on the large number of micrographs which are taken during a motion picture experiment, and reaction times as short as 0.03 sec. can be calculated. The technique is useful for investigating solid-liquid-solid changes both by direct observation and by recording Bragg reflections. In most cases a preliminary effect of electrons upon crystals is to drive off water. In the case of sodium chloride crystals a residual envelope is left. Inside this, small particles, both solid and liquid, are observed to move rapidly due, it is believed, to a combination of Brownian movement and convection. These gradually evaporate and diffuse through the wall. The possibility is discussed that the residual envelope is formed by contamination. Examples are also taken from bombarded, colloidal crystals of tungsten oxide.

GERMAN workers realized at an early date the advantages to be gained in electron microscopy by the use of a battery-biased source, and described some of the effects upon their specimens of the intense beam from such a gun. The major emphasis was placed upon the subject in this country after Hillier and Baker[1] described the self-biasing cathode. Several reports[2–4] have been published since which discuss from stills the effects of electrons upon matter as observed in electron microscopes employing self-biasing sources, and observations of these reactions are often used now to clarify electron microscopic sample interpretation.

Several colloidal crystal systems have been studied by application of the motion picture technique[5] for their reactions under electron radiation. The first of these involves crystals of sodium chloride.[6] In Fig. 1 several stills are shown which are typical of a movie sequence. It will be seen that the contrast of the "moving micrographs" is good and that the resolution and magnifications are useful, if not completely comparable with the best to be expected from the more orthodox methods of electron microscopy. Figure 1A shows an early stage of the bombardment series as the water is being driven off and sections of the crystal are becoming transparent to electrons. Before this the whole crystal was quite opaque. Figures 1 (B–F) are all progressive, intermediate appearances of the same crystal as it changes toward the residual envelope[6] condition which is its final state, Fig. 1G.

The fine particles, which are seen to form within the envelope, move very rapidly in a random fashion under bombardment. This motion slows or ceases whenever the intensity is diminished. From higher resolution micrographs taken in the orthodox manner, Fig. 2, these particles are often seen to be rounded, but in many cases are small cubes. The rounded particles are apparently molten and are frequently noticed to coalesce with others which they meet. The cubes are presumed to be cooler, solid crystals. All the particles continue to decrease in size and contrast until eventually they evaporate completely, diffuse through the envelope as vapor and disappear.

The motion of the particles is probably a combination of convection and Brownian movement of the particles within the confined space of the envelope under the influence of the warm, vaporous material which fills it. That it is filled with such a material under pressure is shown by the facts (1) that the sides of the envelope will often bulge outward and even break if heat is applied too rapidly and (2) that such a break results in the spewing out of vaporous substance from the envelope which deposits as solid particles on the cool, surrounding substrate. These effects are demonstrated very graphically in the moving pictures. It has been thought that Brownian motion would not be studied to advantage in an electron microscope due to the extremely large translations which would be involved at the high magnifications on the very limited viewing screen. Here, however, the motion is constrained within narrow limits by the residual envelope. Figure 3 from another movie sequence shows a ruptured envelope.

The residual envelope has been conjectured[6] to originate from contamination[7] but if so, the contamination must be much more quickly and effectively deposited upon some materials than upon others, for in these studies only sodium chloride has been found to leave such envelopes. This observation agrees with the results of Burton *et al.* who classed sodium chloride along with sodium chlorate, potassium bromide, and iodide as substances which behaved in this way. If contamination explains the occurrence of residual envelopes, this specificity for certain substances is in disagreement with the qualitative observations by Hillier[8] that the rate of deposition was the same for all substances. On the other hand, if Hillier's observation is correct, other explanations must be looked for to explain the presence of

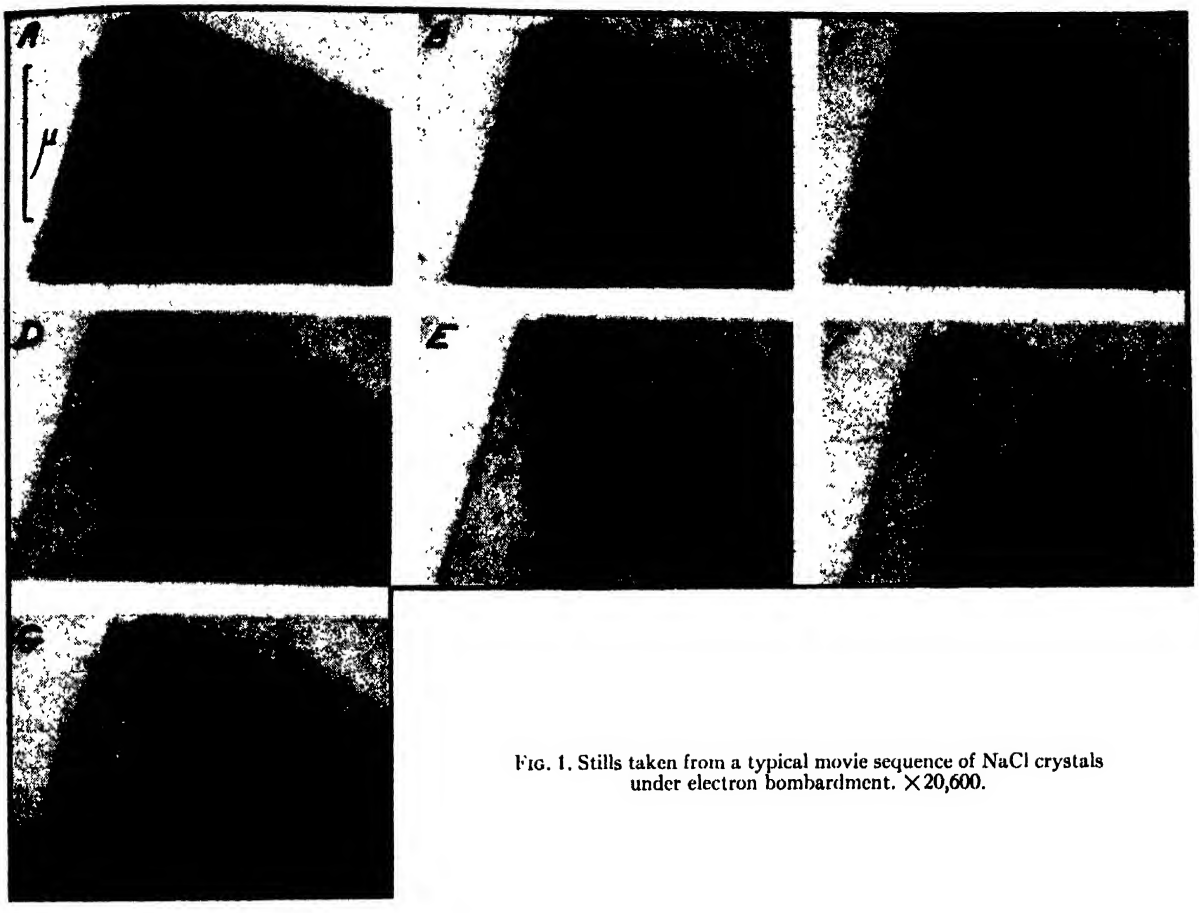

FIG. 1. Stills taken from a typical movie sequence of NaCl crystals under electron bombardment. ×20,600.

residual envelopes. The envelope is always present with sodium chloride regardless of the speed of evaporation, which often occurs instantaneously. It may be significant that those salts which are water soluble tend to leave residual envelopes while the insoluble ones do not. It is interesting to hypothesize that the residual layer is left as a result of trace impurities which concentrate at the original surface during the evaporation of the interior. Salt crystals deposited from saline, organic suspensions yield particularly striking envelopes, Fig. 4, a fact which may indicate that organic impurities are polymerized or condensed at the crystal surface in a radiation-chemical process under the action of the electron beam.

The three-dimensional nature of the residue as a replica of the original crystal has been demonstrated by shadow-casting them after evaporation and by tilting them on broken Formvar films and recording their appearance in movie film. As a replica they give information concerning the surface of the original crystals.

The large number of micrographs taken rapidly by the moving picture technique has resulted in several examples being recorded of a transient appearance of an inherent mosaic structure in sodium chloride crystals, in support of the discussion by Ewald and Renninger[9] that a mosaic exists. The phenomenon was observed to form and disappear quickly, and its presence was detected in only one or two stills of any sequence in which it ap-

FIG. 3. Still taken from a typical movie sequence showing a ruptured envelope at arrow. ×26,000.

peared. Its visibility was therefore a short-lived affair which would not be micrographed as successfully without the use of the moving picture methods. One still is shown in Fig. 5 as an illustration. It is an interior rather

than a surface effect, since it disappears under continued bombardment.

The bombardment effects of electrons upon tungsten oxides (WO_3) have been reported earlier,[1,2] but are more

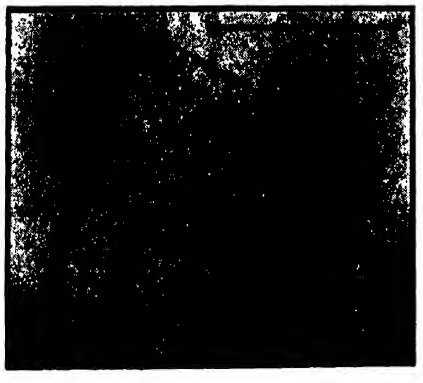

FIG. 5. Still taken from a typical movie sequence, showing the mosaic structure in an evaporating NaCl crystal. ×26,000.

completely explainable from observations made on film. By slowing down the effects considerably it has been confirmed that the mosaic pattern of rods in fresh, early samples is inherent. The initial effect of bombardment is to render these visible but not to create them. Apparently, the heat from the incident beam drives off water of crystallization and some free passage of electrons results. The initial stages of bombardment of these and of most other crystals passes extremely rapidly, depending upon the intensity, and these stages are the most productive in moving picture studies. The effects of melting and recrystallization into other forms are secondary and enter later.

FIG. 6. A typical sequence of frames taken of the effects of electron bombardment upon WO_3. The sequence was taken at 16 frames per second and covered a total time interval of $\frac{1}{4}$ sec. ×7200.

Figure 6 shows a typical sequence of frames taken at an original magnification of ×7200 in the microscope and reproduced here at the same magnification. Since these were taken at 16 frames per second, the observed reactions occurred within a very short interval. The actual exposure time per frame for this example was 1/30 sec., and the whole sequence represents a time interval of $\frac{3}{4}$ sec. In the first one or two frames little if any reaction has occurred although some of the inherent structure is seen to be giving rise to Bragg reflections which appear as a straight, intense line over the crystal surface. Later the inherent mosaic has become visible over the whole body of the somatoid. In the final frames secondary structures due to melting have been introduced at the tip of the crystal.

There is no suggestion of a residual envelope when tungsten oxide is bombarded. Melting is recognizable from the round nature of the melted particles, and recrystallization is interpreted from production of moving Bragg reflections and from a return to the straight-edged morphology. Areas presumed to be melted often give rise to electron reflections. Melted particles are also seen to "bubble" in the moving micrographs as if boiling under the beam.

Moving pictures of carbon black contaminating under the beam demonstrated the particle growth very graphically, but added no new knowledge of the phenomenon.

The Emission of Radiation from Nitric Oxide: Approximate Calculations*

L. E. Benitez** and S. S. Penner
Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California
(Received March 27, 1950)

Emissivity calculations have been carried out for nitric oxide at temperatures from 300°K to 3000°K. The results may be used, as a first approximation, at elevated total pressures.

NITRIC oxide[1] is one of the diatomic molecules which may contribute to radiant heat transfer in high pressure combustion chambers. In particular, nitric oxide at elevated temperatures is encountered in many solid-fuel and liquid-fuel rocket motors. It is, therefore, of obvious practical importance to determine the emissivity of nitric oxide as a function of temperature. According to the procedure for making approximate radiant heat-transfer calculations outlined previously,[2] it is necessary to calculate first an effective band width lations are then used to construct a plot of limiting emissivities for the fundamental and the first overtone of NO as a function of temperature. Finally, emissivity calculations are made by using the limiting emissivities in conjunction with the values of the integrated absorption for the fundamental and the first overtone, estimated from available experimental absorption measurements of NO.

The results of effective band-width calculations, using the procedure described previously[2] and the spectroscopic constants given by Mayer and Mayer,[3] are summarized in Tables I and II for the fundamental and the first overtone of NO, respectively, for two different values of $j_{max.}$ at each temperature. It should be noted that the presence of a Q branch in the infra-red spectrum of NO does not affect the effective band-width calculations made according to our approximate procedure. For values of the limiting rotational quantum number $j_{max.}$ exceeding the value corresponding to the position

of a band head, the limiting frequency has been set equal to the frequency at the band head.[2]

From the data listed in Tables I and II the limiting emissivities have been calculated. The limiting emissivities ϵ_F' and ϵ_0' for the fundamental and the first overtone, respectively, are defined by the relations

$$\epsilon_F' = \int_{\Delta\nu_{n\to n+1}} \rho(\nu)d\nu \Big/ \int_0^\infty \rho(\nu)d\nu,$$

$$\epsilon_0' = \int_{\Delta\nu_{n\to n+2}} \rho(\nu)d\nu \Big/ \int_0^\infty \rho(\nu)d\nu,$$

where $\rho(\nu)$ is the energy density of radiation emitted by a blackbody at a given temperature. The limiting emissivities for the two sets of $j_{max.}$ values are plotted as a function of temperature in Fig. 1.

In order to utilize the plot of limiting emissivities shown in Fig. 1 for radiant heat-transfer calculations, it is necessary to estimate the integrated absorption for the vibration-rotation bands.[2] Reliable numerical values do not appear to be available for NO although qualitative results have been reported by Gillette and Eyster[3] and by Rideal *et al.*[4] Experimental measurements of apparent absorption coefficients of NO and CO at small total pressures with an instrument of low spectral resolution have led to similar experimental results for the integrated absorption for these two gases.[1] On the basis of these studies it is suggested that the emissivity ϵ' be determined by use of the relations

$$\left.\begin{aligned}
\epsilon' &= [1-\exp(-\bar{k}_F pl)]\epsilon_F' \\
&\quad +[1-\exp(-k_0 pl)]\epsilon_0', \\
k_F(T) &= \frac{201}{\Delta\nu_{n\to n+1}} \times \frac{300}{T} \times 116 \\
&= \frac{7.0\times 10^6}{T\Delta\nu_{n\to n+1}}, \text{ (cm-m-atmos.)}^{-1}, \\
k_0(T) &= \frac{200}{\Delta\nu_{n\to n+2}} \times \frac{300}{T} \times 0.88 \\
&= \frac{5.3\times 10^4}{T\Delta\nu_{n\to n+2}}, \text{ (cm-m-atmos.)}^{-1},
\end{aligned}\right\} \quad (1)$$

where the following numerical values have been used at 300°K:

$$\Delta\nu_{n\to n+1} = 201 \text{ cm}^{-1},$$

$$\Delta\nu_{n\to n+2} = 200 \text{ cm}^{-1},$$

$$\bar{k}_F = 116 \text{ (m-atmos.)}^{-1},$$

$$k_0 = 0.88 \text{ (m-atmos.)}^{-1}.$$

The numerical values of $\bar{k}_F$ and k_0 should be regarded as rough approximations subject to revision on completion of current measurements of integrated absorption.

Generalized Microscopy and the Two-Wave-Length Microscope

M. J. Buerger
Crystallographic Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received April 27, 1950)

In the ordinary simple microscope, the same light is permitted to flow through the entire system. A more general microscope can be devised in which light of one wave-length is permitted to flow as far as the diffraction image of the object, then light of a second wave-length is substituted at this plane, and continues to flow through the rest of the optical system. It is shown that for such a generalized microscope, the magnification depends not only on the ordinary image-to-object distance ratio, but also on the ratio of wave-lengths used. Utilizing x-rays and visible light, this second factor is about 10^4 diameters, and the whole magnification is of the order of 3×10^6. This is enough to permit one to see an atom. Apparatus has been built which realizes this theory. A most important characteristic of any such system is that a loss of phase occurs at the first diffraction image where the wave-length substitution takes place. This phase must be supplied by the apparatus. It is accomplished with the aid of phase shifters prepared from a large uniform mica cleavage fragment. The apparatus and the results achieved with it are described.

THE generalized theory of microscopy discussed here was developed by the writer in 1939, in connection with the theory of optically reciprocal gratings,[1] and it was presented at the January 10, 1941 meeting of the New York Academy of Sciences, at the October 20, 1942 meeting of the Rochester Section of the American Optical Society, and on a number of subsequent occasions. The subject matter is, therefore, not entirely new. But what makes it timely and interesting is that a technical development which was in a successful experimental stage in 1941 has now been perfected, and therefore new and very interesting results have recently been achieved with this instrument. The gap in development was due to the intervention of the war, and consequent diversion of interests.

The two-wave-length microscope is a device for magnifying an image in two stages, using a different wave-length in each stage. The magnification then depends not only on the usual ratio of image-to-object distances, but also on the ratio of the wave-lengths used. To understand this action, consider first an ordinary optical system employing the same wave-length of light throughout, shown in Fig. 1. This consists of two lenses L_1 and L_2, of focal lengths D_1 and D_2, respectively, and separated by a distance D_1+D_2. An illuminated object is placed at the left focus of the first (left) lens, and its image is formed at the right focus of the second (right) lens. The dotted lines indicate the geometrical optics of image formation.

Now, this simple process can also be regarded as two stages of diffraction in series. The first lens, with the object at its focus, collects parallel rays emanating from the object and focuses these at its right focal plane. This is the diffraction image of the object. Then those rays emanating from this diffraction image which are parallel are focused by the second lens to become the final image. Thus the final image is also the *diffraction of the diffraction* of the object. The focusing of the diffraction in these two stages by the two lenses is indicated in Fig. 1 by the solid lines.

If the object is periodic, then its diffraction image is in the form of a collection of discrete spectra. Let the periodicity of the object be defined by the lattice of the object. Then,[1] as will be shown, the diffraction image is the weighted reciprocal lattice[2] of the object. The diffraction image of this reciprocal lattice is the final image. To generalize this statement for non-periodic objects, one can restate it in the language of Fourier transforms. The diffraction of the object is its Fourier transform. The diffraction of the diffraction image is therefore the *transform of the transform* of the object. It is well known that this is the enantiomorphous equivalent of the object.

Consider the magnification of the image in terms of this double diffraction process. It simplifies the treatment to carry through the discussion of magnification for a periodic object, thus avoiding the explicit use of Fourier transforms. Let the translations t_1 and t_2 define the periodicity of the pattern of the object in its own plane. Then the wavelets scattered by the pattern units of the object are alternatively in phase and out of phase in a plane at right angles to a set of parallel rows, Fig. 2. If the spacing of such rows is d, then the condition that the wavelets are in phase (Fig. 3) is

$$\sin\delta = n\lambda_1/d. \qquad (1)$$

These re-enforcing waves are focused on the plane of the diffraction image at a point whose distance, t_n^*, from

Combining (1) and (2),

$$t_n^* = D_1 \tan \sin^{-1}(n\lambda_1/d). \tag{3}$$

Provided that δ is small (i.e., that discussion is limited to spectra comparatively near to the optic axis), a close approximation is

$$t_n^* = n(D_1\lambda_1)/d. \tag{4}$$

Thus, the collection of the n spectra constitutes a row of points whose interval is

$$t^* = (D_1\lambda_1)/d. \tag{5}$$

Such a row of spectra occurs normal to *any* set of rows in the object Fig. 2, i.e., they occur parallel to the d_{hk} of any set of rows of crystallographic index (hk) and the law of the interval t_{hk}^* in the spectrum is

$$t_{hk}^* = K/d_{hk}, \tag{6}$$

where K is an experimental constant consisting of the product $(D_1\lambda_1)$.

A collection of points displaying this kind of reciprocity with respect to the spacings of all the rows of a periodic object is known to be a lattice,[2] and in fact it is the reciprocal lattice of the object. Thus the diffraction of a periodic pattern is a set of discrete spectra at points of the reciprocal lattice of the object.

But this reciprocity is deeper than merely the reciprocity in the dimensions of t^* and d; the reciprocity is truly reciprocal. That is, the star can be transferred from the d to the t, and therefore t and d^* are reciprocal, i.e., the translations of the lattice of the object and the spacings of the diffraction image are also reciprocal. That this is so can be quickly appreciated by imagining the direction of the light in Fig. 1 to be reversed. The diffraction from the reciprocal lattice is then the object lattice. Thus it is also true that

$$t_{uv} = (D_1\lambda_1)/d_{uv}^*. \tag{7}$$

(In the above discussion, the starred letters always refer to quantities in the diffraction image, i.e., to the reciprocal lattice.)

Furthermore, it is evident that, since the arrangement of spectra in the diffraction image is on points of a lattice, the forward diffraction of the diffraction image is also periodic. The same law as derived above holds, and the length of a period of the final image corresponds to that derived for a period of the diffraction image, but specifically

$$T = (D_2\lambda_2)/d^*. \tag{8}$$

The over-all magnification of the optical system is evidently

$$M = \frac{\text{length of a period in the image}}{\text{length of a period in the object}} = \frac{T}{t}. \tag{9}$$

Substituting in (9) from (8) and (7), the magnification turns out to be

$$M = (D_2/D_1) \times (\lambda_2/\lambda_1). \tag{10}$$

Now, in the usual optical system, the same light is used for both stages of diffraction, and (10) reduces to $M = D_2/D_1$, which is the usual ratio of image distance to object distance. But tremendous magnifications could be achieved if two very different wave-lengths

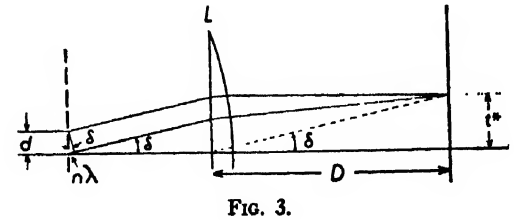

FIG. 3.

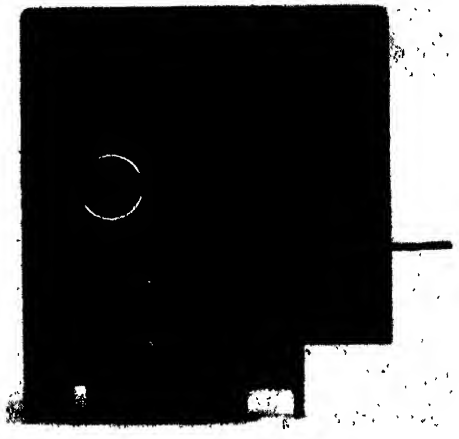

FIG. 4. Device for removing the Lorentz and polarization factors during the recording of de Jong-Bouman photographs. The large metal sheet with the annular opening acts as the layer-line screen. A sector rotates at high speed in front of the opening, propelled by an air jet. The interposing of the metal of the sector in the path of the reflections reduces the time during which each one records, by a factor which is proportional to the product of the Lorentz and polarization factors for the zero level.

were used for the two stages of diffraction. Specifically, if x-rays were used for the first stage, and visible light for the second stage, a factor of 10^4 could be realized apart from the further magnification due to choice of focal lengths of the lenses. Some specific values of the factors in the right of (10) which are used in the instrument described later are approximately

$D_2 = 2\times10^2$ cm
$D_1 = 5$ cm
$\lambda_2 = 5\times10^{-5}$ cm (green light)
$\lambda_1 = 7\times10^{-9}$ cm (molybdenum $K\alpha$-radiation).

With these values, (10) becomes

$$M = \frac{2\times10^2}{5} \times \frac{5\times10^{-5}}{7\times10^{-9}} = 3\times10^5 \text{ times.}$$

With this magnification, an atom 1A in diameter would appear as a circle 0.03 mm in diameter, which is large enough to see with a low power microscope. Such a scheme of magnification would have the advantage that *the resolving power of the system depends on the first wave-length, and consequently this enormous magnification is not empty.*

This system has two inherent disadvantages. In the first place, unless the first radiation of wave-length λ_1, arriving at the diffraction image, can be caused by some device to release the second radiation of wave-length λ_2 in appropriate phase, then the phase of each spectrum

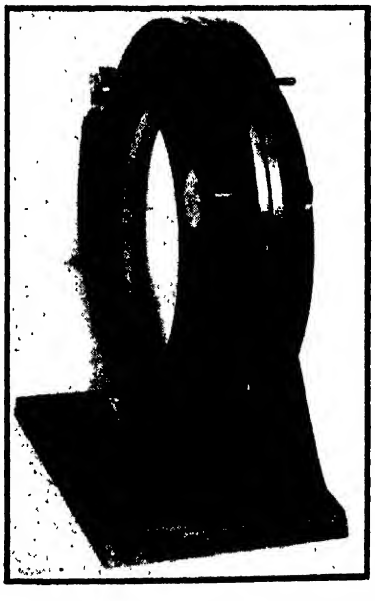

FIG. 5. Device for utilizing a print on film as a diffraction grating. The print is sandwiched between two thick glass flats, and the whole thickness is then rendered optically homogeneous by filling all space between film and flats with a liquid whose refractive index matches that of the film. The liquid is run into the system through the tube seen projecting at the upper right. The (forward) movable flat can be grasped by the transverse handles and removed after releasing the three screws. The clear aperture of the system is about 6 in.

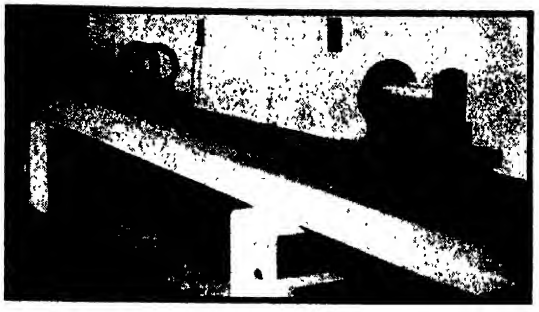

FIG. 6.

of the diffraction image is lost. At present there appears to be no obvious device for accomplishing this phased release of the second radiation. In the absence of such a device, the two-wave-length microscope requires that the phases be supplied. The mechanics of supplying the phases are described later.

Another inherent disadvantage of this system is that if a tri-periodic pattern, such as a crystal, is used as an object, the conditions for diffraction by a three-dimensional grating obtain. One aspect of such diffraction is that, in general, the spectra can only be obtained one at a time as the object is shifted in orientation to satisfy the Bragg condition for each plane one at a time. Thus, the diffraction from the diffraction image could not be made to interfere and build up a final image. Furthermore, if x-rays are to be used in the first stage, they cannot be focused by lenses. But fortunately, both of these difficulties can be avoided because there exist instruments for recording x-ray diffraction in a pattern which is arranged precisely as if the pattern *had* been focused by lenses and as if the several diffraction spectra *had* been produced at once. This is accomplished by the de Jong-Bouman apparatus[3] or by the precession apparatus.[4] The law of magnification for these instruments is precisely (5), where D_1 is the crystal-to-film distance, and λ_1 is the x-ray wavelength.

Thus, in effect, the system *can* be used to form a magnified image of the patterns of crystals provided the appropriate phases of the diffraction by the diffraction image can be supplied. To use the system, it is only necessary to substitute at the plane of the first diffraction image, the positive photograph of the x-ray diffraction pattern (or its equivalent) arranged in reciprocal lattice form by one of the devices mentioned in the last paragraph, and then illuminate this pattern with visible light. In this way, in effect, visible light is substituted for x-rays in the right part of Fig. 1. The philosophy of generalized microscopy is then this: Record (for example, by photography) the diffraction image of the first stage of image formation using radia-

tion of short wave-length; then, placing the positive photograph (or equivalent) of this diffraction image at the correct position of the diffraction image, illuminate it with radiation of longer wave-length. After providing the right phases, the image now obtained is the same as if the original radiation had been used throughout, except that the magnification is scaled up by a factor λ_2/λ_1.

The use of positive photographs of x-ray diffraction arranged in reciprocal lattice form has been practiced by the writer. It has several disadvantages. In the first place, the x-ray diffraction cameras distort the intensities of the spectra by multiplying each by the Lorentz and polarization factors.[5] Fortunately this distortion can be automatically removed during recording by a rapidly rotating sector,[5] shown in Fig. 4. Second, the photographic film surfaces are too irregular for diffraction work. This can be offset by immersing the film in a liquid of its own refractive index, and sandwiched between two optical flats utilizing apparatus such as shown in Fig. 5. This has also been successfully practiced.

But, in spite of its inelegance, a more satisfactory way, from a mechanical point of view, is to determine the intensities of the x-ray diffraction spectra by the Dawton technique[6] (correcting for Lorentz and polarization factors if this has not already been done automatically during recording) and make a mechanical equivalent of the positive diffraction pattern consisting of a metal plate with a hole at each spectral position whose area is proportional to the magnitude of the amplitude $|F_{hkl}|$ of the spectrum. A large number of unit cells of the structure can be accurately imaged in the focused diffraction of such a grating if the largest hole does not exceed about 50 wire gauge (0.070 in. diameter). This equivalent of the first diffraction image has mechanical qualities which lend themselves well to the phase-shifting arrangements to be described.

A view of the assembled optical units of the apparatus which represents the second diffraction stage of Fig. 1

is shown in Fig. 6. This comprises, from left to right, a source of light, a pinhole, two lenses, and a microscope. The light source illuminates the pinhole, which acts as a point source of light. The diverging radiation from this source is collimated by the first lens and strikes the reciprocal-lattice diffraction grating as a plane wave. The diffraction from the grating is focused by the second lens so that the final image occurs near the right side of the assembly. The device at the extreme right is a low power microscope which magnifies the image so that its details are easily visible to the eye.

The units of the optical system are shown in Fig. 7. They are mounted on individual beds. Each unit and bed is fitted with a millimeter scale and vernier attachment so that the unit, if removed for any purpose, can be accurately returned to its correct location.

The optical path of the system is normally shielded from the disturbing influences of stray light by a tubular cover, seen in Fig. 8. The optical system is also fitted with an auxiliary mirror which can be raised into the cone of rays converging from the second lens. This throws the diffraction image back to a point near the grating, where it can be viewed by the operator from this region, Fig. 9. This arrangement permits the operator to make any desired adjustments on attachments to the grating, such as the phase shifters to be described beyond, while watching the results.

The source of light is a water-cooled mercury arc, specifically the General Electric *A-H6*. The mercury green line (5461A) is isolated from the arc spectrum. Shorter wave-lengths are eliminated by a Wratten filter No. 12, whose cut-off is nearly complete below about 4900A. This is placed permanently behind the lens of the microscope objective. Longer wave-lengths, particularly the orange component near 5800A, are eliminated by taking the photographs on orthochromatic film.

The mercury arc illuminates a very small pinhole. The limitations on the size of this pinhole can be appreciated if one notes that, with the magnification mentioned earlier, an atom one angstrom in diameter would appear as a disk about 0.03 mm in diameter. This is about 0.001 in., and the upper limit of the diameter of the pinhole must not substantially exceed this, and preferably it must be considerably less in order to resolve detail in the individual atoms of the image. In the apparatus shown in Fig. 6 there is a turret device, Fig. 7(b), which permits one to swing pinholes of four different sizes into position. The two largest pinholes are 0.0015 and 0.0007 in. in diameter, respectively. These were prepared by drilling holes mechanically in thin pieces of brass sheet. Their principal use is to examine images for atomic position, where atomic detail is not required. The turret device also bears two very much smaller pinholes of graded sizes which were found to occur fortuitously in thin aluminum foil. These are necessary when detailed photographs, such as shown in Fig. 13, are to be taken.

The two lenses are plano-convex and are substantially duplicates, with diameters of 6 in. and focal lengths of 6 ft. They are very perfectly corrected for spherical abberation but, of course, require no correction for chromatic abberation since they are used with monochromatic light.

The microscope at the right end of Fig. 6 has two standard parfocal microscope objectives of 16 and 32 mm focal lengths, respectively, mounted in a special turret so that they can be quickly interchanged, Fig. 7(d). The microscope image can be either examined visually through an eyepiece, or a small film holder can be substituted for the eyepiece, Fig. 6, and the image photographed. As mentioned above, orthochromatic film is used for this purpose in order to eliminate the orange mercury line.

It has been pointed out[1] that any phase shift whatever can be imposed on the rays scattered by a point of the reciprocal grating by interposing in the path of the rays going through the point a tilted flake of mica which has been ascertained to have a truly uniform thickness. This was experimentally proven by the writer to be feasible as early as 1941. For this purpose, a thin cleavage flake having as large an area as possible is separated from an excellent crystal of mica. The thickness uniformity is easily judged by a very simple interferometer method: The flake is merely held close to a strong broad source of monochromatic light, such as a General Electric "Labarc." Interference fringes then appear to contour the mica flake, and these are without discontinuities in fields where the cleavage flake has a uniform thickness. It is a simple matter by

FIG. 8.

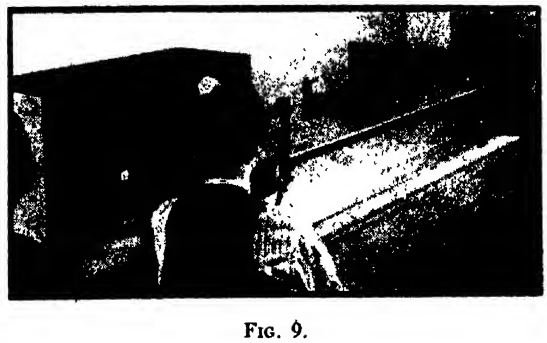

FIG. 9.

FIG. 10.

such observations to map out the regions of the flake which are uniform in thickness. A large uniform area is then selected for the purpose of cutting out the phase shifter units described below.

In order to calibrate the mica sheet so prepared, a small sample of the sheet is cut out and mounted on a rotation device which is placed so that the mica is directly in front of one of two equal circular holes of a two-hole "grating," shown in Fig. 10. The diffraction pattern of the pair of holes can be examined by placing the "grating" in the optical apparatus described above. Without the mica in the system, the diffraction pattern consists of a series of short linear maxima whose long directions are normal to the separation direction of the two holes. When the mica sample is placed in front of one of the holes, these maxima are shifted, in general, in accordance with the phase shift induced by the additional path length through the mica. This path length, and its attendant phase shift, is a function of the angle which the normal to the mica sheet makes with the rays passing through the hole. By measuring the drift of the fringes as a function of the mica angle, the phase shift produced by a particular mica flake can be determined as a function of this angle. For example, the setting of the mica which causes a shift of maxima so that one maximum comes to be located where a minimum occurred with no mica in place, corresponds to a phase shift of π. Proceeding in this way, the angle which the mica should make with the optical axis of the system to cause a phase shift of any required amount can be determined. The theory and practice of constructing phase shifters will be discussed in more detail in another paper.

A practical way of placing the mica sheets at the correct angles in front of the various holes of the grating is illustrated in Fig. 11. This particular example shows phase shifters in place in front of the grating used for producing the image of marcasite, FeS_2, described later and shown in Fig. 13. The individual mica pieces are mounted on small brass blocks in such a way that the mica makes the required angle with the rays through the grating holes. The blocks are placed on shelves along each row of one set of rows in the reciprocal lattice.

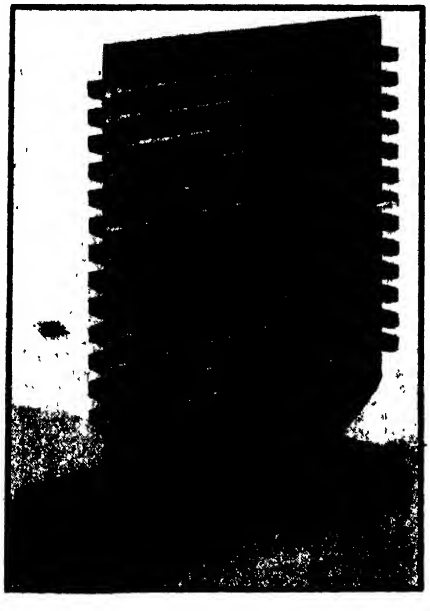

FIG. 11.

FIG. 12. Left to right: (a) Assembly for producing phase shift of π for centrosymmetrical images. (b) Assembly for producing any phase shift required for non-centrosymmetrical images. (c) and (d) The assembly shown in (b) taken apart. The piece in the right is the mica-bearing member whose orientation can be varied within the metal block seen in (c).

It is convenient to have two kinds of phase-shifter blocks. The rather simplified block shown in place in Fig. 11 is desirable when the pattern of the crystal structure projection to be imaged is centrosymmetrical. In such cases the phases can have only the values 0 and π, so only two discrete values of phase must be impressed on the scattering from the holes of the grating. The phases of the waves scattered by those holes whose scattering phase is to be set at zero need not be regulated, for the phase of the plane wave impinging on the grating may be taken as zero. But the phases of the waves scattered by holes whose scattering phase is to be set at π must be controlled by placing in front of each such hole a block bearing a piece of mica set at the correct angle to produce the phase shift of π. The design of this simple phase shifter is shown in Fig. 12. To image an average crystal structure, about 100 phase shifters are ordinarily needed. This requires that the original piece of mica should be of sufficiently large area to permit cutting 100 duplicate pieces from it. Each such fragment is cut so that the rotation of the

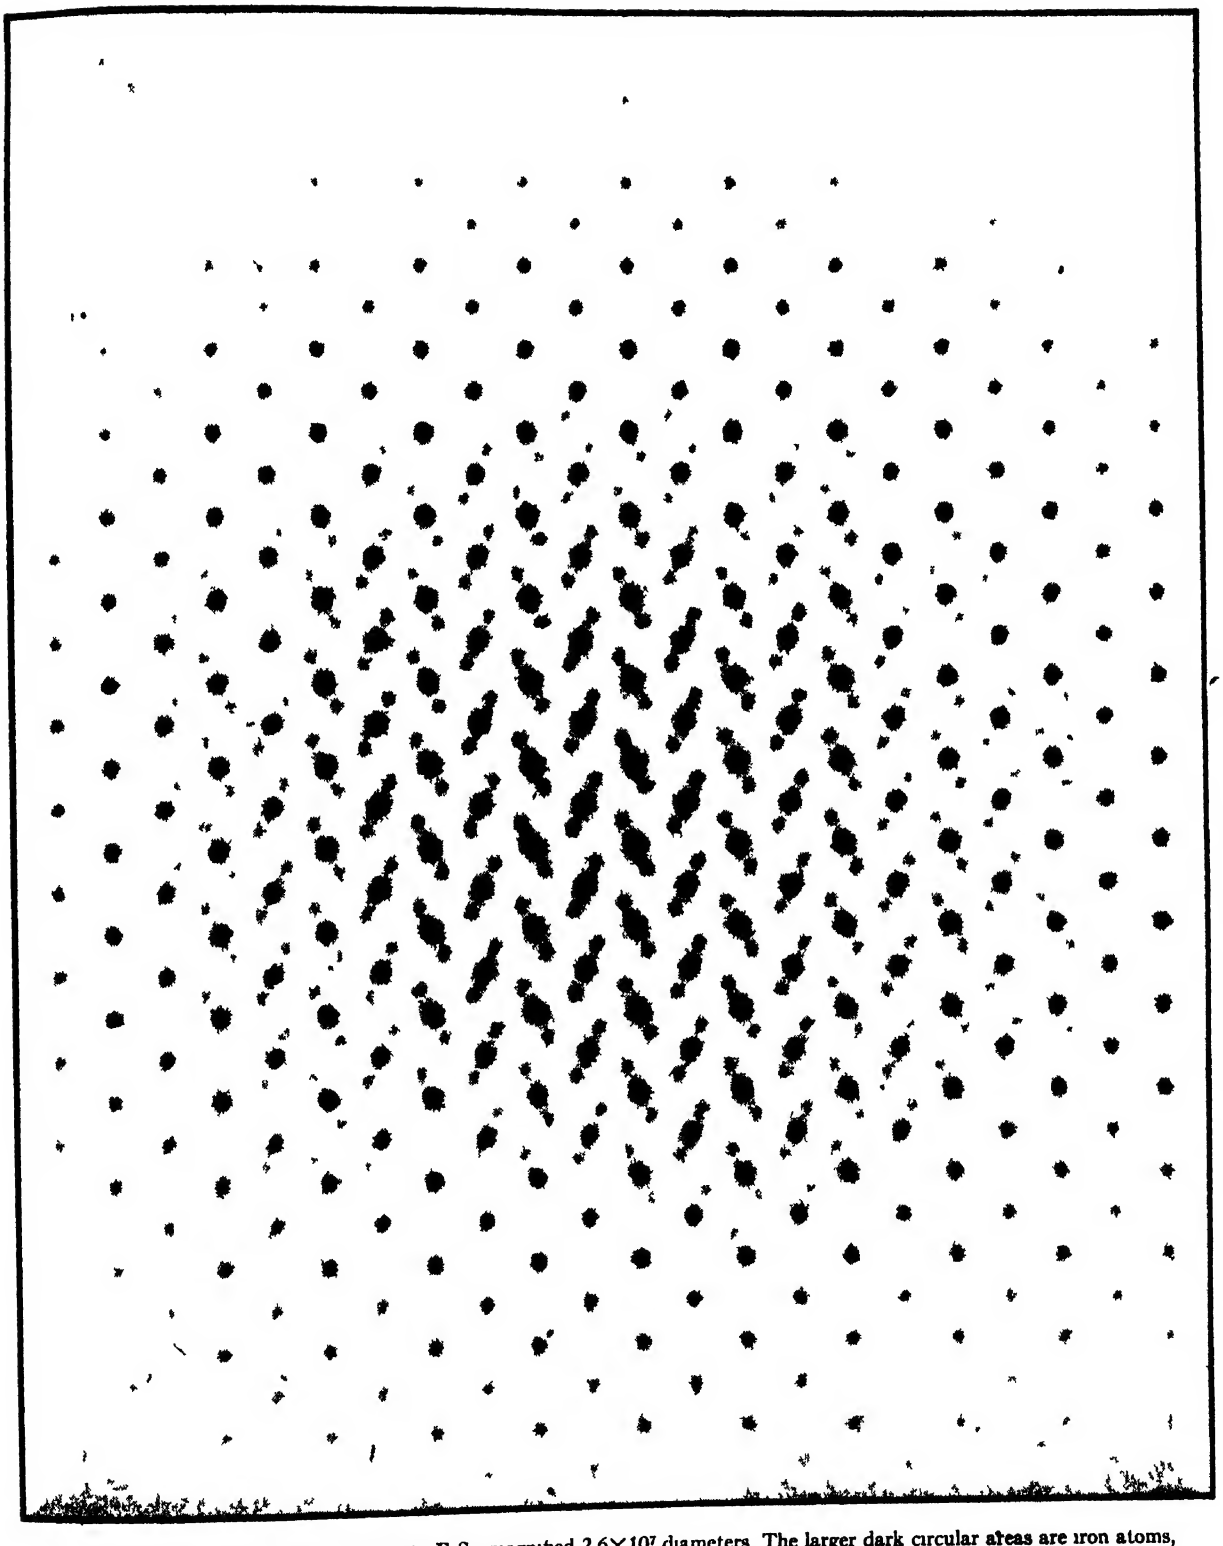

FIG 13 Image of the atoms in *marcasite*, FeS_2, magnified 2.6×10^7 diameters The larger dark circular areas are iron atoms, with 26 electrons each while the fainter darkened areas are sulfur atoms with 16 electrons each

mica is carried out about its optical direction Y, which minimizes the double refraction of the mica.

For imaging projections of crystal structures without centrosymmetry, each spectrum has, in general, its own different phase. To impress all these different phases that the phase-shifter block must have, the mica must be mounted so that its angle with the optical axis of the system can be varied. Figure 12 shows the design of such phase shifters which has been found to be practical. Between 200 and 400 of such units are needed to properly image the average crystal structure projection.

Figure 11 showed the phase shifters in place on the grating appropriate for imaging the crystal structure of marcasite, FeS_2 as seen along the c axis, and Fig. 13 shows the final image produced by the two-wave-length microscope system, utilizing this grating. The iron atoms, with 26 electrons each, are imaged as the heavier spots, while the sulfur atoms, with only 16 electrons each, are imaged as the lighter spots. The photograph is an accurate electron density map of this crystal structure.

To produce this image, the 150 individual $hk0$ spectra within recording range of the 30° precession photograph made with Mo$K\alpha$-radiation were utilized. A few of these spectra had amplitudes of zero. Of the entire 150 possible spectra, 32 required phase shifts of π, and Fig. 11 shows the 32 corresponding phase shifters. The test of the success of the phase shifting is the reproduction of the sulfur atoms, which are imaged as the less dense spots. To image the iron atom positions in this particular pattern requires the use of positive phases only, but to image the sulfur atom positions properly requires that the correct combination of negative and positive phases has been impressed on the grating.

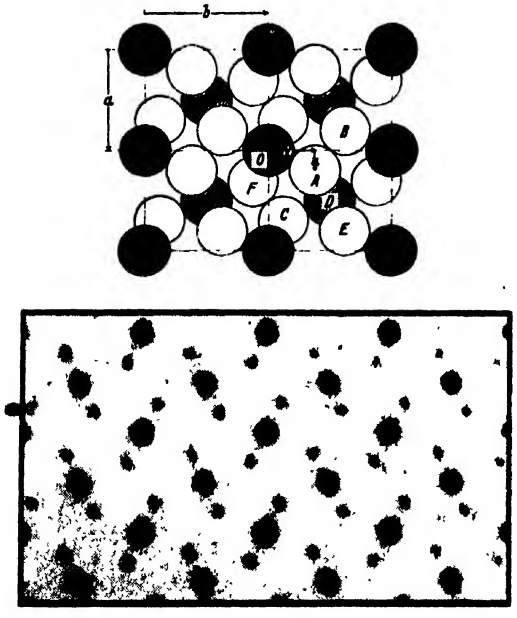

FIG. 14. Below: Image of the atoms in *marcasite*, FeS_2. Above: Diagrammatic representation of the crystal structure of *marcasite*.

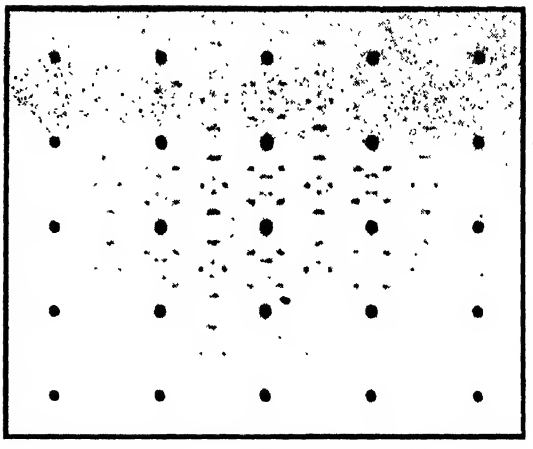

FIG. 15. Photographic Patterson synthesis, $P(xy)$ for *berthierite*, $FeSb_2S_4$.

Figure 14 shows part of Fig. 13 compared with a diagrammatic representation of the crystal structure of marcasite taken from an earlier paper.[7] In the diagrammatic representation, the shadings of the circles do not represent electron density, and their sizes merely illustrate the packing radii of the atoms, which are not related in a simple way to the electron densities in the atoms. With this proviso, the photographic reproduction of the atoms is in striking agreement with the published crystal structure of marcasite.

A word of caution is required. The development just described *does not* mean that now any crystal structure can be photographed. It *does* mean that this can be done provided that the phases which must be set with the mica phase shifters is known. These are the phases of the F's of x-ray diffraction, and they cannot be determined experimentally, although the magnitudes of the F's can. To know the phases requires, in effect, that the locations of the atoms are known. But when the phases are not known, which is the state of affairs as a new crystal structure is first examined, the apparatus described above automatically gives the Patterson synthesis[8,9] of the crystal, a fact which was noted[6] in 1939. An example of such a synthesis is shown in Fig. 15. The Patterson synthesis is related to the true image of the crystal structure in the following way: If one views the crystal structure from a fixed point, he sees a true image of the crystal structure. But if one occupies each of the n atoms of the structure in turn, viewing the crystal structure from each one, and then superposes all n parallel images, the composite image is the Patterson synthesis. Theoretical progress has recently

been made in the direction of eliminating from the Patterson synthesis all crystal structure images but one.[10] When this theory and practice is perfected, it will become possible to set the phases for producing the true image by utilizing the first Patterson image made without phases.[11]

The writer is indebted to the National Research Council Committee on Scientific Aids to Learning for a grant in 1939 to cover the construction of the instrument described in this paper. He is also personally grateful to Drs. Vannevar Bush and Warren Mead for their encouragement in the development. The undertaking was greatly aided by the assistance of Mr. John Tyler, who superintended the engineering of the main optical system, turning ideas into realities. The gratings, phase shifters, and pinholes are the expert handiwork of Mr. John Solo, and the writer is also indebted to a graduate student, Mr. Jay W. Lathrop, for examining and calibrating suitable mica for the phase shifters used to make Figs. 13 and 14.

A Model of Hurricane Formation*

HERBERT RIEHL
University of Chicago, Chicago, Illinois
(Received April 10, 1950)

At first, the description of the energy cycle of the mature tropical storm is amplified on the basis of recent upper air observations. Air particles passing through such a storm at first undergo isothermal expansion as they move toward a center. Then they ascend with release of condensation. At high levels they move outward and mix with the environment giving off heat to the surrounding colder air. Several requisites for maintenance of the observed temperature field are stated.

After a discussion of previous theories of hurricane formation the proposed model is described. The initial intensification of the wind field is brought about by mass divergence at high levels that imposes a pressure reduction on the surface layers. This divergence is the result of interaction between the large-scale disturbances of the upper air inside and outside the tropics. A solenoidal circulation is initiated that acts in the kinetic energy producing sense. But this circulation contains an internal mechanism for its own destruction and is maintained only under certain special conditions which are stated.

SINCE the early 1940's, numerous observations of pressure, temperature and wind have been taken in the atmosphere in the tropics at heights up to 20 km. These make possible a re-examination of the views held concerning the formation of tropical storms. Such a re-examination is the object of this report. New observational data are not offered. For these, the reader is referred to several of the references listed.[1–3]

THERMAL STRUCTURE OF FULLY DEVELOPED STORM

It is of advantage to begin with comments on the hurricane circulation after it has grown to full intensity. In some ways, tropical storms are those disturbances within the atmosphere whose maintenance is easiest to understand at present. Figure 1 is a representative sketch of pressure, temperature and circulation in a vertical section across a well-developed hurricane or typhoon outside the "eye." This figure shows a simple heat engine. Near the surface, air moves from high toward low pressure, converges and ascends. During the ascent, latent heat of condensation is liberated. In consequence the air near the center is warmer than its surroundings through a deep layer and the vertical spacing between the surfaces of constant pressure is larger. The pressure gradient force, directed toward the center, decreases upward and eventually reverses. Air particles moving upward near the center will be accelerated outward throughout the layer of decreasing pressure gradient, if their angular momentum is conserved.[4]

Figure 2 shows the vertical structure of the air surrounding tropical storms and a characteristic curve of the structure inside the rain area on a thermodynamic chart. Curve (b) is the same as that obtained by raising an air particle dry-adiabatically from sea surface to condensation level, and then moist-adiabatically to the 200-mb level. *It follows that the air mass encountered in the rain area below 200 mb consists entirely of particles that have ascended from the lowest levels.* Entrainment of mass from the surroundings does not take place, since such entrainment would produce upper temperatures considerably colder than those of curve (b). The air that

fills the body of a hurricane originally is spread out in a thin sheet along the surface of the earth. This sheet—in which potential temperature and moisture content are nearly constant[5] has a depth of 50–60 mb. If a storm has a radius of 100 km, and if it extends to the 200-mb level, the surface air must be drained off from an area with a diameter of about 800 km in order to produce the first formation of the air mass observed inside the storm. This is an appreciable value.

One aspect of the temperature field has not received the attention it deserves. Byers[6] pointed out that the air spiralling inward toward a center experiences considerable expansion because of the pressure reduction which may have values from about 30 mb up to 100 mb. The temperature therefore should drop at a rate of nearly 1°C per 10 mb pressure reduction on account of adiabatic expansion. *Such decreases never occur. On the contrary, surface temperatures are remarkably constant throughout the body of tropical storms. The air moving inward expands at constant temperature,* and the potential temperature must increase from outskirts toward center. Rapid transfer of heat from ocean to atmosphere makes the isothermal expansion possible. In view of the highly agitated state of the ocean in hurricanes the occurrence of such rapid transfer is easily understood. Computations in a number of representative cases, mostly taken from data published by Deppermann[7], have verified the potential temperature increase. They have shown, moreover, that the moisture content of the air

Two moist adiabatic lines are entered on both sides of the soundings.

also becomes larger by 1 to 2 grams of water vapor per kg of air. This increase is also readily understood.

Figure 3 demonstrates the importance of this local energy source in tropical storms. Curve (b) represents the ascent of the surface air without local heat intake as in Fig. 2. Curve (a) shows an ascent from 960 mb under the assumption that the moisture content has risen by 1.5 g/kg and that the air has expanded isothermally to 960 mb. The difference between the two ascent curves is large. Comparison between curves (a) and (b) in Fig. 2 and curve (a) in Fig. 3 shows *that the area enclosed on the thermodynamic chart between the normal surroundings and the interior of a storm doubles in size if we allow for the local heat source.*

We must now turn to the problem of maintenance of the temperature field sketched in Fig. 1. The streamlines shown in this figure indicate outward transport of warm air aloft which should raise temperatures in the outskirts and destroy the solenoid field. If we make use of the local heat addition just mentioned, it is possible to obtain a temperature field that is partly steady. Let the air ascending near the outskirts of a cyclone follow curve (b) of Fig. 3, and the air nearest the center curve (a). Values intermediate between these extremes will be found in the middle region. If the air following curve (a) ascends the largest distance and the air following curve (b) the least, as sketched in Fig. 1, then the horizontal temperature gradient inside the storm will be maintained in the low and middle troposphere.

Outside the boundary of the storm, the outward transport of very warm air should be observed within a radius of 500 miles and more soon after establishment of a hurricane because of the large mass transport involved. Actually, however, the extremely warm air is not noticed at such a distance from the center. A slow and gradual warming of the surroundings takes place and very high temperatures are never reached. This

permits only one conclusion, namely that the air flowing out at high levels mixes with the surrounding air masses, that have not passed through the circulation, and gives up heat to them. At the same time the mixture is carried away from the storm area by the currents aloft and replaced by cooler air from other portions of the globe. In this way the entire temperature field relative to the storm is maintained. Two things must be noted. The mixing must take place outside the core since, as shown during the discussion of Fig. 2, the air of the environment does not enter the center aloft. It is also necessary to have a mechanism that is able to carry the mixture far away from the storm area and permit other air to approach.

Three phases of the energy cycle of the air passing through the cyclonic circulation have now been described. They are: (1) isothermal expansion with moisture addition; (2) dry-adiabatic expansion to the condensation level, followed by moist-adiabatic expansion; (3) mixing with cooler air aloft, a process that takes place at nearly constant pressure.

Figure 4 illustrates these three steps. For the construction of this figure a sample of air has been chosen that ascends to 200 mb and mixes with the surroundings at that level. The reduction of temperature from −47°C to −52°C at 200 mb, as indicated, is plausible, if we consider that the surroundings normally have a temperature of −55°C which is observed to rise to about −52°C in the situation under discussion. It is readily apparent from Fig. 4 that only a small percentage of the heat released during expansion of the ascending air from 1000 mb to 200 mb is available for conversion into kinetic energy. Maximum conversion is obtained if the air descends dry-adiabatically (following the dashed horizontal line) to the level at which its temperature becomes equal to that of the interior of the storm. The upper area (a) in Fig. 4 is only 12 percent of the total area (a+b) enclosed by the hurricane sounding and the normal surroundings. This represents the maximum efficiency of the circulation which, however, is never realized. As stated before, temperatures comparable to those inside are not observed outside. Therefore only a

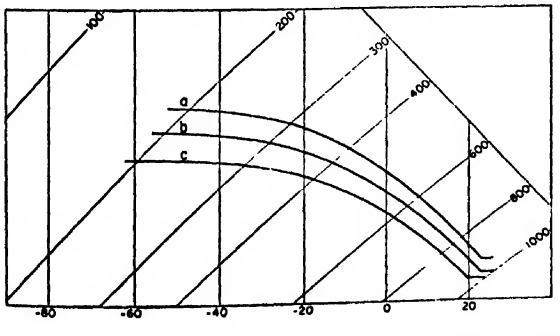

FIG. 3. Tephigram showing (a) ascent of air that has expanded isothermally to 960 mb at the sea surface with pickup of 1.5 g/kg of moisture; (b) same as sounding (b) of Fig. 2; (c) ascent of air with slightly polar characteristics (24°C, 16 g/kg).

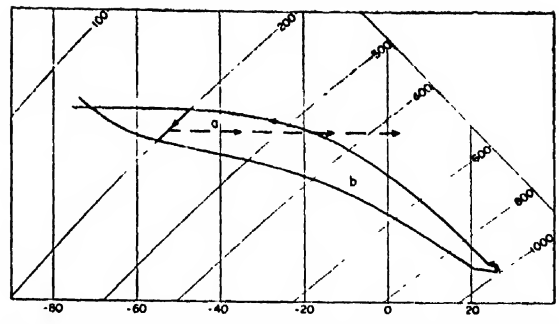

FIG. 4. Tephigram showing isothermal expansion of air at sea surface to 960 mb, dry-adiabatic ascent to condensation level, then moist-adiabatic ascent to 200 mb and horizontal mixing at 200 mb. Dashed horizontal line indicates descent of mixture outside the circulation. Lower curve is same as curve (a) of Fig. 2. The area (a+b) represents total heat gained by hurricane circulation, and area (a) represents maximum amount of energy available for conversion into kinetic energy.

fraction of the energy represented by area (a) actually is used to drive the storm. The vast bulk of the heat released is spread over the globe.

Figure 4 shows clearly that a tropical storm and its surroundings cannot be considered as a closed system. It is a matter of weeks or more until the air that has risen in the storm can return to the surface under the influence of radiation. New air constantly enters the cyclone. In the course of the life of one storm, the air initially located over a large portion of a tropical ocean may pass through its circulation system.

Using the preceding discussion as a base, we are now in a position to examine critically several theories of hurricane formation that have been put forward.

PREVIOUS THEORIES OF HURRICANE FORMATION

Convectional Hypothesis

This is the oldest hypothesis and briefly states the following: an unusually large number of heavy rain squalls and thunderstorms develops for some reason over tropical ocean. These rain clouds then grow together and a cyclonic circulation develops at the ground due to convergence. Because of the heavy rainfall energy is available for an increase of the circulation (curve (b) of Fig. 2).

Most writers have discarded this hypothesis as insufficient for a number of years. But it still recurs in some textbooks. Here we shall mention only one objection: a mechanism for organized mass removal aloft is not specified, so that the area of heavy showers and its immediate surroundings will act almost as a closed system. After ascending the air will descend dry-adiabatically in the environment (following the horizontal lines of Fig. 2) and the environment will soon be warmer than the cloudy area. Any incipient circulation must dissipate. Actually, most heavy rainfalls of the tropics occur when the wind field is very weak or only slightly cyclonic. A sequence of events then takes place

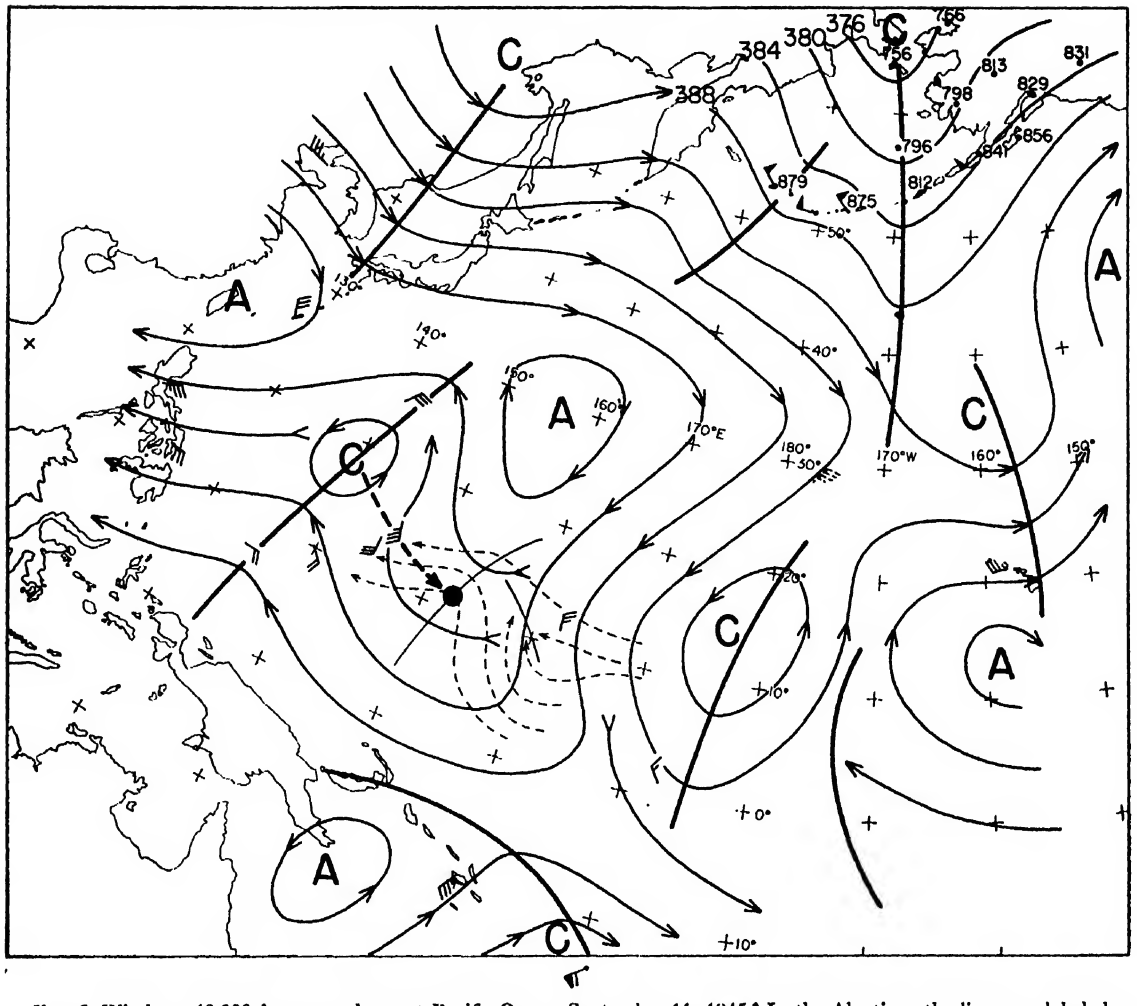

FIG. 5. Winds at 40,000 feet over the west Pacific Ocean, September 11, 1945.[2] In the Aleutians the lines are labeled as contours of the 200 mb surface (hundreds of feet). "*C*" stands for cyclonic circulation, "*A*" for anticyclonic circulation, and heavy solid lines indicate wave troughs and shear lines. In the wind reports a long barb denotes 10 m.p.h., a short barb five m.p.h. and a heavy triangular barb 50 m.p.h. Near the Marianas the 10,000-foot flow is shown by light dashed lines. Heavy dashed line denotes motion of incipient typhoon (heavy dot) relative to upper disturbance in which it had started during several preceding days.

which is fairly similar to that just outlined. Energy must be drawn into these circulations from an outside source in order to maintain them.

Frontal Hypothesis

About 1920, the Norwegian meteorologists formulated a theory of formation of shearing waves at density discontinuities (fronts). It has been since suggested that the zone of convergence, where the trades from northern and southern hemisphere meet, also is a boundary with a small density discontinuity along which shearing instability can develop. Actually, many storms, though by no means all of them, originate near this boundary. It is not possible, however, to accept the frontal hypothesis as an explanation.

TABLE I.

P	1	2	3	4
surface	26.0	26.0	26.0	24.0
900	20.0	20.5	22.5	18.0
700	8.0	11.0	13.5	8.0
500	−6.0	−3.0	0.5	−6.5
300	−33.0	−28.5	−23.5	−34.0
200	−55.0	−53.0	−47.0	−59.0

As in the case of the convection theory, a mechanism for outflow is not provided. There is another serious objection. According to the Norwegian concept, the denser air mass settles underneath the lighter mass, and this release of potential energy can lead to an increase of the kinetic energy. After some time (24–36 hours) the cyclone core at the surface consists entirely of cold air. Most of this cold air sinks in case of cyclones outside the tropics. In fundamental contrast, all air that enters a tropical cyclone near the surface ascends in the core. If a tropical cyclone core becomes filled with air that is even

slightly denser—and usually somewhat drier—than the normal tropical atmosphere, conditions become extremely unfavorable for the growth of a storm. Curve (c) of Fig. 3 illustrates this difficulty. This curve gives the ascent path of air that is very little cooler and drier ($T = 24°C$, specific humidity = 16 g/kg) than the air used for the construction of curve (b) ($T = 26°C$, specific humidity = 18 g/kg). A large temperature difference aloft results. If we compare curve (c) of Fig. 3 and curve (a) of Fig. 2 we see that no positive area is left on the thermodynamic chart. In fact, there is now a slight negative area. For comparison, the data of Figs. 2 and 3 are presented below in tabular form. Temperatures at certain isobaric surfaces are given for: (1) the average tropical atmosphere in the Caribbean; (2) the ascent of the surface air of average properties (26°C, 18 g/kg); (3) the ascent of the same air after isothermal motion to 960 mb with pickup of 1.5 g/kg of moisture; (4) the ascent of air with very slight polar characteristics (24°C, 16 g/kg).

Clearly, the entry of air with slightly polar characteristics must stop any incipient storm. It is a good forecasting rule that even intense hurricanes will weaken if they are affected by polar air while over a tropical ocean.

Hypothesis of "Dynamic Instability"

The foregoing theories are open to still another objection. Both take low level flow convergence as a starting point. Such convergence, however, must lead to pressure rises and not falls at the center, thus killing the beginning circulation. This is a well-known difficulty in cyclone theories. It is necessary to assume that the upper outflow somehow becomes sufficiently large to overbalance the surface inflow. To date, it has not been demonstrated how this is to be accomplished.

It is much more natural to suppose that at first a dynamic pressure fall occurs at the ground, produced by divergence at higher levels. Thereafter low level convergence sets in induced by the imposed pressure field. Sawyer[8] presented a hurricane theory based on this line of attack. He followed the work of Solberg[9] who showed that a symmetrical ring of air can become "dynamically unstable" under certain conditions. This can happen when the rotation of the air in space about the vertical axis (normal to the earth's surface at the place in question) is in the sense opposite to that of the rotation of the earth itself. Consider a ring of particles moving from west toward east along a latitude circle. If Solberg's criterion is satisfied, particles that are accelerated northward or southward will not tend to return to their starting latitude but move farther away from it. Under such circumstances dynamic pressure reductions can be produced.

Although Sawyer's attempt represents considerable progress, it is not conclusive for two main reasons. It is not indicated how the requisite sense of rotation is produced, nor is it shown how the unstable state is maintained. Even if "dynamic instability" exists in the region above a forming storm, the air evicted by this mechanism will sink in the surroundings. We then face the same reversal of the solenoid field which had made it impossible to accept the convectional hypothesis. No treatment exists as yet concerning the production of "dynamic instability." In middle latitudes, there frequently is a narrow zone in the high troposphere south of the maximum westerlies in which Solberg's criterion is satisfied.[10] Within the writer's experience, such a zone cannot be found in low latitudes, at least north of 15°N, in spite of the small value of the rotation of the earth itself (Coriolis parameter). Since data are scarce and scattered in the tropics, it is not easy to prove this assertion. Even at latitude 20°, however, a wind shear of 4 m sec.$^{-1}$/deg. lat., or a radius of flow curvature of 2° latitude at a windspeed of 10 m sec.$^{-1}$, are necessary in the limiting case when the rotation of the air particles relative to the earth is just equal in magnitude to the rotation of the earth itself. No plausible mechanism has been offered for the production of such large values over appreciable areas in the tropics prior to cyclone formation.

In summary, the theories just examined have one principal common drawback: they all consider only internal characteristics of the tropical atmosphere in the area of an initial disturbance. After some intensification this disturbance apparently is thought to be self-propagating. As we have seen, this is impossible. *At all times there must exist a connection between a hurricane and the surrounding atmosphere aloft over wide distances.* Sawyer's attempt is attractive in that it seeks to develop an initial field of upper divergence rather than a field of low level convergence. In the following, we shall retain this approach. But it is more plausible, and suggested by the observations, to specify an external rather than an

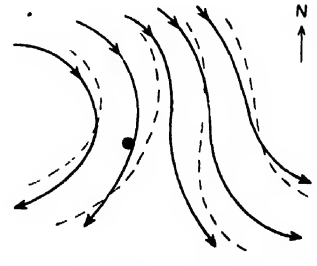

FIG. 6. Model of streamlines and contours (dashed lines) at 200 mb during deepening of a tropical disturbance (heavy dot) in northern hemisphere.

internal mechanism that can produce the requisite field of divergence.

PROPOSED MODEL OF HURRICANE FORMATION

Analysis of numerous charts at different levels over Atlantic and Pacific Ocean during the hurricane and typhoon season has brought out two factors that indicate the operation of external forces over an area within the tropics where a weak initial disturbance is present in the lower layers.[11]

(1) The trade winds of the low atmosphere disappear quickly with height near 500–400 mb (about 6 km). In the upper troposphere (300–150 mb, 9–15 km) we observe a train of large cyclonic and anticyclonic eddies that gradually drift westward[2] (Fig. 5). These eddies often move at a rate that differs from the displacement of the low level tropical disturbance. The latter, therefore, may be located under a different regime of high level winds at different times. Commonly, disturbances first develop in the air underneath an upper cyclone center. Deepening to typhoon strength, however, often takes place as the surface disturbance is being transferred from the influence of an upper cyclone to that of an upper anticyclone.

We shall choose a position of the deepening disturbance relative to the upper flow shown in Fig. 6 as a model. It is to be noted that the surface center and the air associated with it do not participate in the indicated motion of the current at 200 mb. This northerly current blows over the disturbed zone at rates that attain 50 m.p.h. and more.

(2) There is pronounced interaction at high levels between the tropical vortex train mentioned and the long waves in the westerlies outside the tropics. The low latitude eddies drift westward, and the troughs and ridges in the westerlies drift eastward. At times an upper cyclonic center of the tropics, for example, will be situated south of a trough in the westerlies, and at other times an anticyclonic center. Thus the connection between high level disturbances of middle and low latitudes will vary between in-phase and out-of-phase superposition. In Fig. 7 two types of superposition are sketched. Both disturbances have the same sense of rotation in Fig. 7a, but opposite rotation in Fig. 7b. The north-south components of motion are in the same sense in Fig. 7a, but the zonal component between the perturbation centers is opposite. In Fig. 7b, the reverse holds. Thus the amplitude of the composite streamlines and the intensity of the meridional flow will be increased by the superposition sketched in Fig. 7a, but the zonal speed in the central latitude band will decrease. Conversely, the meridional flow weakens in Fig. 7b and the streamline amplitude becomes flatter, while the zonal component in the central portion speeds up.

Without rigorous analysis we cannot know whether superposition produces net changes of kinetic energy. It is possible that the increase of north-south kinetic energy in case of Fig. 7a is obtained entirely through transformation of east-west into north-south kinetic energy. Our requirements are met if the speed of the northerly current shown in Fig. 6 increases in the region of the incipient tropical disturbance, irrespective of the net kinetic energy change over the whole system of middle and low latitude disturbances aloft. As just seen this occurs during in-phase superposition (cf. also Fig. 5), which therefore is requisite for the proposed model.

The Initial Pressure Fall

The effect of the superposition on the pressure field may be deduced from the equations of horizontal motion on the rotating earth

$$\dot{v}_n + v_s(kv + f - \dot{\alpha}) = -1/\rho(\partial p/\partial n), \qquad (1)$$

$$\dot{v}_s - v_n(kv + f - \dot{\alpha}) = 0. \qquad (2)$$

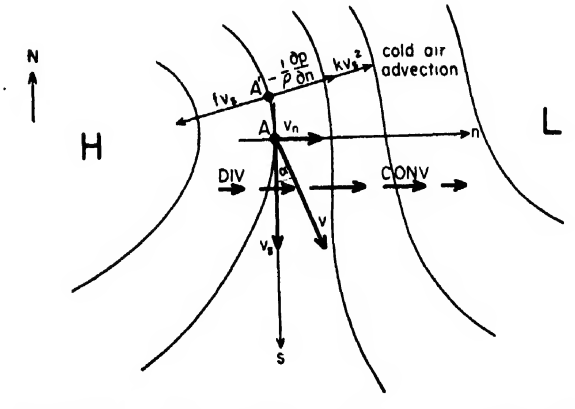

FIG. 8. Illustration of Eqs. (1), (2) at A and of Eq. (4) at A'. H denotes high pressure (resp. high elevation of 200 mb surface) and L low pressure (resp. low elevation of 200 mb surface).

[11] For a discussion of the formation of initial disturbances cf. reference 1.

Here, the coordinates s and n are chosen to lie parallel and normal (toward lower pressure) to the upper isobars (Fig. 8). v is the total motion, v_s the motion along and v_n the motion normal to the isobars (cross-stream circulation); f is the Coriolis parameter, p the pressure, ρ the density, k the trajectory curvature taken positive for cyclonic flow and α the angle between isobars and total motion (Fig. 8). The dots denote substantial differentiation with respect to time. Combination of (1) and (2) yields

$$\frac{1}{2}\frac{dv^2}{dt} = -\frac{v_n}{\rho}\frac{\partial p}{\partial n}, \tag{3}$$

which shows explicitly the well-known relation between acceleration, pressure gradient force and cross-stream flow. If the latter is zero prior to superposition, Eqs. (2) and (3) vanish and (1) becomes the gradient wind equation

$$kv_s^2 + fv_s = -1/\rho(\partial p/\partial n), \tag{4}$$

where $v_s = v$ is the total motion. In case of anticyclonic flow the centrifugal force kv_s^2 and the pressure gradient force $-1/\rho(\partial p/\partial n)$ act to the left of the isobars looking downstream; the Coriolis force fv_s acts to the right (Fig. 8).

We now let the superposition take place, manifested by an increase of $-1/\rho(\partial p/\partial n)$. The Coriolis force fv_s no longer affords balance. A cross-isobar flow v_n toward lower pressure is indicated and also an increase of the total motion (kinetic energy). Figure 6 shows the streamlines of the total motion while the cross-stream flow is in progress.

On account of the motion normal to the isobars mass divergence takes place to the right of the northerly current looking downstream, and mass convergence to its left (Fig. 8). In the region of divergence the surface pressure falls because of the mass removal, and the initial surface disturbance begins to deepen. This is the desired result, and it is brought about entirely by a coincidence: presence of the surface depression under the northerly current at the time that in-phase superposition develops. Otherwise the superposition—an event observed in several areas of the globe on every day—has no particular consequences for reasons to appear later. Nor does the existence of a weak low-level depression in a position as sketched in Fig. 6 warrant a forecast of typhoon formation per se.

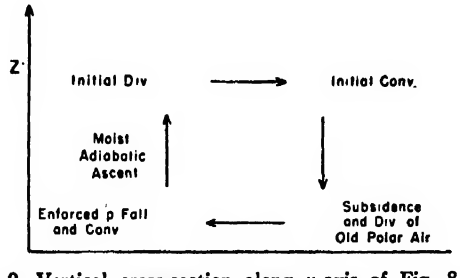

FIG. 9. Vertical cross-section along n-axis of Fig. 8. Model illustrates hypothetical development of vertical cross-stream circulation leading to deepening of the surface depression.

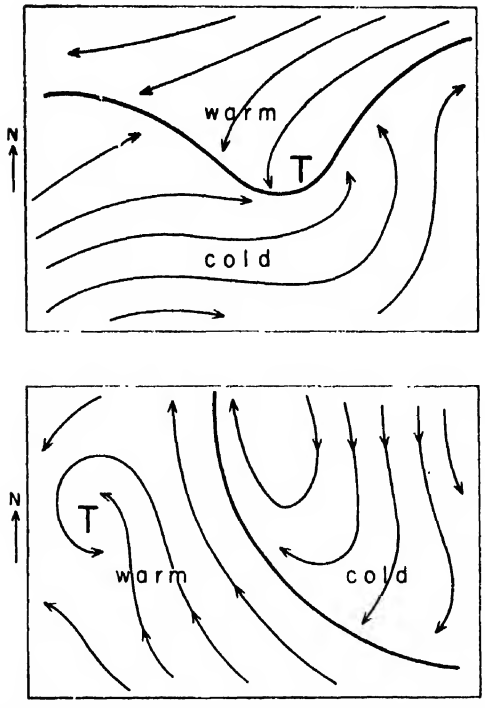

FIG. 10. Classical model of typhoon formation at "equatorial front" (above) and proposed revision (below) with cyclonic vortex situated entirely in the warm air.

Cross-Stream Circulation

The generation of the high level cross-stream flow and attendant field of convergence and divergence has several obvious consequences. Surface convergence develops under the region of upper divergence and, conversely, surface divergence develops under the region of upper convergence. It follows from continuity requirements that air must ascend along the right margin of the northerly current aloft and descend along its left margin (looking downstream). Figure 9 shows the complete cross-stream circulation in vertical cross-section along the n-axis, which points from high toward low pressure aloft. This circulation acts as a left-handed screw about the s-axis. The observations show that temperatures are higher on the right of this axis than on its left (Fig. 2). Therefore the warm air rises and the cold air sinks. The vertical circulation is in the kinetic energy producing sense.

We can now make use of another fact supplied by the observations. In the situation described a strong equatorward acceleration of the low level northeast trade frequently is noted along the eastern end of the upper northerly current and still farther east (500–1000 km from the tropical depression). Sometimes this acceleration is coupled with arrival of a polar air mass from the north.[3] Such polar air masses are gradually transformed

to tropical air during their equatorward passage. They are also observed to spread laterally and therefore sink. This sinking of old polar air adds to the descent in the eastern portion of the circulation cell shown in Fig. 9 and therefore acts to accelerate the whole cell. The polar air, of course, cannot invade the area of the tropical depression itself, if there is to be a storm. It bypasses this area going southward (Fig. 10). If, for some reason, the polar outbreak takes place too far to the west, the whole development ceases.

It is of interest that the model here proposed does find a role for old polar air, so prominently mentioned in many previous studies. This role differs radically from that formerly assigned to the polar air. Figure 10 illustrates the difference in viewpoint on the relative position of polar air and tropical disturbance. According to the present model, the sinking of the accelerated northeast trade provides a second mechanism that is suitable to remove air aloft from the area of the tropical depression and allow it to settle at a considerable distance. It is to be noted that this particular mechanism is not encountered in all instances. Among several alternatives, the formation of clockwise eddies in the low latitude trade stream has been mentioned.[2]

Maintenance of Cross-Stream Circulation

It is necessary now to examine the crucial problem of maintenance of the vertical circulation cell that has been initiated. There are two principal factors that act to restore equilibrium as soon as it is disturbed. One of these is the Coriolis force; the other the vertical stratification of the atmosphere. Except under special assumptions—which are often unrealistic—Eqs. (1, 2) do not yield a unique answer as there are too many variables. Consider, for instance, a situation near latitude 20° when initially $v_s = 10$ m sec.$^{-1}$ and $k = 10^{-6}$ m^{-1} (radius of curvature of 1000 km). Then $fv_s = 4 \times 10^{-2}$ cm sec.$^{-2}$ and $kv_s^2 = 10^{-2}$ cm sec.$^{-2}$. Let the windspeed v double in consequence of changes in the pressure gradient force Eq. (3). As $v_n \ll v_s$ in most situations of the kind here discussed, we can still estimate the magnitude of the forces in Eq. (1) by setting $v_s \sim v$. Both kv_s^2 and fv_s increase by 4×10^{-2} cm sec.$^{-2}$ provided k remains constant. In this case a true dynamic instability would have been achieved, especially as the term $-\dot{\alpha}v_s$, whose magnitude is hard to judge, acts in the same direction as the centrifugal force. The increase of restoring force is balanced by the increase of the centrifugal force. Thus the initial increment of the pressure gradient force remains unbalanced. As k is small, however, large percentual changes of this quantity are possible. Moreover, the cross-stream circulation affects the mass distribution and therewith the pressure gradient force. Only one definite statement is possible. A cross-stream circulation, once initiated, is much more easily maintained when the flow is anticyclonically curved than when it is cyclonically curved. In the latter case, fv_s and kv_s^2 act together as restoring forces.

The energy aspects yield a more conclusive answer. Let us return to curve (a) of Fig. 2 which serves as a representative sample of non-saturated air as encountered in the tropics. When such air is raised following the dry-adiabatic path indicated by the horizontal lines of Fig. 2, cooling results at all heights. When it sinks, warming takes place. Assuming that the vertical displacements sketched in Fig. 9 occur in non-saturated air, it follows that the western portion of the circulation cell will cool and that the eastern portion will become warmer. This acts to destroy the initial temperature gradient between eastern and western cell ends. It also acts to lower the pressure at high levels in the west and raise it in the east, reducing the increment in the pressure gradient force aloft that had been obtained through superposition. Clearly, the vertical circulation cell contains an internal mechanism for its own destruction under the circumstances described. The order of magnitude of vertical displacement requisite to stop the circulation is small. It may be estimated at 100 m.

It is quite probable that most vertical circulations actually come to an end in this way. If there is to be a hurricane, further necessary conditions must be introduced. At the eastern cell end, the temperature field relative to the incipient disturbance can be maintained if the warming due to subsidence is balanced by continuous advection of colder air. Circumstances are favorable for this to occur. The frequent equatorward movement of an old polar airmass in the low levels 500–1000 km east of a developing disturbance has already been mentioned. *At high levels, the superposition and attendant increase of streamline amplitude make possible prolonged displacement of cooler air from middle latitudes toward the tropics.* The data support this suggestion. Observations in a number of representative cases have shown that temperatures remained constant, or even decreased, in the eastern parts of the vertical circulation cells, in spite of subsidence.

In the region of ascent, temperature falls can be prevented by condensation. If the air that forms the tropical depression in the lower layers is saturated (area 10^3–10^4 sq. km), its ascent follows the moist rather than the dry-adiabatic path and no cooling will occur. *Thus it is essential to have such a saturated air mass available.* The saturation is produced by formation and dissipation of numerous cumulus clouds in the disturbed area. Moisture is funnelled upward by this mechanism and then spread laterally aloft. It is of importance to note that this process takes place mainly below six km. As stated initially, a rapid transition from trade wind to upper vortex regime is observed near that level. The lower air columns have only a slow drift relative to the surface depression. Whereas the air at 200 mb can pass over it in perhaps three hours, the low level air may remain in its orbit for days. Thus the moisture that is funnelled aloft,

is not carried away and gradual saturation below the level of wind reversal is made possible.

It is of much interest to note that such penetration of moisture is known to coincide with a gradual approach of the temperature lapse rate to the moist adiabatic. When saturation is complete, the vertical stratification of the atmosphere is nearly neutral and no longer unstable with respect to moist adiabatic displacements of particles. The local buoyancy force becomes relatively unimportant. This observation reveals another difference between dynamic and thermal theories of hurricane formation. The latter wish to obtain energy for the development of a circulation from vertical instability with respect to moist-adiabatic ascent. For practical purposes, this means that the atmosphere is unsaturated except for the rising parcels. As just seen, this is precisely the situation in which a large-scale vertical circulation cell will not be maintained. Of course, it would be best to operate with a field of upper divergence on a lower atmosphere that is saturated and has a temperature lapse rate in excess of the moist adiabatic. Since this cannot be obtained in reality, *an atmosphere as given by curve (b) of Fig. 2 represents optimum conditions for cyclone formation. Condensation energy is converted into kinetic energy not through local overturning of a vertically unstable atmosphere, but through large-scale vertical circulations. It follows that any mechanism, applied to the lower atmosphere, that operates to establish curve (b) of Fig. 2 will augment the chances of hurricane development.*

Conclusion

The foregoing pages have attempted to determine the reasons why tropical storms form under certain circumstances. In particular, we have sought to establish a mechanism for the removal of air over a cyclogenetic zone at high levels. This led to an inversion of previous attacks on the problem. Former investigators at first tried to find reasons for an increase of the cyclonic circulation from low-level considerations and then looked for ways and means to remove the air ascending in the vortex core. Such an approach restricts the analysis to internal factors—latent heat of condensation and internal structure of the field of motion.

In this report, the mechanism for outflow is established prior to deepening, and the cyclone is considered to deepen in response to upper divergence. A total of three energy sources has been applied to this end. The in-phase superposition of high and low latitude wave trains in the upper troposphere directly intensifies the speed of the high level northerly current that has been analyzed under the assumption that the balance of forces within it is the decisive factor. Subsidence of a southward moving mass of polar air provides a second energy source underneath the left-hand portion of this current, and the latent heat of condensation acts as third source on its right.

As yet, atmospheric processes cannot be measured directly but must be inferred from the three-dimensional structure of the atmosphere and its changes with time. These processes are not tied uniquely to the configurations of upper or lower flow pattern. We know, for instance, that it is not common to have ascent with high level divergence in the eastern portions of dynamic highs. Most of the time convergence and descent prevail aloft in these areas. Again, hurricanes have been observed to deepen when passing underneath upper troughs. But the shape of these troughs and the temperature distribution within them are not unique. Streamline and/or trajectory curvature can be cyclonic or anticyclonic.

Certain basic features of the *processes* that lead to cyclone formation must be alike if the same result is to be achieved at the surface. This study has attempted to uncover some of these processes. It is a task for the future to analyze other types of flow pattern configuration that lead to cyclogenesis.

ACKNOWLEDGMENT

The writer is greatly indebted to Dr. H. R. Byers, who took much time in helping to organize the material of this report. Drs. J. Bjerknes and E. Palmén discussed several aspects of the problems with the writer, and some phases of the study were undertaken following these discussions. Acknowledgment also is due to Dr. T. C. Yeh and Mr. N. La Seur, who participated in the analysis of many aspects of the topics treated.

Nuclei of Strain in the Semi-Infinite Solid

RAYMOND D. MINDLIN AND DAVID H. CHENG
Columbia University, New York, New York
(Received April 28, 1950)

Stress functions are given for forty nuclei of strain in the semi-infinite elastic solid. The corresponding stresses have the property that the traction vanishes across the plane boundary of the solid. The nuclei are derived, by processes of superposition, differentiation and integration, from the solution of the elasticity equations for the single force in the interior of the semi-infinite solid.

I. INTRODUCTION

THERE is an interesting group of solutions of the equations of the linear theory of elasticity known as nuclei of strain. For the isotropic solid of indefinite extent the fundamental solution of this type is that of Kelvin[1] for a single force applied at a point. By differentiation of this solution a family of additional nuclei can be obtained, examples of which are[1] the double force and the double force with moment. These, in turn, can be combined to form nuclei such as the center of dilatation and the center of rotation. By further differentiation, various types of doublets and multiplets are obtained. Alternatively, the preceding solutions may be integrated to form line distributions, such as[1] semi-infinite lines of centers of dilatation, or doublets, or double forces with moment, etc.

The solutions of many interesting problems may be expressed in terms of combinations of these nuclei or have been discovered by a process of superposition of nuclei. Examples are Lamé's problem[2] of the spherical container under internal and external pressure, Boussinesq's and Cerruti's problems[3] of the single force acting at the surface of a semi-infinite solid, Southwell's problem[2] of the spherical cavity in an infinite solid under simple tension, the analogous solution by Goodier[4] for the spherical inclusion and Mindlin's solution[5] for the single force in the semi-infinite solid.

The last named solution occupies the same position for the semi-infinite solid as Kelvin's solution does for the solid of indefinite extent. The nuclei derived from it, by differentiation and integration, all satisfy the condition of vanishing traction on a plane boundary so that, in contemplating the solution of new problems with at least one plane, traction-free surface, a portion of the boundary conditions is already satisfied.

Since the solution for the single force in the semi-infinite solid is itself formed from the superposition of eighteen nuclei derived from Kelvin's solution (six for each of the three components of the force), the calculation of nuclei for the semi-infinite solid is a formidable one. The possible usefulness of such nuclei is so great, however, that this task was undertaken and the results for forty nuclei are reported below.[6] The methods employed are the same as those described by Love[1] in connection with the calculation of nuclei in the solid of indefinite extent. The results are given in very condensed form by expressing them in terms of the Galerkin vector stress function. The displacement vector $\mathbf{u}$ is given in terms of the Galerkin vector $\mathbf{F}$ by

$$2G\mathbf{u}=2(1-\nu)\nabla^2\mathbf{F}-\nabla\nabla\cdot\mathbf{F}, \tag{1}$$

where G is the shear modulus, ν is Poisson's ratio and ∇, $\nabla\cdot$ and ∇^2 are the gradient, divergence and Laplacian operators, respectively.

II. REDUCTION FROM THREE COMPONENTS TO ONE

Certain nuclei are obtained by the superposition of three others and the immediate result is a three-component Galerkin vector. This may be simplified, in some cases, by reduction to a one-component vector, say $\mathbf{F}'=\mathbf{k}Z'$, so that

$$2G\mathbf{u}=2(1-\nu)\mathbf{k}\nabla^2Z'-\nabla(\partial Z'/\partial z). \tag{2}$$

To find the function $\mathbf{F}'$ corresponding to a given $\mathbf{F}$, (1) and (2) are equated to obtain the differential equation

$$2(1-\nu)\mathbf{k}\nabla^2Z'-\nabla(\partial Z'/\partial z)=2(1-\nu)\nabla^2\mathbf{F}-\nabla\nabla\cdot\mathbf{F}, \tag{3}$$

which is to be solved for Z' in terms of $\mathbf{F}$.

Case 1: $\nabla^2\mathbf{F}=0$

Operating on (3) with $\nabla\cdot$ and $\nabla\times$ and using the condition $\nabla^2\mathbf{F}=0$, there results

$$\nabla\nabla^2Z'=0$$

from which ∇^2Z' is a constant which may be taken as zero since, by (2), it contributes only a rigid body displacement. Hence (3) reduces to

$$\nabla(\partial Z'/\partial z)=\nabla\nabla\cdot\mathbf{F} \tag{4}$$

the first integral of which is

$$\partial Z'/\partial z=\nabla\cdot\mathbf{F}$$

plus a constant which may be omitted since it does not contribute to the displacement. The second integral of (4) is

$$Z'=\int \nabla\cdot\mathbf{F}dz$$

plus a function of x and y which may be omitted since it does not contribute to the displacement.

Case 2: $\nabla\times\nabla\times\mathbf{F}=\nabla^2\nabla\cdot\mathbf{F}=0$

Since

$$\nabla\times\nabla\times\mathbf{F}=\nabla\nabla\cdot\mathbf{F}-\nabla^2\mathbf{F},$$

Eq. (3) reduces, in this case, to

$$2(1-\nu)\mathbf{k}\nabla^2Z'-\nabla(\partial Z'/\partial z)=(1-2\nu)\nabla\nabla\cdot\mathbf{F}. \quad (5)$$

Operating on (5) with $\nabla\cdot$ and $\nabla\times$ and using the condition $\nabla^2\nabla\cdot\mathbf{F}=0$, we find, as before, that $\nabla^2Z'=0$. Hence (5) reduces to

$$\nabla(\partial Z'/\partial z)=-(1-2\nu)\nabla\nabla\cdot\mathbf{F}$$

from which, by the procedure used in Case 1,

$$Z'=-(1-2\nu)\int\nabla\cdot\mathbf{F}dz.$$

III. HALF-SPACE NUCLEI IN TERMS OF GALERKIN VECTORS

The half-space considered is defined by $Z\geqslant 0$. Point nuclei are at $(0, 0, c)$ and one end of each line nucleus is at the same point. $\mathbf{i}$, $\mathbf{j}$, $\mathbf{k}$ are unit vectors in the x, y, z directions, respectively, and

$$R_1^2=x^2+y^2+(z-c)^2, \quad R_2^2=x^2+y^2+(z+c)^2.$$

A multiplying constant is omitted in each stress function.

A. Single Force

(1) Single force in x direction

$$\mathbf{i}\left\{R_1+R_2-\frac{2c^2}{R_2}+4(1-\nu)(1-2\nu)\times[(z+c)\log(R_2+z+c)-R_2]\right\}+\mathbf{k}\left[\frac{2cx}{R_2}+2(1-2\nu)x\log(R_2+z+c)\right].$$

(2) Single force in y direction

$$\mathbf{j}\left\{R_1+R_2-\frac{2c^2}{R_2}+4(1-\nu)(1-2\nu)\times[(z+c)\log(R_2+z+c)-R_2]\right\}+\mathbf{k}\left[\frac{2cy}{R_2}+2(1-2\nu)y\log(R_2+z+c)\right]$$

(3) Single force in z direction

$$\mathbf{k}\left\{R_1+[8\nu(1-\nu)-1]R_2+4(1-2\nu)[(1-\nu)z-\nu c]\log(R_2+z+c)-\frac{2cz}{R_2}\right\}.$$

B. Double Force

(1) Double force in x direction

$$\mathbf{i}x\left[\frac{1}{R_1}+\frac{1}{R_2}-\frac{4(1-\nu)(1-2\nu)}{R_2+z+c}+\frac{2c^2}{R_2^3}\right]+\mathbf{k}\left[\frac{2c}{R_2}-\frac{2cx^2}{R_2^3}+\frac{2(1-2\nu)x^2}{R_2(R_2+z+c)}+2(1-2\nu)\log(R_2+z+c)\right].$$

(2) Double force in y direction

$$\mathbf{j}y\left[\frac{1}{R_1}+\frac{1}{R_2}-\frac{4(1-\nu)(1-2\nu)}{R_2+z+c}+\frac{2c^2}{R_2^3}\right]+\mathbf{k}\left[\frac{2c}{R_2}+2(1-2\nu)\log(R_2+z+c)+\frac{2(1-2\nu)y^2}{R_2(R_2+z+c)}-\frac{2cy^2}{R_2^3}\right].$$

(3) Double force in z direction

$$\mathbf{k}\left[\frac{z-c}{R_1}-(1-4\nu)\frac{z-c}{R_2}-\frac{2cz(z+c)}{R_2^3}+4\nu(1-2\nu)\log(R_2+z+c)\right].$$

C. Double Force with Moment

(1) Double force in x direction with moment about y axis

$$\mathbf{i}\left[\frac{z-c}{R_1}-\frac{z-3c}{R_2}-\frac{2c^2(z+c)}{R_2^3}-4(1-\nu)(1-2\nu)\log(R_2+z+c)\right]+\mathbf{k}2x\left[\frac{c(z+c)}{R_2^3}-\frac{2(1-\nu)}{R_2}\right].$$

(2) Double force in x direction with moment about z axis

$$\mathbf{i}y\left[\frac{1}{R_1}+\frac{1}{R_2}+\frac{2c^2}{R_2^3}-\frac{4(1-\nu)(1-2\nu)}{R_2+z+c}\right]+\mathbf{k}2xy\left[\frac{1-2\nu}{R_2(R_2+z+c)}-\frac{c}{R_2^3}\right].$$

(3) Double force in y direction with moment about x axis

$$\mathbf{j}\left[\frac{z-c}{R_1}-\frac{z-3c}{R_2}-\frac{2c^2(z+c)}{R_2^3}-4(1-\nu)(1-2\nu)\log(R_2+z+c)\right]+\mathbf{k}2y\left[\frac{c(z+c)}{R_2^3}-\frac{2(1-\nu)}{R_2}\right].$$

(4) Double force in y direction with moment about z axis

$$\mathbf{j}x\left[\frac{1}{R_1}+\frac{1}{R_2}+\frac{2c^2}{R_2^3}-\frac{4(1-\nu)(1-2\nu)}{R_2+z+c}\right]+\mathbf{k}2xy\left[\frac{1-2\nu}{R_2(R_2+z+c)}-\frac{c}{R_2^3}\right].$$

(5) Double force in z direction with moment about x axis

$$\mathbf{k}y\left\{\frac{1}{R_1}+\frac{8\nu(1-\nu)-1}{R_2}+\frac{4(1-2\nu)[(1-\nu)z-\nu c]}{R_2(R_2+z+c)}+\frac{2cz}{R_2^3}\right\}.$$

(6) Double force in z direction with moment about y axis

$$\mathbf{k}x\left\{\frac{1}{R_1}+\frac{8\nu(1-\nu)-1}{R_2}+\frac{4(1-2\nu)[(1-\nu)z-\nu c]}{R_2(R_2+z+c)}+\frac{2cz}{R_2^3}\right\}.$$

D. Line of Double Forces with Moment

(1) Type C(1) along x axis from $x=0$ to $x=-\infty$

$$\mathbf{i}\left[(z-c)\log(R_1+x)-(z-3c)\log(R_2+x)-\frac{2c^2(z+c)x}{R_2(R_2^2-x^2)}\right]-\mathbf{k}\left[\frac{2c(z+c)}{R_2}+8\nu(1-\nu)R_2+4(1-\nu)(1-2\nu)(z+c)\log(R_2+z+c)\right].$$

(2) Type C(2) along x axis from $x=0$ to $x=-\infty$

$$\mathbf{i}y\left[\log(R_1+x)+\log(R_2+x)+\frac{2c^2x}{R_2(R_2^2-x^2)}\right]+\mathbf{k}y\left[2\nu(1-2\nu)\log(R_2+z+c)-2(1-\nu)(1-2\nu)\frac{z+c}{R_2+z+c}+\frac{2c}{R_2}\right].$$

(3) Type C(3) along y axis from $y=0$ to $y=-\infty$

$$\mathbf{j}\left[(z-c)\log(R_1+y)-(z-3c)\log(R_2+y)-\frac{2c^2(z+c)y}{R_2(R_2^2-y^2)}\right]-\mathbf{k}\left[\frac{2c(z+c)}{R_2}+8\nu(1-\nu)R_2+4(1-\nu)(1-2\nu)(z+c)\log(R_2+z+c)\right].$$

(4) Type C(4) along y axis from $y=0$ to $y=-\infty$

$$\mathbf{j}x\left[\log(R_1+y)+\log(R_2+y)+\frac{2c^2y}{R_2(R_2^2-y^2)}\right]+\mathbf{k}x\left[2\nu(1-2\nu)\log(R_2+z+c)-2(1-\nu)(1-2\nu)\frac{z+c}{R_2+z+c}+\frac{2c}{R_2}\right].$$

(5) Type C(5) along z axis from $z=c$ to $z=\infty$

$$\mathbf{k}y\left\{\log(R_1-z+c)+[8\nu(1-\nu)-1]\log(R_2+z+c)-\frac{4(1-2\nu)z}{R_2+z+c}-2\nu(1-2\nu)\left[\log(R_2+z+c)+\frac{R_2}{R_2+z+c}\right]-2z\left[\frac{1}{R_2}+\frac{z(z+c)}{R_2(x^2+y^2)}-\frac{z}{(x^2+y^2)}\right]\right\}.$$

(6) Type C(6) along z axis from $z=c$ to $z=\infty$

$$\mathbf{k}x\left\{\log(R_1-z+c)+[8\nu(1-\nu)-1]\log(R_2+z+c)-\frac{4(1-2\nu)z}{R_2+z+c}-2\nu(1-2\nu)\left[\log(R_2+z+c)+\frac{R_2}{R_2+z+c}\right]-2z\left[\frac{1}{R_2}+\frac{z(z+c)}{R_2(x^2+y^2)}-\frac{z}{(x^2+y^2)}\right]\right\}.$$

E. Center of Dilatation

(1)
$$\mathbf{i}[\log(R_1+x)+(1-4\nu)\log(R_2+x)]+\mathbf{k}\frac{2z}{R_2}.$$

(2)
$$\mathbf{j}[\log(R_1+y)+(1-4\nu)\log(R_2+y)]+\mathbf{k}\frac{2z}{R_2}.$$

(3)
$$\mathbf{k}\left[\log(R_1+z-c)+(1-4\nu)\log(R_2+z+c)+\frac{2z}{R_2}\right].$$

All three yield the same displacements and stresses.

F. Line of Centers of Dilatation

(1) Along x axis from $x=0$ to $x=-\infty$

$$\mathbf{i}\{x\log(R_1+x)-R_1+(1-4\nu)[x\log(R_2+x)-R_2]\}+\mathbf{k}2z\log(R_2+x).$$

(2) Along y axis from $y=0$ to $y=-\infty$

$$\mathbf{j}\{y\log(R_1+y)-R_1+(1-4\nu)[y\log(R_2+y)-R_2]\}+\mathbf{k}2z\log(R_2+y).$$

(3) Along z axis from $z=c$ to $z=\infty$

$$\mathbf{k}\{R_1-(z-c)\log(R_1+z-c)+(1-4\nu)\times[(z+c)\log(R_2+z+c)-R_2]+2z\log(R_2+z+c)\}.$$

G. Doublet

(1) Axis of doublet parallel to x axis

$$\mathbf{i}\left(\frac{1}{R_1}+\frac{1-4\nu}{R_2}\right)-\mathbf{k}\frac{2xz}{R_2^3}.$$

(2) Axis of doublet parallel to y axis

$$\mathbf{j}\left(\frac{1}{R_1}+\frac{1-4\nu}{R_2}\right)-\mathbf{k}\frac{2yz}{R_2^3}.$$

(3) Axis of doublet parallel to z axis

$$\mathbf{k}\left[\frac{1}{R_1}-\frac{1-4\nu}{R_2}+\frac{2z(z+c)}{R_2^3}\right].$$

H. Linearly Varying Line of Doublets with Strength Proportional to Distance from the Origin

(1) Type G(1) along y axis from $y=0$ to $y=-\infty$

$$\mathbf{i}\{R_1-y\log(R_1+y)+(1-4\nu)[R_2-y\log(R_2+y)]\}+\mathbf{k}\frac{2xz}{R_2+y}.$$

(2) Type G(1) along z axis from $z=c$ to $z=\infty$

$$\mathbf{i}\{R_1+z\log(R_1-z+c)+(1-4\nu)[R_2-z\log(R_2+z+c)]\}+\mathbf{k}2xz\left[\frac{1}{R_2}+\frac{z(z+c)}{R_2(x^2+y^2)}-\frac{z}{x^2+y^2}\right].$$

(3) Type G(2) along x axis from $x=0$ to $x=-\infty$

$$\mathbf{j}\{R_1-x\log(R_1+x)+(1-4\nu)[R_2-x\log(R_2+x)]\}+\mathbf{k}\frac{2yz}{R_2+x}.$$

(4) Type G(2) along z axis from $z=c$ to $z=\infty$

$$\mathbf{j}\{R_1+z\log(R_1-z+c)+(1-4\nu)[R_2-z\log(R_2+z+c)]\}+\mathbf{k}2yz\left[\frac{1}{R_2}+\frac{z(z+c)}{R_2(x^2+y^2)}-\frac{z}{x^2+y^2}\right].$$

(5) Type G(3) along x axis from $x=0$ to $x=-\infty$

$$\mathbf{k}\left\{R_1-(1-4\nu)R_2-x[\log(R_1+x)-(1-4\nu)\log(R_2+x)]-\frac{2z(z+c)}{R_2+x}\right\}.$$

(6) Type G(3) along y axis from $y=0$ to $y=-\infty$

$$\mathbf{k}\left\{R_1-(1-4\nu)R_2-y[\log(R_1+y)-(1-4\nu)\log(R_2+y)]-\frac{2z(z+c)}{R_2+y}\right\}.$$

I. Center of Rotation

(1) Center of rotation about x axis (Type C(5)—Type C(3))

$$\mathbf{j}\left[-\frac{z-c}{R_1}+\frac{z-3c}{R_2}+4(1-\nu)(1-2\nu)\log(R_2+z+c)+\frac{2c^2(z+c)}{R_2^3}\right]+\mathbf{k}y\left\{\frac{1}{R_1}+\frac{4\nu(1-2\nu)+3}{R_2}-\frac{2c^2}{R_2^3}+\frac{4(1-2\nu)[(1-\nu)z-\nu c]}{R_2(R_2+z+c)}\right\}.$$

(2) Center of rotation about y axis (Type C(6)—Type C(1))

$$\mathbf{i}\left[-\frac{z-c}{R_1}+\frac{z-3c}{R_2}+4(1-\nu)(1-2\nu)\log(R_2+z+c)+\frac{2c^2(z+c)}{R_2^3}\right]+\mathbf{k}x\left\{\frac{1}{R_1}+\frac{4\nu(1-2\nu)+3}{R_2}-\frac{2c^2}{R_2^3}+\frac{4(1-2\nu)[(1-\nu)z-\nu c]}{R_2(R_2+z+c)}\right\}.$$

(3) Center of rotation about z axis (Type C(4)—Type C(2))

$$(\mathbf{j}x-\mathbf{i}y)\left[\frac{1}{R_1}+\frac{1}{R_2}+\frac{2c^2}{R_2^3}-\frac{4(1-\nu)(1-2\nu)}{R_2+z+c}\right].$$

J. Line of Centers of Rotation

(1) Type I(1) along y axis from $y=0$ to $y=-\infty$

$$\mathbf{j}\left[-(z-c)\log(R_1+y)+(z-3c)\log(R_2+y)+\frac{2c^2(z+c)y}{R_2(R_2^2-y^2)}\right]+\mathbf{k}\left\{R_1-[4(1-2\nu)^2-3]R_2+4(1-2\nu)[z+(1-2\nu)(z+c)]\log(R_2+z+c)+\frac{2c^2}{R_2}\right\}.$$

(2) Type I(1) along z axis from $z=c$ to $z=\infty$

$$\mathbf{j}\left\{R_1+R_2-\frac{2c^2}{R_2}+4(1-\nu)(1-2\nu)\times[(z+c)\log(R_2+z+c)-R_2]\right\}+\mathbf{k}y\left\{\log(R_1-z+c)+[2\nu(1-2\nu)+1]\log(R_2+z+c)+\frac{2c^2}{R_2(R_2+z+c)}-\frac{2[R_2(z-c)-z^2]}{x^2+y^2}+\frac{2(1-2\nu)}{R_2+z+c}[\nu R_2+2\nu(z+c)-2z]\right\}.$$

(3) Type I(2) along x axis from $x=0$ to $x=-\infty$

$$\mathbf{i}\left[-(z-c)\log(R_1+x)+(z-3c)\log(R_2+x)+\frac{2c^2(z+c)x}{R_2(R_2^2-x^2)}\right]+\mathbf{k}\left\{R_1-[4(1-2\nu)^2-3]R_2+4(1-2\nu)[z+(1-2\nu)(z+c)]\log(R_2+z+c)+\frac{2c^2}{R_2}\right\}.$$

(4) Type I(2) along z axis from $z=c$ to $z=\infty$

$$\mathbf{i}\left\{R_1+R_2-\frac{2c^2}{R_2}+4(1-\nu)(1-2\nu)\times[(z+c)\log(R_2+z+c)-R_2]\right\}+\mathbf{k}x\left\{\log(R_1-z+c)+[2\nu(1-2\nu)+1]\log(R_2+z+c)+\frac{2c^2}{R_2(R_2+z+c)}-\frac{2[R_2(z-c)-z^2]}{x^2+y^2}+\frac{2(1-2\nu)}{R_2+z+c}[\nu R_2+2\nu(z+c)-2z]\right\}.$$

(5) Type I(3) along x axis from $x=0$ to $x=-\infty$

$$-\mathbf{i}y\left[\log(R_1+x)+\log(R_2+x)+\frac{2c^2x}{R_2(R_2^2-x^2)}\right]+\mathbf{j}\left[R_1+R_2-\frac{2c^2}{R_2}\right].$$

(6) Type I(3) along y axis from $y=0$ to $y=-\infty$

$$\mathbf{i}\left[R_1+R_2-\frac{2c^2}{R_2}\right]-\mathbf{j}x\left[\log(R_1+y)+\log(R_2+y)+\frac{2c^2y}{R_2(R_2^2-y^2)}\right].$$

IV. COMPONENTS OF DISPLACEMENT AND STRESS

The formulas for the components of displacement and stress corresponding to each of the nuclei listed in the preceding section are listed in Appendices I and II.[7]

[7] On file at the Department of Civil Engineering, Columbia University, New York 27, New York.

Thermoelastic Stress in the Semi-Infinite Solid

RAYMOND D. MINDLIN AND DAVID H. CHENG
Columbia University, New York, New York
(Received April 28, 1950)

The solution of the elasticity equations for the center of dilatation in the semi-infinite solid is introduced into Goodier's theory of thermoelastic stress. It is shown that the problem of potential to be solved is identical with that for the solid of indefinite extent. The results are applied to the case of an expanding (or contracting) spherical inclusion embedded in an elastic body near its surface.

I. INTRODUCTION

GOODIER[1] has shown that the elastic effect of a non-uniform distribution of temperature (T) in an infinite body is the same as that of a distribution of centers of dilatation of strength $-\beta/4\pi$ where

$$\beta=\alpha T(1+\nu)/(1-\nu) \tag{1}$$

and α and ν are the coefficient of linear thermal expansion and Poisson's ratio, respectively. Since α and T always appear together, what is said of a non-uniform distribution of temperature applies also to a space variation of the coefficient of linear thermal expansion. Goodier's theory has been applied to two problems of thermal stress in the infinite elastic body by Myklestad.[2]

If the body is not infinite the singularities within it give rise to tractions and displacements at its surface and the removal of these is a boundary-value problem in elasticity theory. However, Goodier noted that, if the solution of the elasticity equations for the center of dilatation is known for the bounded body, the thermoelastic problem is reduced, again, to an integration if the method of singularities is employed.

In this paper it is shown that, for the semi-infinite body with traction-free surface, the additional integral has the same form as that for the infinite body so that, if the latter is known, the calculation of displacement and stress reduces to a process of differentiation only. The result is then applied to a case of a spherical inclusion in the semi-infinite body. Use is made of the solution, given in an accompanying paper,[3] for the center of dilatation in the semi-infinite body.

II. THERMOELASTIC DISPLACEMENT

The Galerkin vector stress function for a center of dilatation of strength A at (ξ, η, ζ) in the infinite, isotropic, elastic solid is[4]

$$\mathbf{F}=-2AG\mathbf{k}\log(R_1'+z-\zeta),$$

where G is the modulus of rigidity, $\mathbf{k}$ is a unit vector in the z direction and

$$R_1'^2=(x-\xi)^2+(y-\eta)^2+(z-\zeta)^2.$$

Hence Goodier's nucleus of thermoelastic strain is given by

$$\mathbf{F}=(G\beta/2\pi)\mathbf{k}\log(R_1'+z-\zeta).$$

In an accompanying paper[3] it is shown that the corresponding nucleus at (ξ, η, ζ) in the semi-infinite body $z\geqslant 0$ (with the plane $z=0$ free of traction) is represented by

$$\mathbf{F}_0=(G\beta/2\pi)\mathbf{k}[\log(R_1'+z-\zeta)+(1-4\nu)\log(R_2'+z+\zeta)+2(z+\zeta)/R_2'-2\zeta/R_2'],$$

where

$$R_2'^2=(x-\xi)^2+(y-\eta)^2+(z+\zeta)^2.$$

Thus, for each center of dilatation at (ξ, η, ζ) in $z>0$, the plane $z=0$ is freed of traction by applying, at the image point $(\xi, \eta, -\zeta)$, a center of dilatation, a double force and a doublet, each of the proper strength.

The displacement $\mathbf{u}_0$ associated with $\mathbf{F}_0$ is calculated from

$$2G\mathbf{u}_0=2(1-\nu)\nabla^2\mathbf{F}_0-\nabla\nabla\cdot\mathbf{F}_0$$

and may be written in terms of operations on $1/R_1'$ and $1/R_2'$ as follows:

$$4\pi\mathbf{u}_0=-\beta\nabla(1/R_1')-\beta\nabla_2(1/R_2'),$$

where

$$\nabla_2=(3-4\nu)\nabla+2\nabla z(\partial/\partial z)-4(1-\nu)\mathbf{k}\nabla^2 z$$

is a vector operator in which, for example, the scalar operator $\nabla^2 z$ signifies that the operand is first to be multiplied by z and then operated upon by ∇^2.

For a distribution $\beta(\xi, \eta, \zeta)$ in a region V_1 in $z>0$, the displacement is given by

$$\begin{aligned}4\pi\mathbf{u}&=4\pi\int_{V_1}\mathbf{u}_0 d\tau\\&=-\nabla\int_{V_1}\frac{\beta}{R_1'}d\tau-\nabla_2\int_{V_1}\frac{\beta}{R_2'}d\tau\\&=-\nabla\int_{V_1}\frac{\beta}{R_1'}d\tau-\nabla_2\int_{V_2}\frac{\beta}{R_1'}d\tau\\&=-\nabla\varphi_1-\nabla_2\varphi_2,\end{aligned} \tag{2}$$

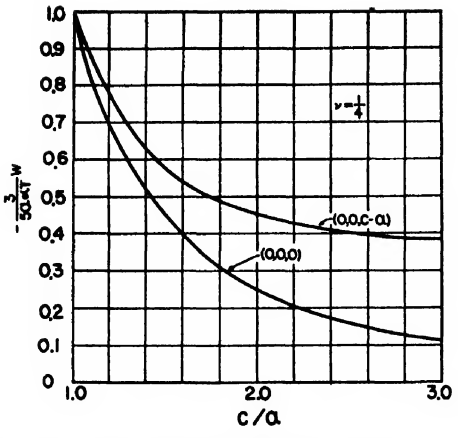

FIG. 1. Displacement normal to surface at points (0, 0, 0) and (0, 0, $c-a$).

where $d\tau=d\xi d\eta d\zeta$ and V_2 is the image of V_1 in the plane $z=0$. The volume integrals pass through ∇ and ∇_2 since the latter are x, y, z operators. The first integral is the potential (φ_1) of a distribution of matter of density β in V_1 as in Goodier's theory. The second integral (φ_2) is simply the reflection transformation of φ_1 in the plane $z=0$, so that the integration need not be repeated. For any distribution of β whose potential is known, the calculation of displacement in the semi-infinite body thus reduces to the simple process of applying the operators ∇ and ∇_2. Although φ_1 and φ_2 are mutual images, the corresponding displacements are not. This is due to the difference between ∇ and ∇_2.

III. APPLICATION TO SPHERICAL INCLUSION

Let V_1 be a sphere of radius a with center at (0, 0, c) where $a\leqslant c$. The radii to a field point (x, y, z) from (0, 0, c) and from its image (0, 0, $-c$) are denoted by $R_1=[x^2+y^2+(z-c)^2]^{\frac{1}{2}}$ and $R_2=[x^2+y^2+(z+c)^2]^{\frac{1}{2}}$ respectively. Let α be the excess of the coefficient of thermal expansion of the material within V_1 over that of the surrounding medium and let T be a uniform

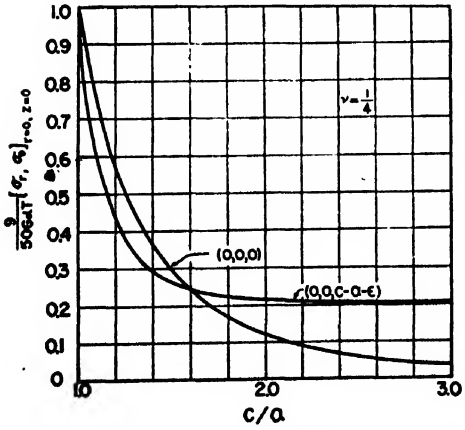

FIG. 2. σ_r and σ_θ at points (0, 0, 0), (0, 0, $c-a-\epsilon$).

temperature rise. Then β is given by (1) in $R_1<a$ and is zero in $z\geqslant 0$, $R_1>a$. The elastic constants of the two regions are assumed to be the same.

From the well-known results for the potential of a homogeneous sphere[5] we have, for exterior points ($z\geqslant 0$, $R_1>a$)

$$\varphi_1=4\pi a^3\beta/3R_1, \quad \varphi_2=4\pi a^3\beta/3R_2$$

and, for interior points ($R_1<a$)

$$\varphi_1=2\pi\beta(3a^2-R_1^2)/3, \quad \varphi_2=4\pi a^3\beta/3R_2.$$

Substituting in (2) and performing the operations ∇ and ∇_2, we have, for exterior points,

$$\mathbf{u}_e=\frac{a^3\beta}{3}\left\{\frac{\mathbf{R}_1}{R_1^3}+\frac{(3-4\nu)\mathbf{R}_2}{R_2^3}-\frac{6z(z+c)\mathbf{R}_2}{R_2^5}-\frac{2\mathbf{k}}{R_2^3}[(3-4\nu)(z+c)-z]\right\},$$

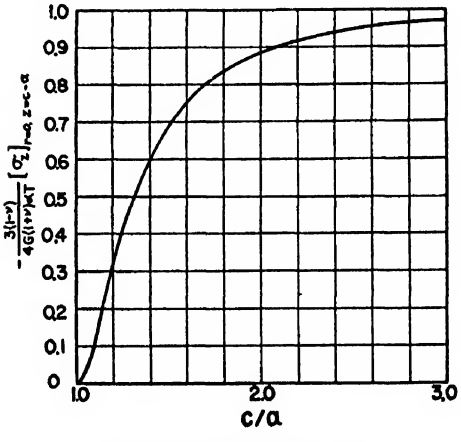

FIG. 3. σ_z at point (0, 0, $c-a$).

and, for interior points,

$$\mathbf{u}_i=\mathbf{u}_e+\frac{a^3\beta\mathbf{R}_1}{3}\left(\frac{1}{a^3}-\frac{1}{R_1^3}\right),$$

where $\mathbf{R}_1$ and $\mathbf{R}_2$ are the position vectors from (0, 0, c) and (0, 0, $-c$), respectively. It may be observed that, for exterior points, the displacement is the same as that for a single center of dilatation at the center of the sphere.

The stress is calculated from the displacement by means of the usual thermoelastic relation. In dyadic notation[6] this is

$$\Psi=\lambda\mathbf{I}[\nabla\cdot\mathbf{u}-\beta(1-\nu)/\nu]+G(\nabla\mathbf{u}+\mathbf{u}\nabla)$$

where Ψ is the stress dyadic, $\mathbf{I}$ is the idemfactor and

[5] W. D. MacMillan, *Theory of the Potential* (McGraw-Hill Book Company, Inc., New York, 1930), p. 40.
[6] C. E. Weatherburn, *Advanced Vector Analysis* (G. Bell and Sons, London, 1928).

$\lambda=2G\nu/(1-2\nu)$. In performing the calculations for interior points, β is given by (1) while for exterior points $\beta=0$. The cylindrical components are, for exterior points,

$$\sigma_r=\sigma_\theta-2G\beta a^3r^2\left[\frac{1}{R_1^5}+\frac{3-4\nu}{R_2^5}-\frac{10z(z+c)}{R_2^7}\right],$$

$$\sigma_\theta=\frac{2G\beta a^3}{3}\left[\frac{1}{R_1^3}+\frac{3-8\nu}{R_2^3}-\frac{6z(z+c)}{R_2^5}+\frac{12\nu(z+c)^2}{R_2^5}\right],$$

$$\sigma_z=\frac{2G\beta a^3}{3}\left[\frac{1}{R_1^3}-\frac{1}{R_2^3}-\frac{18z(z+c)}{R_2^5}+\frac{3(z+c)^2}{R_2^5}-\frac{3(z-c)^2}{R_1^5}+\frac{30z(z+c)^3}{R_2^7}\right],$$

$$\tau_{rz}=-2G\beta a^3r\left[\frac{z-c}{R_1^5}+\frac{3z+c}{R_2^5}-\frac{10z(z+c)^2}{R_2^7}\right],$$

$\tau_{\theta r}=\tau_{z\theta}=0$.

For interior points the formulas are the same except that in each of the normal components all the terms containing R_1 are replaced by $-2/a^3$, while the term containing R_1 in the shear component vanishes.

The magnitudes of the components of stress and displacement at the point on the sphere nearest the free surface and at the point on the free surface nearest the sphere are plotted in the Figs. 1, 2, and 3 as functions of the depth of the center of the sphere below the surface. It is interesting to observe that for an expanding sphere close to the surface the tensile stress in the surrounding medium can become $4(1+\nu)$ times as great as for the sphere in an infinite medium.

The Generalized Response of Linear Systems for Arbitrary Initial Conditions

JOHN R. MOORE
Aerophysics and Atomic Energy Division, North American Aviation, Inc. and Department of Engineering, University of California, Los Angeles, California

(Received May 1, 1950)

A method is presented for the solution of ordinary linear differential equations with constant coefficients. This method stays wholly in the time domain and obtains a general solution in a compact form including the effects of initial conditions. The differential equation as treated involves a driving function made up of the sum of terms involving the system input and its derivatives. The general solution is also given in terms of weighting functions operating on the input (in the driving function) and including outside the weighted integral, terms involving initial conditions of the input as well as the dependent variable.

INTRODUCTION

THIS paper presents a short method of computing the response of single input-single output linear systems with constant parameters to a large variety of driving functions. The result of this method is a general formula for the response expressed in terms of integrals of the input, the classical exponential transient terms and initial values of both the input and response functions together with their derivatives. The mathematical development is primarily in terms of functions in the time domain. The method and formulas are equally applicable to any linear differential equations with constant coefficients whether it be thought of in terms of a time dependent "input" and "response" or merely as a problem in mathematics.

SOLUTION OF THE DIFFERENTIAL EQUATION

The present paper takes the differential equation

$$G(p)\theta=KH(p)i \qquad (1)$$

[where θ is the dependent variable, i the input (function of variable t) $p\equiv d/dt$ and $G(p)$ and $H(p)$ are polynomials in p with constant coefficients] and obtains the general solution for θ, including the effect of initial conditions on θ and its derivatives.

The solutions may be made applicable to the case of multiple roots (two or more of the R_j equal) by standard limiting procedures.

The present method takes its cue from the classical method of successive substitution.* It was originally derived by the writer following a realization that the order of successive substitution is completely arbitrary and may be rearranged at will.

Starting with $G(p)$ in its factored form, n similar quantities, Θ_j are defined such that,

$$(p-R_j)\Theta_j\equiv G(p)\theta=KH(p)i. \qquad (2)$$

This is, apparently, equivalent to

$$\Theta_j=\frac{G(p)\theta}{p-R_j}=\frac{\prod_{i=1}^{n}(p-R_i)\theta}{p-R_j}=\frac{-\partial G(p)\theta}{\partial R_j}. \qquad (3)$$

* This is similar to the "Factorization Method" described in *Elementary Differential Equations*, by T. C. Fry (D. Van Nostrand Company, Inc., New York, 1929), seventh printing, pp. 182–186.

Solving (2) for Θ_j, n equations are obtained of the form

$$\Theta_j(t)=\Theta_j(0)e^{R_jt}+K\int_0^t e^{R_j(t-\tau)}H(p)i(\tau)d\tau. \quad (4)$$

Here

$$\Theta_j(0)=\frac{G(p)}{p-R_j}\theta\bigg|_{t=0}=\frac{-\partial G(p)}{\partial R_j}\theta\bigg|_{t=0}\equiv\frac{-\partial G(p_0)}{\partial R_j}\theta, \quad (5)$$

where

$$p_0{}^k\theta\equiv(d^k\theta/dt^k)\,|_{t=0}.$$

Since, by (2), each Θ_j contains θ and its derivatives through $p^{n-1}\theta$, it is possible to solve for θ from the n equations typified by (4) obtaining a linear combination of the various Θ_j. Although this could be done by the method of determinants, it is much simpler to proceed as follows.

Assume the linear combination is

$$\theta(t)=\sum_{v=1}^{n}k_v\Theta_v(t). \quad (6)$$

From Eq. (3),

$$\Theta_v(t)=\prod_{r=1}^{n\ (v)}(p-R_r)\theta(t), \quad (7)$$

where the superscript on the product symbol denotes omission of the term for which $v=r$. Substitution of (7) into (6) gives:

$$\theta(t)\equiv\sum_{v=1}^{n}k_v\prod_{r=1}^{n\ (v)}(p-R_r)\theta(t). \quad (8)$$

Equation (8) is an identity which must hold not only for all t but also for all functions $\theta(t)$. In particular, let $\theta(t)=e^{R_jt}$:

$$e^{R_jt}\equiv\sum_{v=1}^{n}k_v\prod_{r=1}^{n\ (v)}(R_j-R_r)e^{R_jt}. \quad (9)$$

All of the products in Eq. (9) contain (R_j-R_j) as a factor except when $v=j$. Hence:

$$k_j=\frac{1}{\prod_{r=1}^{n\ (j)}(R_j-R_r)}=\frac{1}{-\lim_{p\to R_j}[\partial G(p)/\partial R_j]}$$

$$\equiv\frac{1}{-[\partial G(R_j)/\partial R_j]}. \quad (10)$$

Substituting (10) and (4) into (6) gives the general formula:

$$\theta=\sum_{j=1}^{n}\left\{\frac{e^{R_jt}\dfrac{\partial G(p_0)}{\partial R_j}\theta-K\displaystyle\int_0^t e^{R_j(t-\tau)}H(p)i(\tau)d\tau}{[\partial G(R_j)/\partial R_j]}\right\}. \quad (11)$$

INTRODUCTION OF INPUT INITIAL CONDITIONS

Equation (11) contains $H(p)i$. This is often not as convenient to use as another form containing $H(R_j)i$ with initial conditions on i and its derivatives. To derive this form from (11), $H(p)$ is written as a summation, giving

$$\sum_{j=1}^{j=n}k_j\int_0^t e^{R_j(t-\tau)}H(p)i(\tau)d\tau$$

$$=\sum_{j=1}^{j=n}\sum_{\alpha=0}^{\alpha=m}\int_0^t k_je^{R_j(t-\tau)}h_\alpha p^\alpha i(\tau)d\tau. \quad (12)$$

Integrating each term by parts, gives elements of the form

$$\int_0^t e^{R_j(t-\tau)}p^\alpha i(\tau)d\tau$$

$$=(p^{\alpha-1}+R_jp^{\alpha-2}+\cdots+R_j{}^{\alpha-2}p+R_j{}^{\alpha-1})i(t)$$

$$-e^{R_jt}(p_0{}^{\alpha-1}+R_jp_0{}^{\alpha-2}+\cdots+R_j{}^{\alpha-2}p_0+R_j{}^{\alpha-1}p_0{}^0)i$$

$$+R_j{}^\alpha\int_0^t e^{R_j(t-\tau)}i(\tau)d\tau. \quad (13)$$

The form of (13) may be simplified by using the relation

$$(x-R_j)[x^{\alpha-1}+R_jx^{\alpha-2}$$

$$+\cdots+R_j{}^{\alpha-2}x+R_j{}^{\alpha-1}]=x^\alpha-R_j{}^\alpha \quad (14)$$

so that, symbolically

$$(p^{\alpha-1}+\cdots+R_j{}^{\alpha-1})i(t)\equiv[(p^\alpha-R_j{}^\alpha)/(p-R_j)]i(t) \quad (15)$$

and

$$e^{R_jt}(p_0{}^{\alpha-1}+\cdots+R_j{}^{\alpha-1}p_0{}^0)i$$

$$\equiv e^{R_jt}[(p_0{}^\alpha-R_j{}^\alpha p_0{}^0)/(p_0-R_j)]i. \quad (16)$$

Substitution of these equations into (12) gives

$$\sum_{j=1}^{j=n}k_j\int_0^t e^{R_j(t-\tau)}H(p)i(\tau)d\tau$$

$$=\sum_{j=1}^{j=n}k_jH(R_j)\int_0^t e^{R_j(t-\tau)}i(\tau)d\tau$$

$$+\sum_{j=1}^{j=n}k_j\sum_{\alpha=0}^{\alpha=m}h\alpha\left[\frac{p^\alpha-R_j{}^\alpha}{p-R_j}-e^{R_jt}\frac{(p_0{}^\alpha-R_j{}^\alpha p_0{}^0)}{p_0-R_j}\right]i$$

$$=\sum_{j=1}^{j=n}k_j\left\{H(R_j)\int_0^t e^{R_j(t-\tau)}i(\tau)d\tau\right.$$

$$\left.-e^{R_jt}\left[\frac{H(p_0)-H(R_jp_0{}^0)}{p_0-R_j}\right]i+\left[\frac{H(p)-H(R_j)}{p-R_j}\right]i\right\}. \quad (17)$$

This may be simplified by noting that the relations between the k_j and R_j make

$$\sum_{1}^{n} k_j R_j^{\alpha} = 0, \quad (0 \leq \alpha \leq n-2). \tag{18}$$

Thus, (17) becomes

$$\sum_{j=1}^{j=n} k_j \int_0^t e^{R_j(t-\tau)} H(p) i(\tau) d\tau$$

$$= \sum_{j=1}^{j=n} k_j \left\{ H(R_j) \int_0^t e^{R_j(t-\tau)} i(\tau) d\tau \right.$$

$$- e^{R_j t} \left[\frac{H(p_0) - H(R_j p_0^0)}{p_0 - R_j} \right] i$$

$$\left. + R_j^{n-1} \sum_{\beta=n}^{\beta=m} h_\beta \frac{(p^{\beta-n+1} - R_j^{\beta-n+1}) i}{p - R_j} \right\} \tag{19}$$

which makes the final solution for θ

$$\theta = -\sum_{1}^{n} \left[\frac{\partial G(R_j)}{\partial R_j} \right]^{-1}$$

$$\times \left\{ \frac{\{G(p_0)\theta - K[H(p_0) - H(R_j p_0^0)]i\}}{p_0 - R_j} \right\} e^{R_j t}$$

$$+ KH(R_j) \int_0^t e^{R_j(t-\tau)} i(\tau) d\tau$$

$$\left. + R_j^{n-1} \sum_{\beta=n}^{\beta=m} h_\beta \frac{(p^{\beta-n+1} - R_j^{\beta-n+1}) i}{p - R_j} \right\}, \tag{20}$$

where the last summation exists only if $H(p)$ is of the same order as, or higher order than $G(p)$.

CONCLUSION

The foregoing development attempts to carry out the general solution of the differential equation of an idealized linearized system including the often neglected effect of initial conditions both on the input and the response. The end formula is only slightly more difficult to remember than that of the Heaviside expansion theorem, yet covers a more general case. The method of solution is much simpler than the method of successive substitutions and yields more usable results for high order equations than the more usual type of Laplace transform solution.

The Thermal Expansion Coefficient and the Melting Point of Cubic Elements

M. E. Straumanis
University of Missouri, School of Mines and Metallurgy, Department of Metallurgy, Rolla, Missouri
April 10, 1950

IN the Fig. 1 the linear expansion coefficient, as defined by $\alpha=(1dl)/(ldT)$, of cubic elements is plotted against the melting point T_F of the same elements.[1] The curve shows clearly that generally the linear expansion coefficient of cubic elements decreases with increasing melting point. There are no exceptions from this rule, only deviations from the curve. These deviations might be caused (1) by some differences in the structure of the cubic elements, or (2) by inaccurate determinations of the expansion coefficients at room temperature. Further work will show the nature of these deviations. The curve presented seems not to be a simple one, although the melting points of the 5 alkali elements fit well to the empirical equation $\alpha\sqrt[3]{T_F}=\text{const}$, T_F being expressed in °C.

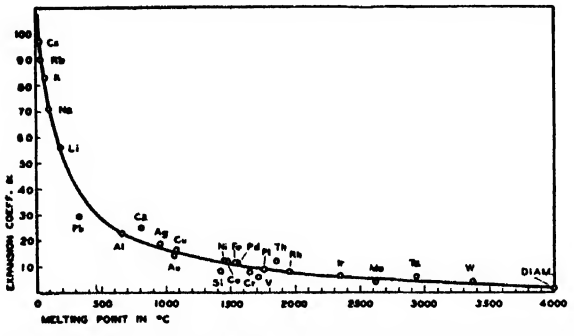

FIG. 1. Linear expansion coefficient $\alpha\times10^6$ of cubic elements at room temperature *versus* melting point of the same elements.

It might be that plotting the cubical expansion coefficient in the same manner as already shown, all at room temperature solid elements would be located on or near the curve.

No relations between melting point and expansion coefficient could be found in the literature, except some indications made by Grüneisen[2] and Lindemann.[3]

[1] The coefficients and melting points in Fig. 1 were obtained from the International Critical Tables, Vol. I, 103, from Hodgman's *Handbook of Chemistry and Physics* and from Landoldt-Börnstein, *Physikalischechemische Tabellen*.

The Tracing and Interpretation of Asymmetrical Hysteresis Loops*

G. M. Ettinger**
Department of Electrical Engineering, New York University, New York, New York
May 3, 1950

IN the course of development of a hysteresis loop tracer with cathode-ray tube presentation (to be described elsewhere), the requirement arose to display the asymmetrical hysteresis loops[1] which are exhibited by magnetic materials subjected simultaneously to a.c. and d.c. magnetizing forces. Figures 1a to 1e show a series of loops which were obtained for "permalloy C" with increasing d.c. polarization. The polarizing current was produced by connecting in series with the magnetizing winding on the sample a metal rectifier shunted by a variable resistance.

To trace the curve of incremental permeability *vs.* d.c. polarizing field, the a.c. sensitivity of the (direct coupled) horizontal deflection amplifier in the hysteresis loop tracer was reduced to zero. The trace on the cathode-ray tube therefore changed to a straight line whose length was proportional to the peak flux density in the sample, while its displacement from the axis of B (shown dotted in Fig. 1) gave a measure of the d.c. magnetizing force. Such lines are superposed on their corresponding hysteresis loops in Fig. 1, while Fig. 2 shows a number of these lines photographed on the same film. Their envelope is the curve of $B_{a.c.}$ *vs.*

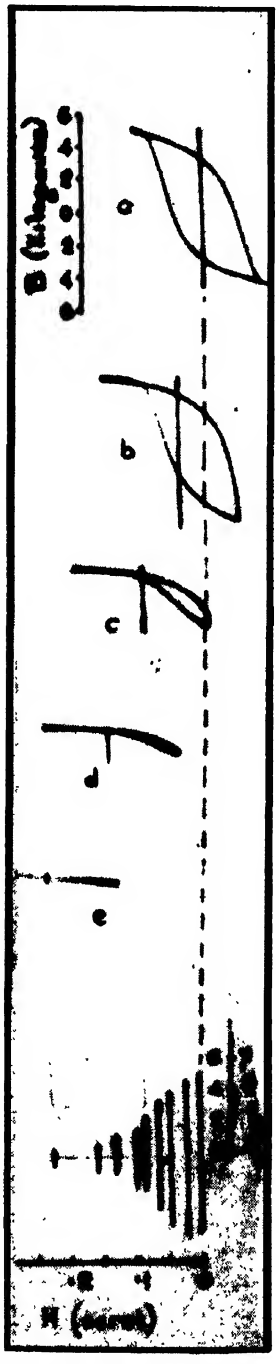

FIG. 1. Asymmetrical hysteresis loops.

FIG. 2. A.c. permeability *vs.* polarizing field for "permalloy C."

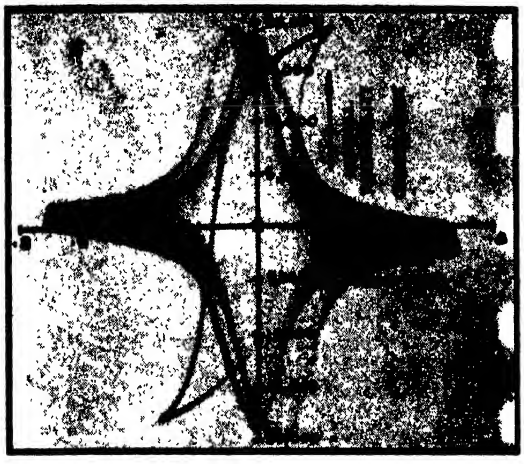

FIG. 3. Butterfly curve for "permalloy C."

$H_{d\,c}$. The peak value of the alternating component of magnetizing force was kept constant during the test, so that Fig. 2 represents, to a different scale, a portion of the $\mu_{a\,c}/H_{d\,c}$ or "butterfly" curve which is of importance in magnetic amplifier work. Other workers[2,3] have employed bridge or potentiometer methods to obtain this curve.

It is possible to observe the complete butterfly curve (from positive to negative saturation) on the screen of a long persistence cathode-ray tube if the potentiometer controlling the d.c. polarization is slowly driven to and fro by a reversing motor or a cam Figure 3 is a photograph of the "butterfly curve" for "permalloy C," obtained by this method. A hysteresis loop is superposed for calibration purposes.

Mechano Chemistry of the Dispersion of Mercury in Liquids in an Ultrasonic Field

EVELYN C. MARBOE AND W. A. WEYL
The Pennsylvania State College, School of Mineral Industries, State College, Pennsylvania
May 5, 1950

IN a previous publication[1] on the mechano-chemical properties of water it was pointed out that the strength of the binding forces between water and a metal may play a role in certain types of cavitation corrosion. It is the object of this report to describe some simple experiments which illustrate the role which the binding forces between metallic mercury and a liquid play on the dispersion of this metal in the liquid. For our problem, the use of liquid mercury offers the advantage that there can be no work-hardening of the metal, a factor which complicates the corrosion through cavitation for solid metals. Some parallel experiments were carried out with metallic gallium in order to make certain that the phenomena observed were not characteristic for mercury alone. All experiments were carried out with a quartz crystal type of high frequency generator. (Ultrason Model U-300 of the Televiso Products Company, Chicago, Illinois.)

Experiment No. 1. For a certain intensity of the ultrasonic field (0.2 kv, 20 ma at 25°C) the system, mercury-paraffin oil, was found to remain unaffected. Addition of stearic acid to the paraffin oil, however, caused dispersion of the metal. This experiment which confirms previous work[2] indicates clearly the importance of the forces acting between the metal and the hydrocarbon. A molecular film of Hg-stearate links together the incompatible media and, thus, makes dispersion possible and also stabilizes the emulsion by preventing the droplets from coalescing.

Experiment No. 2. The intensity of the ultrasonic field was adjusted (1 kv, 130 ma at 25°C) so that mercury in distilled water produced a slight turbidity after an exposure of five minutes. Under these conditions the water remained clear if it had been deaired by boiling. The effect of the air on the dispersion of the metal in water is explained as follows.

Oxidation of the mercury produces Hg^{+} and Hg^{2+}, both cations having a high polarizability. As has been pointed out in a previous report[3] ions of this type are adsorbed at a metal surface in a fashion which may be described as:

Metal—metallic bond—polarized cation—ionic bond—water.

By changing the metallic character of the metal surface into one resembling that of an ionic substance, the strong binding forces are provided between metal and water which are essential for the dispersion.

Experiment No. 3. The same experiment was repeated with distilled and deaired water. No turbidity was observed after five minutes exposure. Now a few drops of a saturated $HgCl_2$ solution were added in order to provide Hg^{2+} ions. Immediately a deep gray dispersion of Hg droplets in the diluted $HgCl_2$ solution began to form.

The connecting link between metal and water is the Hg^{2+} ion which becomes strongly polarized in the asymmetrical force field of the metal-water interface. Addition of KCl solution to the Hg^{2+} containing water changes the Hg^{2+} into a complex anion of the type $(HgCl_4)^{2-}$ and, as a result, mercury is no longer easily dispersed. Only the cation Hg^{2+}, but not the anion $(HgCl_4)^{2-}$, has the metallophilic properties essential for producing dispersion and stabilizing the emulsion. This experiment has its analog in the effect of KCl upon the solubility of metallic lead in fused lead chloride.

R. Lorenz[4] determined the influence of alkali chloride on the solubility of metallic lead in fused $PbCl_2$ at 610°C (Table I).

TABLE I. Solubility of metallic lead in the system $PbCl_2$—KCl.

$PbCl_2$	KCl	Solubility X10,000
10 mole	0 mole	3.74%
9 mole	1 mole	2.27%
8 mole	2 mole	1.51%
7 mole	3 mole	0.64%
6 mole	4 mole	0.06%

The solubility of the metal in the fused salt is the result of the presence of Pb^{2+} ions which, in the asymmetrical force field of the Pb—$PbCl_2$ interface, are strongly deformed and thus are able to link the metal atoms with the ionic medium. Addition of KCl to the melt changes the $PbCl_2$ into K_2PbCl_4. The anion $(PbCl_4)^{2-}$ cannot act as a metallophilic group.

Experiment No. 4. Liquids containing polar molecules exert image forces upon the mercury and, as a result, increase the dispersability of the mercury in a liquid. Under conditions which did not lead to a dispersion of Hg metal in the non-polar carbon tetrachloride, the metal could be dispersed in the strongly polar nitrobenzene.

Summary. Dispersion of Hg in a liquid under the influence of ultrasonic vibrations requires the presence of strong forces between the metal and the medium. Strengthening the forces between the two incompatible media enhances dispersion and stabilizes the emulsion. This can be achieved in three ways:

1. Compound formation between the metal and a part of the liquid, e.g., addition of stearic acid to paraffin oil leading to a molecular film of the metal stearate.

2. Image forces induced in the metal surface by molecules with a permanent dipole, e.g., nitrobenzene.

3. Metallophilic groups such as strongly polarizable cations, e.g., Hg^{2+}. The mechanism of their action is known from several phenomena involving adhesion[5] (silver to glass by means of tin ions) and solution[6] (gold ruby glass requires the presence of metallophilic ions, such as Sn^{4+}, Bi^{3+}, Pb^{2+}).

The Barium Oxide on Tungsten Cathode Interface*

EUGENE B. HENSLEY AND JOHN H. AFFLECK
University of Missouri, Columbia, Missouri
May 17, 1950

IT is now recognized that the electrical behavior of oxide coated cathodes may be influenced either directly or indirectly by the presence of an interface compound formed by the reaction of the oxide coating with the base metal.[1] Tungsten and tungsten nickel alloys have been used as the base metal in experimental tubes and have found some commercial application in certain subminiature tubes. We have identified the interface compound for these cathode systems as being composed principally of barium tungstite, $BaWO_3$, when the coating is pure BaO. The corresponding tungstites are found when SrO or the solid solution (BaSr)O are used for the coating. An extensive search of the literature has failed to reveal any mention of the existence of these compounds; consequently particular care has been taken in their identification. Because of the small amounts of the interface compounds formed, x-ray diffraction methods of analysis have been used.

Cathodes were prepared by spraying $BaCO_3$ with an organic binder onto 10 mil tungsten wires which had been cleaned by electrolyzing in a KOH bath. The cathodes were then mounted in vacuum tubes and exhausted to a final pressure of 5×10^{-8} mm of Hg. The $BaCO_3$ was then reduced to the oxide by passing heater current through the tungsten wires and the tubes were sealed off with the pressure again at 5×10^{-8} mm. The tubes were then placed on life test for various periods of time and at various cathode temperatures. No emission current was drawn from any of the experimental cathodes included in this report.

After aging for a definite period of time the tubes were broken open, the oxide coatings were removed mechanically and x-ray diffraction patterns were made of the exposed interface. In order to be sure the interface compound was stable in air, the first samples were opened in a dry-box and then coated with a protective coating of waterproof wax. No change in the interface pattern was noticed between the cathodes treated in this manner and those which were not. The x-ray powder diffraction patterns were made with a camera of 7.16 cm radius and using Cu Kα-radiation filtered through 0.0007 in. nickel.

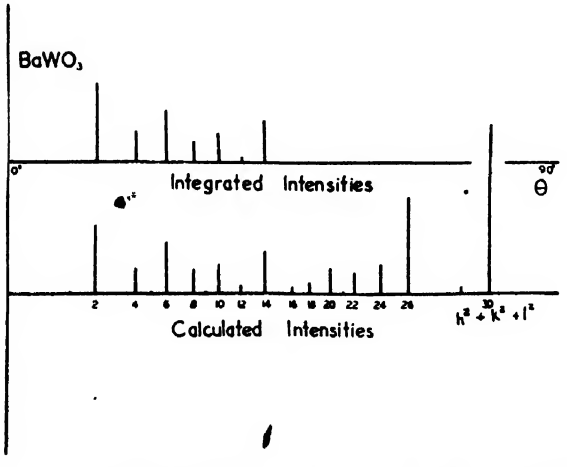

FIG. 1. The integrated intensities and Bragg angles of the x-ray powder diffraction lines of $BaWO_3$ compared with their calculated values.

The x-ray diffraction lines showed the interface compound to have a cubic structure with a lattice spacing of 4.30 *kX*. In addition to these and the tungsten lines, a few other lines were sometimes present which were probably due to tungsten oxides but they were always too weak to permit identification. Assuming the interface compound to have a perovskite ($CaTiO_3$) structure with a formula $BaWO_3$, the intensities were calculated and are shown in Fig. 1 together with the integrated intensities obtained by microphotometering the x-ray diffraction films. The calculation of these intensities involved the use of absorption factors for coated cylinders.[2] The lines beyond a Bragg angle of 45° were too broad to be measured. This broadening was probably due to the small crystal sizes and also to the fact that most perovskite type crystals are pseudo-cubic, causing the lines in the back reflections to have a multiple structure.

Cathodes consisting of SrO on W were also prepared and the x-ray analysis indicated the presence of $SrWO_3$ with a lattice constant of about 4.12 *kX*.** These lines were much weaker than those obtained from the barium compound, indicating the BaO reacts more easily with the W than does the SrO. Also prepared were cathodes with a coating of equal molar solid solution (BaSr)O on W. The lattice constant of the resultant $(BaSr)WO_3$ was 4.24 *kX*, indicating greater than an equal molar fraction of barium. Similar results to the above have been obtained when the cathode was formed on a 3 mm diameter nickel sleeve containing 4.7 percent tungsten impurity. Commercial hearing aid tubes[3] using a 0.5 mil tungsten wire base for the oxide cathode have been examined and the tungstite interface was observed to be present both in new tubes and in tubes which had been operated for 500 hours.

In order to determine whether the reaction requires the presence of any other material than the BaO and W, a special tube was constructed in which the BaO was deposited onto clean W by evaporation. $BaCO_3$ was sprayed onto a small spiral of pure platinum wire[4] which was then mounted in the vacuum tube with the tungsten wire passing along the axis of the spiral. First the $BaCO_3$ was reduced to BaO by passing current through the Pt wire. The W wire was then cleaned by raising its temperature to 1800°C. BaO was evaporated onto the cold W by raising the temperature of the Pt to about 1400°C until no oxide remained visible on the Pt. The W wire with its coating of BaO was heated to 850°C for 24 hours after which the cathode was removed and placed in the x-ray diffraction camera. X-ray diffraction patterns showed that $BaWO_3$ had been formed as in the previous tubes.

Several attempts were made to prepare $BaWO_3$ in larger quantities by heating mixtures of various tungsten and barium compounds in a vacuum furnace as for example powdered tungsten and barium carbonate. All these experiments resulted in forming the tungstate $BaWO_4$ instead of the tungstite $BaWO_3$. The lowest pressures obtainable in the vacuum furnace were of the order of 10^{-5} mm of Hg. When a mixture of powdered W and $BaCO_3$ was coated on a cathode sleeve and heated in a vacuum of about 10^{-7} mm the x-ray analysis showed a large percentage of $BaWO_3$ present and no $BaWO_4$. From these experiments it seems probable that the tungstite is formed only in a good vacuum and at higher pressures the tungstate is formed.

An investigation of chemical properties of $BaWO_3$ has not yet been carried out. However, it has been observed that although the tungstite is relatively stable when exposed to air over a period of several months, if a sample is placed in water for several minutes much of the tungstite oxidizes over into the tungstate.

A series of identical tubes were prepared and life tested at a temperature of 875°C in order to determine the variation in interface thickness with life. An x-ray method was employed for these thickness measurements.[2] The times recorded include the

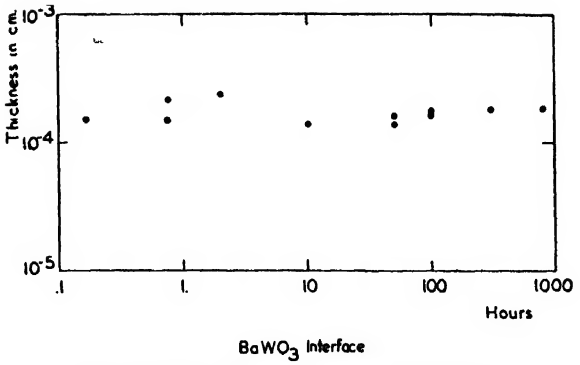

FIG. 2. Variation of interface thickness as a function of time at a temperature of 875°C.

time required to reduce the $BaCO_3$ to the oxide. Results are presented in Fig. 2 for the 15 cathodes examined. It can be seen that at this temperature the interface reaches its final thickness during the conversion process (less than 10 minutes) and remains essentially constant at 1.5×10^{-4} cm during the subsequent life of the tube. It should be pointed out that if the tungsten is present only as an impurity in another metal such as nickel, the rate of diffusion of the W may lead to an increase in thickness with life. Also drawing emission current from the cathode may well influence the interface thickness.

We wish to extend our thanks to Professor A. S. Eisenstein for many helpful discussions, and also to Mr. Harold John, who carried out the chemical preparations and to Mrs. Hope Lorch, who constructed most of the tubes.

An Alternative Method for the Summation of Fourier Series

I. F. MORRISON
Department of Civil and Municipal Engineering, University of Alberta, Edmonton, Alberta, Canada
May 25, 1950

AS an alternative to the interesting method for the summation of certain types of Fourier Series presented in the April issue by L. A. Pipes, a more direct approach can be made by using summation formulas for trigonometric series in terms of the Bernoulli and Euler polynomials. There are four of these formulas, which are, perhaps, not quite as well known as they might be, for they are generally quite useful, especially in such cases as are referred to in this paper.

One of them, for example, is,

$$\bar{B}_{2\nu+1}(x)=(-1)^{\nu+1}\frac{2(2\nu+1)!}{(2\pi)^{2\nu+1}}\sum_{n=1}^{\infty}\frac{\sin 2\pi nx}{n^{2\nu+1}}$$

in which $\bar{B}_{2\nu+1}(x)$ is the Bernoulli polynomial in the interval $0\leqq x<1$. The series is absolutely and uniformly convergent for values of $\nu>0$, but not for $\nu=0$ in the neighborhood of the points $x=\pm0, \pm1, \pm2, \cdots$. To illustrate, consider Example II of the paper. If one puts $\nu=0$ in the expression above, there results

$$-\bar{B}_1(x)=+\frac{1}{\pi}\sum_{n=1}^{\infty}\frac{\sin 2\pi nx}{n}$$

which is in the same form as

$$F_2(t)=\frac{2}{\pi}\sum_{n=1}^{\infty}\frac{1}{n}\sin\left(\frac{n\pi t}{s}\right),$$

Eq. (4.7) of the paper with $2x=t/s$. $-\bar{B}_1(x)=\frac{1}{2}-x$ is a periodic function with period 1. The graph starts with a value $+\frac{1}{2}$ at $x=0$ and becomes discontinuous at $x=+1$ where it experiences a discontinuity $+1$, after which the cycle is repeated. Thus, the graph, with ordinates multiplied by 2, is the same as that of Fig. 2 of the paper.

The other examples in the paper can be dealt with in the same way.

Creep-Time Law for Zinc Crystals

E. P. T. TYNDALL
Department of Physics, State University of Iowa, Iowa City, Iowa
May 25, 1950

THE creep of suitably oriented zinc single crystals has been found to follow a very simple empirical law: $S=At^M$, in which S is the strain (non-elastic) occurring in time t, counted as zero at the instant of applying the load, and A and M are constants. The crystals have been tested under constant load and therefore constant stress since the reduction in area is negligible. Series of runs have been made in which the crystal was first loaded to just beyond the linear (elastic, or Hooke's law) region and then allowed to creep. The load was then increased by a small increment and a second run made; a further increase in load produced a third run and so on for five or six runs. The constant M, which is the slope of the straight line obtained for each run when plotted as log strain against log time, is about 0.5, varying somewhat from this mean value in different runs. The values of the constant A in any one series of runs lie on straight lines when plotted as log$A$ against the stress. The positions of the lines on such a plot depend on the history of the specimen and the purity of the zinc. Their slopes are nearly the same. The simple law has been found only with complete consistency for crystals in which one of the translation directions lies very close (within about 2°) to the direction of the projection of the length of the specimen into the basal (slip) plane, or, otherwise stated, the angle between slip plane and length of specimen is the same as the angle between the length and the nearest translation direction. The law appears to hold quite accurately for series of runs extending from strains of 10^{-7}, about the least observable strain, to strains somewhat above 10^{-3}. There is no indication of a separation into the two processes generally heretofore recognized, transient and steady-state creep.

For crystals with the translation direction 5° or more out of line with the projection of the length the behavior was definitely different. Some followed the pattern of transient plus slow creep found previously[1] while others had occasional large jumps, or (in one case) stepwise creep in which rapid creep followed slow creep at regular intervals. Crystals were also found in which, after a time of rapid creep, further strain followed the creep law above but with the constant M quite small, about 0.1 or 0.2. This appears to be typical of crystals with the angle mentioned above between approximately 15° and 30°. The simple creep law may be considered as a special case of the Andrade law proposed some years ago for creep in polycrystalline lead and copper.

Fracture Modes in High Purity Metals

T. J. AGNOR AND M. E. SHANK
Massachusetts Institute of Technology, Cambridge, Massachusetts
May 29, 1950

IT has been commonly accepted in many quarters that only iron and ferritic steels undergo a change in impact fracture mode with decreasing temperature. In such materials fracture changes from ductile type to brittle cleavage type and the absorbed energy drops markedly. The exact temperature of such

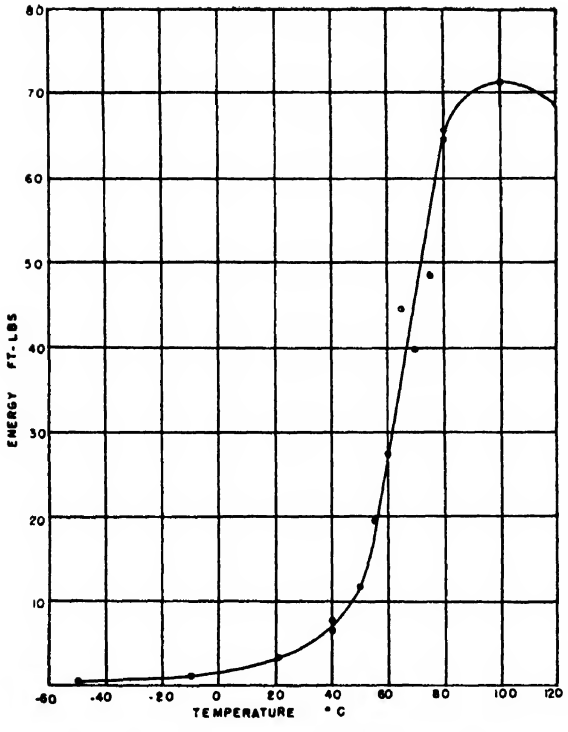

FIG. 1. Transition curve for high purity polycrystalline zinc.

transition depends upon composition and heat treatment of the material. Investigation by the authors into the behavior of high purity zinc by means of standard Charpy tests shows similar behavior of this metal. The material used was of 99.9955 percent purity, containing 0.0021 percent Pb, 0.0017 percent Cd, 0.0006 percent Fe, and 0.0001 percent Sn. It was hot-worked to an average grain diameter of 0.013 mm. The transition curve is shown in Fig. 1. The fractured surfaces, Fig. 2, have a macroscopic appearance that is superficially indistinguishable from that found in ferritic steels. Moreover, microscopic examination of the zinc fractures indicates brittle cleavage facets adjacent to large areas of ductile fracture in specimens whose gross macroscopic fracture appearance is entirely ductile. In some instances, large, deep voids have been opened in the material, apparently due to the triaxial stress conditions developed during fracture. It is evident, therefore, that transition temperatures exist for high purity metals other than iron and ferritic steels, and in fact for a metal not even of the body-centered lattice type.

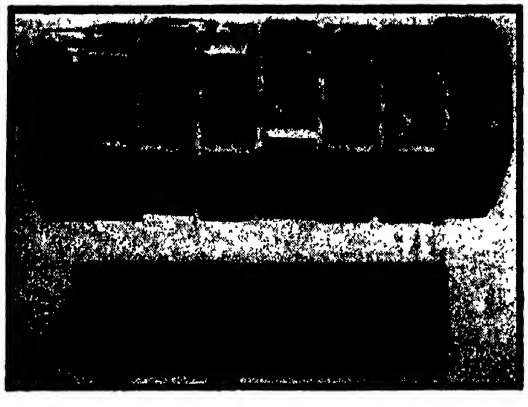

FIG. 2. Photograph of specimens showing fractured surfaces. Order of specimens, from highest to lowest temperature, is right to left on upper row, then left to right on lower row.

Similar work was carried out on high purity, vacuum-cast iron, major impurities in which were 0.063 percent O, 0.00038 percent H, 0.002 percent C. Nitrogen was not detectable. The iron had an average grain size of 0.31 mm, grain refinement being particularly difficult in such material. A very sharp transition temperature was found at 80°C. This is far above the usual transition ranges reported for ordinary Armco Iron,[1] and it does not seem probable that the difference is due entirely to the coarse grain size. On the basis of carbon and nitrogen present it would seem likely to expect a transition range in the neighborhood of −40° to −100°C. That it does not occur here apparently indicates the effect of the relatively high oxygen content. Since the work of Low and Gensamer[2] indicates that oxygen has no effect on aging or yield point in steels, the present evidence would serve to support the belief[3] that the mechanism of the transition temperature in metals is entirely unrelated to aging and inhomogeneous yielding phenomena.

Intensity Correction Factors for X-Ray Spectrometer Transmission Pole Figure Determinations

SUZANNE VAN DIJKE BEATTY
Chemical Department, Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania
May 25, 1950

A TABLE has been computed to expedite the reduction of intensity contours obtained with a recording x-ray spectrometer using the transmission method for pole figure determination. This method is particularly suited for thin sheet material having very small grain size and is valuable in the determination of the textures of rolled materials.

In this type of pole figure work, the counter is held stationary at a given value of 2θ corresponding to a given reflection from the sample. The sample is then rotated about the vertical axis making an angle α with the Bragg angle. For each value of α, the sample is in turn rotated about the horizontal axis making an angle β with the rolling direction. Intensity corrections are necessary since the path length in the sample varies with different values of α and θ. The correction factor at any θ is taken as unity when $\alpha=0$. It is clear that no correction is needed for different values of β since the path length in the sample remains unchanged. The final intensity depends also on the absorption of the sample and on its thickness. Fortunately we need only the product μt so that the absorption factor can be determined experimentally from the relation $e^{-\mu t}=I/I_0$. The intensity of a strong reflection from quartz, for example, is recorded both with and without the sample to be studied in front of the counter slit. The ratio of the two intensities gives the required absorption factor. The correction factor also involves the diffracting angle θ since the path length and total volume of the sample irradiated differ.

The equation giving the intensity correction factor is given by:[1]

$$\frac{I_0}{I_{\pm\alpha}}=\frac{\mu t\exp(-\mu t/\cos\theta)}{\cos\theta}\times\frac{(\cos(\theta\pm\alpha)/\cos(\theta\mp\alpha))-1}{\exp(-\mu t/\cos(\theta\pm\alpha))-\exp(-\mu t/\cos(\theta\mp\alpha))}. \quad (1)$$

This is a special case of the expression given by Smoluchowski and Turner[2] and it was found[1] that more exact values are obtained when α is negative, i.e. with clockwise rotation of the shaft of the sample holder.

The factors are given for every 5° of α from 5° to 60° inclusive. For each value of α, every 10° in 2θ is listed between 10° and 80° and every 0.1 interval of the absorption factor from 0.1 to 0.9. Families of curves are given for every 5° of α in Figs. I to XII.

The tables may serve not only as a source of correction factors, but as a guide in the preparation of the sample and data. By plotting the factors as a family of curves for each value of θ or of $e^{-\mu t}$, one can see at a glance which set of values will require the least correction. The problem of optimum settings is also discussed by L. G. Schulz[3] in a recent paper.

A limited number of these tables is available for free distribution from the Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania. Requests for the tables should be addressed directly to the author.

Determination of Elastic Constants in Single Crystals with Especial Reference to Silver Chloride

DAVID L. ARENBERG
U. S. Naval Air Development Center, Johnsville, Pennsylvania
June 1, 1950

USING the ultrasonic pulse method[1] to measure the velocity of sound at 15 mc/sec. in different directions, the elastic constants of silver chloride have been determined. Two single crystals, F-16-a-2 and F-16-a-7, were oriented and ground by West and Makas of the Polaroid Corporation. After annealing carefully, the crystals were developed to produce a silver electrode on the surfaces.[2] Corrections were applied to account for the thickness of the piezoelectric transducers, but due to the large temperature and pressure coefficients of silver chloride, complete agreement between different sets was not obtained. No short time effect on the velocity was noticed when a strong light shone on the crystals. The sound absorption coefficient was low and hence not measured. The values for F-16-a-2 are believed to be better than for the set from F-16-a-7. The value 5.589 g/cc determined by Bridgman[3] from x-ray data was used for the density rather than the handbook value of 5.56.

Selected values for crystal F-16-a-2 are 0.605, 0.364, and 0.0624 times 10^{12} dynes/cm^2 for C_{11}, C_{12}, and C_{44} respectively.

Since it is not always possible to obtain orientations of crystals that allow simple calculations between the elastic constants and velocities, approximate formulas were developed and the measurements in the *hkl* directions made to check them. One can derive explicit formulas that are very good first-order approximations for all orientations and exact in certain planes and points, such as all directions in the plane normal to an 001 axis and also in the 111 direction for cubic crystals. One uses the direction cosines involving rotations about three axes with the IRE conventions given by Cady[4] of angles φ, θ, and ψ. φ and θ have their usual significance of azimuth and colatitude in spherical coordinates but ψ, which represents rotation about the Z''' axis, will be indeterminate for a pulse traveling in an infinite medium, and must be either eliminated or associated with some properties of the waves to have physical significance.

The choice of coordinates used by the experimenter is an arbitrary one which cannot influence the velocity in the medium. It is observed that if the piezoelectric transducers, particularly those generating complex waves, are mounted on the specimen the time delay between members of the series of echoes received from a single pulse will differ by increments which are integral multiples of a linear combination of the delays due to any of the three different modes having different velocities traversing the specimen once. Even with a pure mode generator operating at normal incidence, mode transfer can occur at each reflection resulting in a complex system of echoes which can, however, be analyzed into the three different fundamental modes. Changing the orientation of a shear wave transducer on the specimen can only influence the relative amplitudes of the echoes. With sufficient care in orientation, only one period between echoes will be observed.

One can therefore associate the angle ψ with the plane of polarization of the quasi-transverse waves in the crystal and by *ad hoc* reasoning apply Fermat's principle that the velocities of the waves assume stationary values so that all $\partial C_{ii}/\partial\psi=0$. The angle ψ is then uniquely determined as a function of φ and θ and will give the velocities and plane of polarization to a first-order approximation as shown below. Higher order correction terms can be added later.

One selects the expressions for C_{44}', C_{55}', and C_{33}' for operation and defining for cubic crystals:

$$A=8-\sin^2\theta(7+\cos^4\varphi) \tag{1}$$

$$B=2\cos\theta\sin^4\varphi \tag{2}$$

$$C=A-2(1-\cos^4\varphi) \tag{3}$$

$$\tan 2\psi=B/C \tag{4}$$

$$r=C_{11}-C_{12}-2C_{44}, \tag{5}$$

we can get the elastic constants along the Z''' axis:

$$C_{33}'=C_{11}-r\frac{A\sin^2\theta}{4}=C_{11}-r\alpha \tag{6}$$

$$C_{44}'=C_{44}+r\frac{\sin^2\theta}{8}(A-(B^2+C^2)^{\frac{1}{2}})=C_{44}+r\beta \tag{7}$$

$$C_{55}'=C_{44}+r\frac{\sin^2\theta}{8}(A+(B^2+C^2)^{\frac{1}{2}})=C_{44}+r\gamma. \tag{8}$$

Also for any direction in the crystal, the velocities are:

$$V_L'=(C_{33}'/\rho)^{\frac{1}{2}} \tag{9}$$

$$V_t'=(C_{44}'/\rho)^{\frac{1}{2}} \tag{10}$$

$$V_T'=(C_{55}'/\rho)^{\frac{1}{2}}. \tag{11}$$

After determining all C_{ii}' from measurements and manipulating (6), (7), and (8), one gets the inverse relations:

$$C_{11}=C_{33}'+\frac{\alpha(C_{55}'-C_{44}')}{\gamma-\beta} \tag{12}$$

$$C_{12}=C_{33}'-C_{44}'-C_{55}'-(1-2\alpha)\frac{(C_{44}'-C_{55}')}{\gamma-\beta} \tag{13}$$

$$C_{44}=\frac{\gamma C_{44}'-\beta C_{55}'}{\gamma-\beta}. \tag{14}$$

If φ and θ are known with respect to the crystal axes the three velocity measurements in one direction, such as the 110, would suffice to give all three constants except for a certain arbitrariness in the relation between γ, β, and C_{44}' and C_{55}'. For most ionic crystals, the anisotropy factor $(C_{11}-C_{12})/2C_{44}$ is >1.00 and for metallic crystals <1.00, so that this choice can be made. Errors in measurement and misorientation are least important in the 001 and 111 directions, but here $V_t'=V_T'$ and velocities must be measured in two directions.

Furthermore, with highly anisotropic crystals, one can obtain an approximate idea of the orientation of the crystal by measuring the transverse velocities in three or more directions. The

Examination of Thin Overgrowths by Multiple Scattering of Electrons

L. G. SCHULZ
Institute for the Study of Metals, University of Chicago, Chicago, Illinois

June 14, 1950

ELECTRON diffraction by the reflection method is commonly employed in the study of oriented overgrowth on single crystals.[1] In Fig. 1A is shown the usual experimental arrangement. When the overgrowth is produced by evaporation and deposition in a vacuum the deposit forming the overgrowth is occasionally too small to be detected easily. To enhance the scattering of very small deposits the angle θ might be decreased. This leads to difficulties, however, because of refraction effects and increased background scattering. It has been found that a better procedure is to employ the reflected beam from the substrate as the incident beam on the deposit. In drawing B of Fig. 1 the part of the incident beam I which is reflected is indicated by I'. Since I' is an incident beam in respect to the deposit there will be a second diffraction process resulting in the beams I''. The angle θ' is associated with the crystal constants of the deposit.

With the arrangement of drawing B one can take advantage of much smaller scattering angles for the deposit than by the direct approach of drawing A. The part of the beam I (in drawing B) which is intercepted by the deposit must be scattered through a total angle of $2\theta\pm\theta'$ to reach the same general area of the photograph as the beams I''. Because of the rapid decrease in intensity with angle of scattering only the spots due to I'' (and to I''') appear in the photograph.

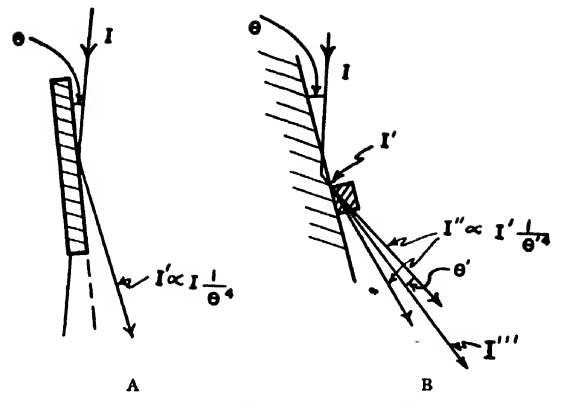

FIG. 1. Experimental arrangements. Drawing A shows the usual reflection arrangement; drawing B shows the new method employing multiple scattering of electrons.

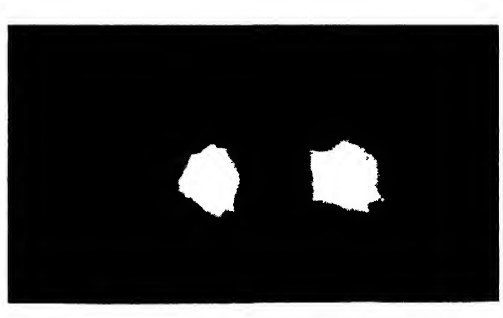
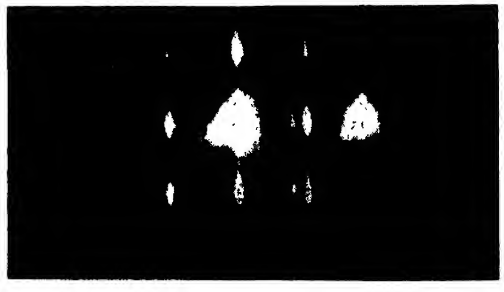
The results from an application to a study in polymorphism are presented in Fig. 2. Photograph (a) is from a single crystal of LiF, the two points being the (600) and (620) reflections. Photograph (b) is from the same crystal but after a deposit of CsBr averaging 2A in thickness has been added. This small deposit has migrated over the substrate and grown into crystals approximately 100A on an edge. An analysis of photograph (b) reveals that the CsBr crystals have a NaCl type structure, rather than the usual CsCl type, and that they are oriented with their axes parallel to the corresponding axes of the substrate.

In Fig. 2 each of the two beams from the LiF substrate is an incident beam in respect to the deposit. As a result there are two secondary diffraction patterns. The displacement of the two patterns relative to each other is the same as the separation of the two LiF points. Consequently the separation of any pair of corresponding points from the two secondary patterns can be used as



(a)



(b)

FIG. 2. Results of an application of the new method. CsBr has been deposited by evaporation and deposition in a vacuum onto a single crystal of LiF. (a): LiF (heavy exposure); (b): 2A of CsBr added to LiF.

an internal standard making possible an accurate determination of the crystal constants of the deposit.

Details concerning the range of application, together with additional results, will be given later.

This research was supported in part by Army Air Force Contract No. AF 33 (638)-6534.

A Note on Thermoelectric Generation of Current

MAX B. GREEFF
Upper Montclair, New Jersey
July 5, 1950

TELKES wrote a very thorough and interesting article[1] about the efficiency of a thermoelectric generator. A formula is given for the calculation of the efficiency for any thermocouple whenever the Wiedemann-Franz-Lorenz law is applicable. The calculations given in Table I of the article show that the efficiency of a thermocouple may become much better than has been anticipated in the past, provided we have a couple delivering power beyond 200 microvolts per °C. In fact, at 500 microvolts per °C we may expect an efficiency of 20.9 percent if the temperature gradient between hot and cold junctions is 500°C.

However, there is a limitation in Telkes' formula to which Papet[2] calls our attention. The electrical efficiency, depending on the relation of internal and external resistances, is fixed at 50 percent (internal and external resistances are assumed equal); this being the condition of maximum energy output of the thermoelectric generator. Though we are much concerned in obtaining high energy, it is not always most efficient to operate the generator at maximum energy output.

For example, let us calculate a complete characteristic of a generator assuming 4 different cases of construction: (1) applying thermocouple elements of 100 microvolts per °C; (2) applying thermocouple elements of 500 microvolts per °C; (3) changing the relation of internal and external resistances of case (2); (4) reducing the number of elements in case (3).

The energy output of all 4 cases remains the same (Table I).

TABLE I.

Generator case	*I*	*II*	*III*	*IV*
Power of each couple microvolts per °C	100	500	500	500
Generator e.m.f. volts	100	100	100	55.5
Number of couples required	2000	400	400	222
Voltage utilized volts	50	50	95	50
Amperage utilized amp.	25	25	13.2	25
Wattage utilized kilowatts	1.25	1.25	1.25	1.25
Resistance intern. ohms	2	2	0.4	0.22
Resistance extern. ohms	2	2	7.2	2.00
Resistance total ohms	4	4	7.6	2.22
Resistance per couple ohms	0.001	0.005	0.001	0.001
A efficiency Telkes %	2.34	20.9	—	—
B electrical $\frac{r_2}{r_1+r_2}$ %	50	50	95	90
C eff. total $=2A \times B$ %	2.34	20.9	39.8	37.6

We see immediately that there is more than one way to construct a thermoelectric generator of a given output. At maximum output, Cases *I* and *II*, we may adopt the calculated efficiencies offered by Telkes. But Cases *III* and *IV* require discussion as they are not at maximum output. Consequently, we are not allowed to apply Telkes' efficiency for these cases. We may, however, compare the two cases *III* and *IV* with Case *I* which has the same resistance per element and only differs in the number of elements.

Case *III* has 1/5 the number of elements as has Case *I*, producing the same energy. Consequently, Case *III* has 5 times the efficiency as Case *I*, using only 1/5 the amount of fuel. The efficiency therefore is $5 \times 2.34 = 11.60$ percent.

Case *IV* has 1/9 the number of elements as has Case *I*, producing the same energy. Consequently, Case *IV* has 9 times the efficiency as Case *I*, using only 1/9 the fuel. Therefore, the efficiency is $9 \times 2.34 = 21.06$ percent.

We could construct a generator of the same elements and equal output, but at different voltage, whose efficiency is still higher, choosing the special Case *V* where the numerical figures for voltage and amperage are practically equal.

This Case *V* would require only 160 elements or thermocouples to deliver a voltage of 36 volts at an amperage of 35 amp. Using only 1/12.5 of the number of elements as in Case *I*, the efficiency is $12.5 \times 2.34 = 29$ percent. Under these circumstances the generated e.m.f. would be 40 volts and the electrical efficiency 90 percent.

On the Negligible Changes Produced in the Stress-Strain Curve by Immersion of a Copper Single Crystal in Mercury

J. B. WACHTMAN, JR.
Carnegie Institute of Technology, Pittsburgh, Pennsylvania
July 6, 1950

IN his proposed explanation of slip bands, Frank[1] considers internal processes and reflections of fast dislocations at the surface of a single crystal as dislocations of opposite sign. He suggests that immersing a single crystal in a liquid of higher density will suppress reflections of dislocations. If reflection of dislocations plays an appreciable role as compared with internal processes in the formation of slip bands, one might expect the suppression of reflections to change the stress-strain curve.

Single crystals of 99.999 percent pure copper were grown to A.S.T.M. standard tensile specifications (2-in. gauge length, 0.25-in. diameter). The crystals were oriented and then annealed in vacuum for 20 hours at 600°C.

These samples were then subjected to tensile tests in a Baldwin Southwark Tate-Emery 60,000-pound testing machine; the extension being determined from the travel of the head of the testing machine as determined by a dial gauge. This method of extension measurement was checked on three crystals by measuring the separation of two marks on the crystal initially 1 inch apart with two cathetometers. The stress and strain were resolved by assuming that single slip took place until a position of symmetry with respect to two slip systems was reached after which it was assumed that equal slip on both systems took place. Three crystals were pulled partly in air and partly under mercury. Table I gives, for each crystal, the resolved shear strain at which double slip begins, the resolved shear strain at which mercury was added, and the final load.

TABLE I.

Crystal No.	Final load	Resolved shear strain at beginning of double slip	Resolved shear strain at which mercury was added
3	1022 lb.	53.8%	No Hg added
4	764	48.4%	9.5%
6	768	29.5%	No Hg added
10	1012	52.1%	No Hg added
11	731	56.4%	0.0%
13	823	64.0%	10.3%

The resolved stress-strain curves for the crystals strained in air are shown in Fig. 1 as calculated from the cathetometers and the dial gauge extensometer. The two methods of calculation yield curves in good agreement with each other for crystals 3 and 10. The curve for No. 6 computed from the dial gauge has an unusual bump in it and does not agree well with the other curve for No. 6 at intermediate strains. The strain determined from the

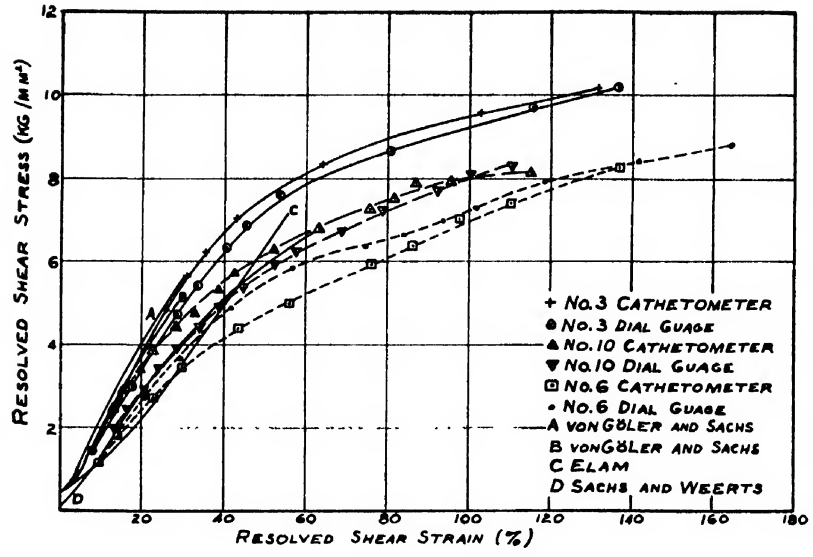

FIG. 1. Stress-strain curves obtained on copper crystals in air.

dial gauge may be in error because of inhomogeneous deformation near the grips, slipping of the grips in the machine, or sticking of the plunger in the dial gauge. Since the high strain data yields close agreement it seems reasonable to assume that the error at intermediate strain was caused by sticking of the dial gauge plunger and that the high and low strain portions of No. 6 curve, in agreement with No. 3 and No. 10, indicate that inhomogeneous deformation near the grips and slipping of the grips do not produce large errors in the strain computed from the dial gauge.

The curves for No. 4 and No. 13 lie well within the range of the curves run in air. The curve for No. 11 does drop below the lowest of the curves run in air but the greatest stress difference between it and the curve for No. 6 is 0.8 kg/mm² which is to be compared with a spread of 2.9 kg/mm² between the curves run in air. Thus if the weakness of No. 11 is ascribed to the mercury (which is improbable in view of the curves for No. 4 and No. 13) the effect is smaller than the normal variation in annealed, high purity crystals.

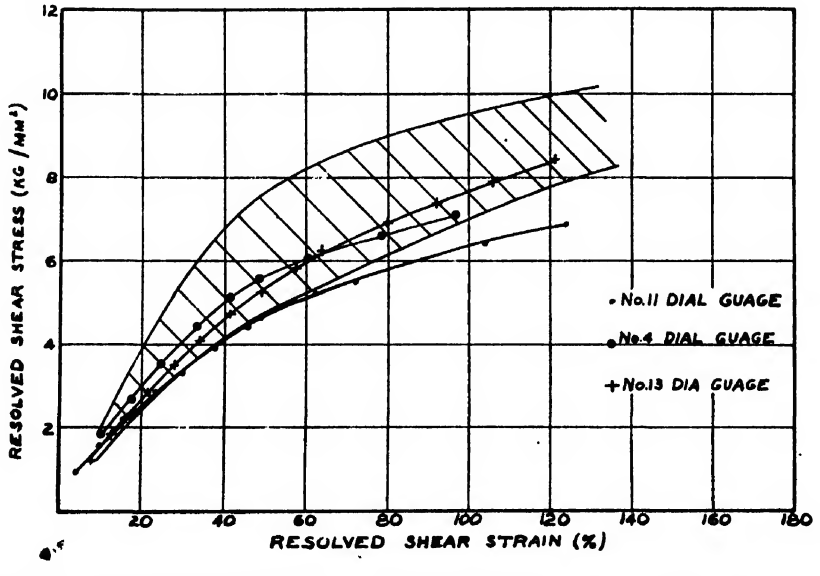

FIG. 2. Comparison of stress-strain curves obtained in air and in mercury. The shaded region gives the spread of the curves obtained in air.

Curves by von Goler and Sachs,[2] by Sachs and Weerts,[3] and by Elam[4] are also shown in Fig. 1.

The curves obtained from the mercury experiments are shown in Fig. 2. The shaded region indicates the spread of the curves obtained on specimens run in air.

The curvature and the roughness of the surface of the crystals made a microscopic examination of the slip lines impossible but to the naked eye the appearance of the slip lines was the same on crystals strained under mercury and those strained in air.

In conclusion it appears that immersion of copper single crystals in mercury does not have any important influence on the resolved stress-strain curve.

The author wishes to express his gratitude to Dr. J. S. Koehler for his aid.

The Effect of Input Configuration on Antenna Impedance*

J. R. Whinnery
University of California, Berkeley, California
(Received February 13, 1950)

It is known that the configuration of the input driving system may be of importance to the impedance of antennas at high frequencies. In this paper, a region in the vicinity of the input is considered as a transducer between the TEM mode on the driving transmission line and the spherical nearly-TEM mode on the antenna system, and the constants of this transducer are found both by calculation and measurement for a particular case. The calculation is based upon quasi-static concepts, utilizing an electrostatic field map obtained from an electrolytic tank to give the approximate form of the electric field lines. The measurement is made by finding three input reactances corresponding to the input region closed by three spun aluminum hemispheres of different radii. The three sets of data, taken at each frequency, are sufficient to determine the constants of the transducer. They are expressed here as a pi-network for comparison with calculated values.

The main portion of the antenna is analyzed substantially as in Schelkunoff's approach, with the TM modes in space and in the antenna region expressed as a shunt admittance at the end of the antenna in the TEM mode equivalent circuit. This admittance is then transformed to the desired reference on the antenna by a perturbation calculation. From there it is transformed to a desired reference on the feed line by means of the input network constants. Values calculated in this way are compared with measured values over the range 200 to 1000 mc/sec. for the particular monopoles studied. Agreement is not perfect, but appears considerably better than without consideration of the specific input configuration.

INTRODUCTION

IT is true that in many practical antenna problems, especially at frequencies below 100 mc/sec., the actual input driving means may add only a small contribution to input admittance. In these cases, it is not necessary to consider the actual input configuration in a mathematical analysis of the antenna, but, if an infinitesimal driving gap is assumed, the infinite susceptance singularity which would ordinarily result from this assumption must be avoided in some way. It will be described in the following paragraphs how this is accomplished in three of the modern methods of antenna analysis.

For frequencies above 100 mc/sec. (and for some antennas below this range), the actual input configuration may be important to the input impedance of an antenna. If the local capacitance of the actual input system is known, a first approximation may be had by adding the corresponding susceptance to the input admittance calculated by any of the analyses which have removed the local effects by avoiding the singularity. As an example, in the measured curves of Brown and Woodward,[1] their Fig. 13 shows curves of input resistance *versus* antenna length for antennas identical except with respect to their input configurations. These curves differ widely. They were able to explain much of the difference in these results in terms of an effective shunt capacitance across the input. However, it is clear that for many practical antenna inputs (for example some of those sketched in Fig. 1 for driving a monopole antenna above plane ground from a coaxial line), the effect of the input is too complex to be represented by a simple shunt capacitance, and a more general study of the input configuration is desirable.

It is the purpose of this paper to describe a point of view that may be applied to the input configuration of certain antennas, with examples of its use. The approach, especially that of the quasi-static method to be described, is applicable to a variety of boundary-value problems, such as those of discontinuities in wave guides.

THE SOURCE PROBLEM IN STANDARD ANTENNA ANALYSES

In the analysis of forced oscillations on spherical[2] and spheroidal[3] antennas, Stratton and Chu summed series of the appropriate wave solutions to fit the boundary conditions of the conducting antenna with an infinitesimal gap at its center across which the driving voltage is applied. The expected infinite capacitance results, since the series for susceptance are observed to diverge. The authors, in commenting on this, have pointed out that, for a finite gap, the amplitudes of

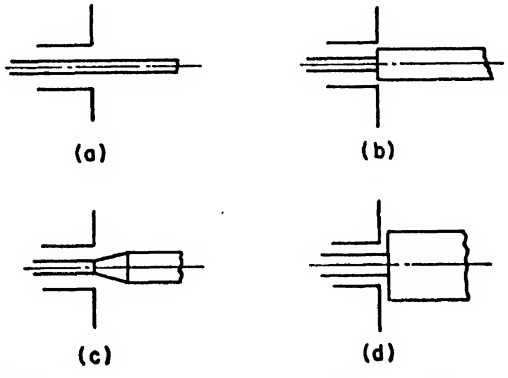

FIG. 1. Various input configurations for monopole antennas.

wave orders in the series would eventually approach zero as an order is reached great enough to give many reversals in sign in the angular function over the extent of the gap. They therefore recommend terminating the susceptance series after a finite number of terms to correspond to some actual gap. Infield[4] has made some estimates of the number of terms to retain for a given allowed error.

In Schelkunoff's analysis of the ideal biconical antenna,[5] the gap problem causes no mathematical difficulty, for, since the source applied between the tips of the two cones is a point source and not a "ring" or "slice" source as in the corresponding cylindrical dipole, there is no singularity in the admittance function. In his extension of results to thin antennas of other shapes, for example the cylindrical dipole of Fig. 2, it would appear that the original gap problem would return. Schelkunoff has a carefully outlined procedure for considering the specific gap,[6] but, even in the direct application of his perturbation solution with antenna admittance computed exactly at the origin, the infinite susceptance does not appear, and the calculated results agree well with measured values over the range of antennas for which input configuration is not important.

In order to explain the avoidance of the singularity in the Schelkunoff perturbation calculation, consider its application to the cylindrical antenna of Fig. 2. Each element of the antenna is considered first as an element of the biconical antenna passing through that radius, and the characteristic impedance computed for that point from the biconical line formula.

$$K = 120 \ln \cot(\psi/2) \cong 120 \ln[2z/\rho(z)]. \qquad (1)$$

There are at least two steps in this approximation, the neglect of the finite slope of the cone passing through $\rho(z)$ in comparison with the zero slope of the cylinder, and the substitution of $2z/\rho(z)$ for $\cot(\psi/2)$. Both of these are valid for large values of $z/\rho(z)$, and these approximations enter into the limitations of the method to thin antennas. However, the approximations also fail near the origin for antennas of any size, and they fail in just such a way that the infinity of susceptance is avoided. Thus the local capacitance effects and the susceptance effects from the antenna proper are separated by this process, and the resulting admittance is satisfactory for the large number of practical cases for which the local input effects are of small importance to the antenna impedance.

For consideration of the effects of a finite gap, Schelkunoff[6] recommends that one transfer the terminating admittance obtained from his biconical line analysis only to such a radius from the origin that the approximations described above (requiring that $z/\rho(z) \gg 1$) are valid, but also small enough compared with wave-length so that quasi-static ideas may be used in this region. This admittance is then transformed to $z=0$ by uniform line equations corresponding to the biconical antenna passing through this radius. To the resulting finite admittance, one adds the difference between the capacitive susceptance of the actual cylinder, including its physically real gap, and that of the imaginary biconical antenna utilized in the above step to avoid the singularity at the origin. The method to

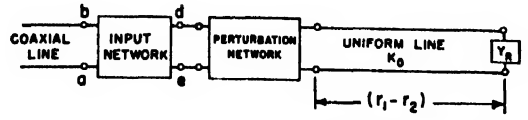

FIG. 5. Alternative equivalent circuit for the antenna of Fig. 3.

be described in this paper is in many respects an extension of this recommended procedure to other input configurations.

A third important method for the analysis of antenna impedance is that based upon approximate solutions of the integral equation developed by Hallen.[7-9] Since this analysis assumes the source as an infinitesimal gap in the cylinder across which there is a discontinuity in the scalar potential equal to the applied voltage, it would be expected to encounter the infinite susceptance difficulty described. However, it is common in these analyses to make an approximation to the angular integration in computing the vector potential, which amounts to assuming the current concentrated along the axis for purposes of computing the potential. This in effect evidently replaces the "slice" source at the gap by a point source, and so avoids the singularity as in the previous analyses.

THE POINT OF VIEW OF THIS PAPER

The point of view to be followed in this paper is: first, that the antenna system should be considered as a transducer from the feeding line to the waves in space as in Schelkunoff's analysis; secondly, that the problem should be divided into two parts, one consisting of the main body of the antenna to be analyzed substantially as in Schelkunoff's approach, and the other consisting of a region near the input, taking account of the actual input configuration. Considering specifically the monopole above ground plane, fed by a coaxial line (Fig. 3), one imaginary spherical surface is drawn through the end of the antenna at radius r_2 separating regions III and IV, and the matching of spherical wave functions across this surface is accomplished as in Schelkunoff's analysis, or by other methods. The effect of the TM modes in regions III and IV is expressed as a shunt admittance at the end of the antenna in the principal wave equivalent circuit, and this admittance is transformed to radius r_1, say by the non-uniform line formulation of Schelkunoff. All this is as in Schelkunoff's recommended procedure described above. However, at this stage, the entire region II between a reference plane $a-b$ in the coaxial line and the imaginary spherical surface $d-e$ of radius r_1 is considered as a two-terminal-pair network or transducer** whose parameters may be found either by calculation or by measurement. Once the parameters are known, and expressed in any of the possible forms (T networks, pi networks $\mathfrak{A}\mathfrak{B}\mathfrak{C}\mathfrak{D}$ constants, etc.), the admittance may be simply transformed from $d-e$ at radius r_1 to the reference $a-b$ in the coaxial line, yielding the desired information.

The reference plane $a-b$ is first selected far enough from the end of the line so that the local waves from the discontinuity have died out and the electric field is substantially radial; similarly the radius r_1 is selected far enough from the discontinuity so that the electric field lies substantially in the spherical surface $d-e$. This is the basic assumption of the approach. There could fail to be any such spherical surface if the antenna were too fat, or if it were not long enough compared to the dimensions of the input. That is, it is desired to select r_1 so that it satisfies the inequalities

$$r_1 \gg b_1 \tag{2}$$

$$r_1 \ll r_2, \tag{3}$$

where the $\gg$ is interpreted in this case only as "appreciably greater than." A reasonable selection of r_1 could thus be found easily for most antennas up to 1000 mc/sec., but not for most microwave antennas. In addition to the above inequalities, it is usually possible to choose r_1 to satisfy

$$r_1 \ll \lambda, \tag{4}$$

which is not essential, but does simplify the analysis.

The assumption that there is some region over which the electric field lines are substantially spherical, so that the analyses of the input configuration and the discontinuity at the end of the antenna may be separated, is much like that encountered in wave-guide discontinuity problems. If there are two discontinuities in a

** For the application of classical network theory to general electromagnetic structures, see for example, Montgomery, Dicke, and Purcell, *Principles of Microwave Circuits*, M.I.T. Rad. Lab., Vol. 8 (McGraw-Hill Book Company, Inc., New York, 1948).

wave guide far enough apart so that the local waves from each have effectively died out in some intermediate region, the dominant mode only existing in this region, the analysis of the two may proceed separately, the network for each found when alone in the guide, and the results of both found by combining by means of the transmission line equations. If they are so close that there is no such region, then they cannot be so separated.

The over-all equivalent circuit for the antenna (Fig. 4) will then consist of the input network representing region II, the non-uniform line representing the region III, and the terminating admittance Y_R representing the radiation and discontinuity effects at the end of the antenna. As will be shown later, it is possible to represent the non-uniform line by a uniform line of average characteristic impedance with a perturbation network at its input, so that the over-all equivalent circuit would then become as in Fig. 5. Of course, although the reference plane $a-b$ in the coaxial line should first be selected in the analysis far enough from the discontinuity so that there is only the principal TEM mode, and all measurements should be made at least this far from the end effect, the reference on the transmission line equivalent circuit can then be shifted at will by ordinary transmission line transformations. This will almost always be done, shifting the reference to the end of the line, since it forms the most natural reference.

THE SPECIFIC PROBLEMS STUDIED AS EXAMPLES

The point of view outlined above could be applied to a number of input configurations, such as those of Fig. 1. The particular configuration chosen for study was that of Fig. 1b, in which a $\frac{3}{4}$-in. O.D., $\frac{1}{4}$-in. I.D. coaxial line feeds a $\frac{1}{2}$-in. diameter cylindrical antenna with an abrupt step between the center conductor of the coaxial line and the antenna. This input structure was used on the three different antennas pictured in Fig. 6, each eleven inches long and $\frac{1}{2}$ inch in diameter at the base. That of Fig. 6(a) is a circular cylinder closed by a plane cap at the end, that of Fig. 6(b) is a cylinder left open at the end, and that of Fig. 6(c) is tapered in the last $5\frac{3}{16}$ inches, forming a cone with its apex at the antenna end. The input impedance for each was calculated, including the effects of the input configuration by means of the equivalent input network, and compared with measured values for a frequency range of 200 to 1000 mc/sec.

A SECOND-ORDER QUASI-STATIC CALCULATION OF THE INPUT NETWORK

In order to fulfill simultaneously the two inequalities of Eqs. (2) and (3) for the $\frac{1}{2}$-inch diameter antenna,

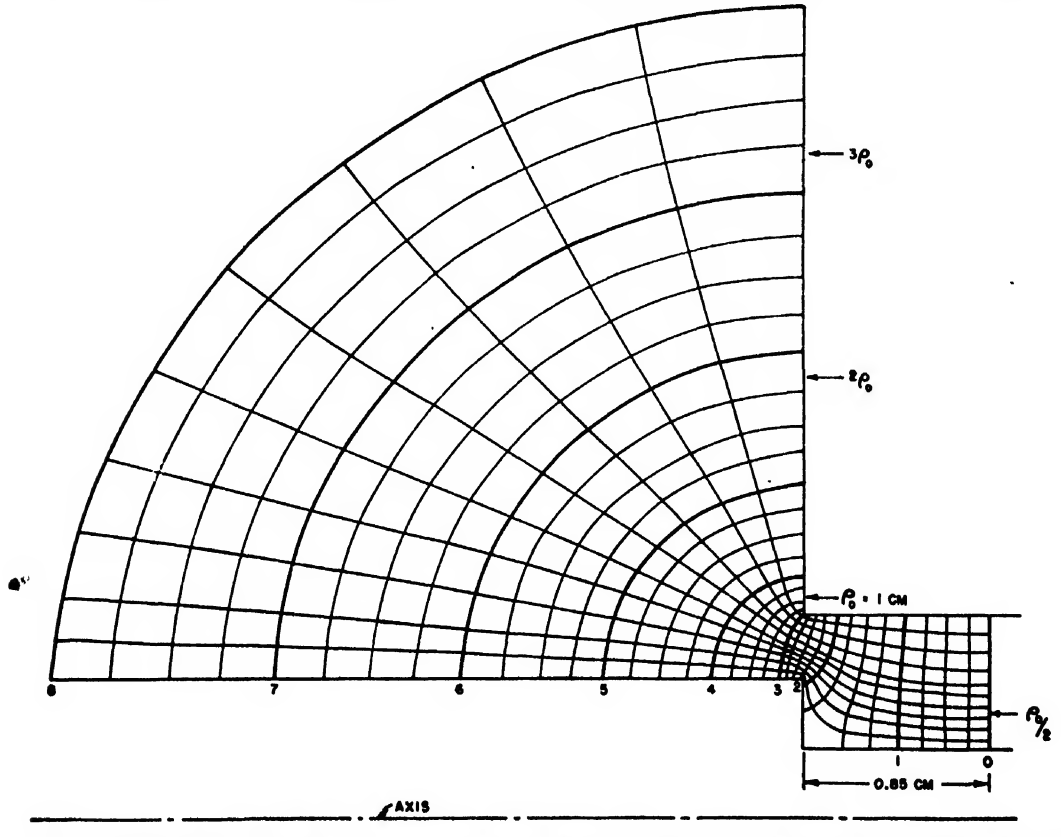

FIG. 7. Electrostatic field map of the antenna input region. Heavy flux lines indicate the divisions for the application of the second-order quasi-static analysis.

eleven inches long, fed by the $\frac{3}{4}$-inch (outer conductor inside diameter) coaxial line, the output reference sphere at radius r_1 was chosen as 3.45 cm. This yields $r_1/b=3.63$ and $r_2/r_1=8.1$, which is believed to be a satisfactory fulfillment of these inequalities. The inequality of Eq. (4) is also satisfied over the range of interest since the shortest wave-length (corresponding to 1000 mc/sec.) is 30 cm. An analysis by quasi-static methods is then appropriate for approximate determination of the input network.

A first-order equivalent circuit may be obtained from quasi-static ideas by determining for the region a series inductance L and a shunt capacitance C. The way in which the capacitance is divided between the branches of a pi (or the inductance between the arms of a T) affects the transforming properties of the network only to terms of the order ω^2LC. As is shown in Appendix A, the quasi-static ideas may be extended to give the proper division of the capacitance between the branches of the pi network for low frequencies. This is useful because the elements of the pi network actually remain substantially constant over a wide range of frequencies. For example, the experimental results show that the inductance and capacitances of the pi network representing the input configuration of the present problem change little up to 1500 mc/sec., which is considerably beyond the range of interest in this study.

The method is a quasi-static method in that it utilizes the electrostatic field map for the region, and so assumes that it is proper to approximate the wave equation by Laplace's equation. The electric field map utilized was obtained from an electrolytic tank, tilted about an axis as required for axially symmetric problems, utilizing tap water as an electrolyte, and excited by a 1000-c.p.s. signal generator. The field map obtained is shown in Fig. 7. The over-all region is subdivided by the flux tube boundaries, as indicated in Fig. 8, into regions small enough so that each of these may be represented by a symmetrical T. These are then cascaded to represent the over-all region. In the calculation of the matrix of the over-all network, terms of the order ω^2LC are retained, but higher powers of $(\omega[LC]^{\frac{1}{2}})$ are neglected. As is shown in Appendix A, results can be expressed by the pi-network of Fig. 9 with

$$L=\sum_{k=1}^{N} L_k, \tag{5}$$

$$C_a=C_n\sum_{k=1}^{N}(k-\tfrac{1}{2})\frac{L_k}{L}, \tag{6}$$

$$C_b=C_n\sum_{k=1}^{N}(N-k+\tfrac{1}{2})\frac{L_k}{L}. \tag{7}$$

The capacitance of the nth tube may be obtained from the electrostatic field map in the usual manner.

$$C=2\pi\epsilon\rho_0(N_f/N_v), \tag{8}$$

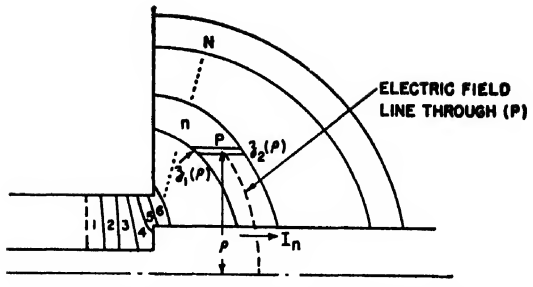

FIG. 8. Construction indicating the nth flux tube of the electrostatic field map of the region.

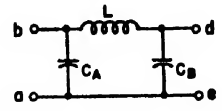
FIG. 9. Pi-network representing the over-all input region.



where ρ_0=radius at which side ratios of curvilinear rectangles is made unity; N_f=number of flux tubes; N_v=number of potential divisions; ϵ=dielectric constant$\cong$8.85 $\mu\mu$f/meter for air or space. The inductance of the nth tube may be obtained by graphically integrating the magnetic flux over the section of the nth tube. The magnetic field for this purpose may be related to the current in the nth tube. Thus if the line integral of magnetic field is evaluated at radius ρ passing through any point P in the nth tube (Fig. 8), it can be set equal to the current I_n, since a surface through P following an electric field line (shown dashed) would have no displacement current passing through it. So

$$H_\phi=I_n/2\pi\rho.$$

Here the current in the individual subdivision is assumed constant, and this can be satisfied by making the divisions small enough. The inductance of the nth tube is then

$$L_n=\frac{1}{I_n}\int\int \mu H_\phi d\rho dz=\frac{\mu}{2\pi}\int\int_{\text{tube section}}\frac{d\rho dz}{\rho}. \tag{9}$$

Either the ρ or z integration may be performed so that only one needs to be made graphically. Performing the z integration,

$$L_n=\frac{\mu}{2\pi}\int_{\rho\,\min}^{\rho\,\max}\frac{[z_2(\rho)-z_1(\rho)]}{\rho}d\rho, \tag{10}$$

where $z_2(\rho)$ and $z_1(\rho)$ represent the limits in z represented by the tube at a given value of radius.

For application of the method to the present problem, the region represented by the electrostatic map of Fig. 7 was divided into eight sub-regions, indicated by the heavy lines. With $N_v=10$, $N_f=4$, and $\rho_0=1$ cm, the capacitance per division from Eq. (8) was calculated as 0.222 $\mu\mu$f. The graphical integration for computation of the inductance according to Eq. (10) yielded

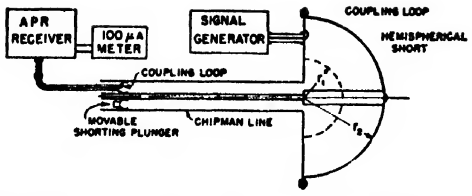


FIG. 10. Test set-up for measurement of the input region.

the following results:

$$L_8=4.14\times10^{-9}\text{ henrys}$$
$$L_7=3.03\times10^{-9}\text{ henrys}$$
$$L_6=1.88\times10^{-9}\text{ henrys}$$
$$L_5=0.954\times10^{-9}\text{ henrys}$$
$$L_4=0.318\times10^{-9}\text{ henrys}$$
$$L_3=0.153\times10^{-9}\text{ henrys}$$
$$L_2=0.858\times10^{-9}\text{ henrys}$$
$$L_1=0.865\times10^{-9}\text{ henrys.}$$

Thus, using Eqs. (5)–(7)

$$L'=\sum_{k=1}^{8}L_k=12.19\times10^{-9}H, \tag{11}$$

$$C_A'=\frac{0.222}{12.19}\left[\frac{L_1}{2}+\frac{3L_2}{2}+\cdots\frac{15L_8}{2}\right]=1.250\ \mu\mu\text{f}, \tag{12}$$

$$C_B'=\frac{0.222}{12.19}\left[\frac{15L_1}{2}+\frac{13L_2}{2}+\cdots\frac{L_8}{2}\right]=0.527\ \mu\mu\text{f}. \tag{13}$$

The values of Eqs. (11)–(13) are primed because it is now desired for convenience to move the reference in the transmission line to the end of the line by subtracting out the part of the network arising from the transmission line's *principal* wave. Note that this still leaves in the network the effects of the higher order waves in the transmission line region. Writing the above network as the cascade connection of two networks, the desired one and the network representing the principal transmission line wave over the length 0.85 cm, which by usual formulas yields values of $L_0=1.87\times10^{-9}$ henry and $C_0=0.436\times10^{-12}$ Fd, the approximate elements of the desired network can be found as follows:

$$L=L'-L_0=10.32\times10^{-9}\text{ henry}, \tag{14}$$

$$C_a=\frac{L'}{L}C_A'-C_0\left(1+\frac{L_0}{2L}\right)=1.005\ \mu\mu\text{f}, \tag{15}$$

$$C_b=C_B'-\frac{L_0}{L'}\left(C_A+\frac{C_0}{2}\right)=0.340\ \mu\mu\text{f}. \tag{16}$$

EXPERIMENTAL DETERMINATION OF THE INPUT NETWORK

One of the common methods for determining the constants of a network for representation of wave-guide discontinuities utilizes the measurement of input admittances Y_{i1}, Y_{i2}, Y_{i3}, corresponding to known load admittances Y_{L1}, Y_{L2}, Y_{L3}. The admittance parameters for the network may then be calculated from the equations

$$Y_{11}=\frac{(Y_{i1}-Y_{i3})(Y_{i1}Y_{L1}-Y_{i2}Y_{L2})-(Y_{i1}-Y_{i2})(Y_{i1}Y_{L1}-Y_{i3}Y_{L3})}{(Y_{i1}-Y_{i3})(Y_{L1}-Y_{L2})-(Y_{i1}-Y_{i2})(Y_{L1}-Y_{L3})} \tag{17}$$

$$Y_{22}=\frac{(Y_{i1}Y_{L1}-Y_{i2}Y_{L2})-Y_{11}(Y_{L1}-Y_{L2})}{Y_{i2}-Y_{i1}} \tag{18}$$

$$Y_{12}^2=(Y_{11}-Y_{ik})(Y_{22}+Y_{Lk}),\quad k=1,2,3. \tag{19}$$

The known load admittances are often obtained by placing shorts on the output guide, and the input admittances measured by determining the standing wave ratio and position of a voltage node on the input guide. If losses in the system are negligible, the admittances are pure susceptances, and all Y's may be replaced by the corresponding B's (where $Y=jB$) in Eqs. (17)–(19).

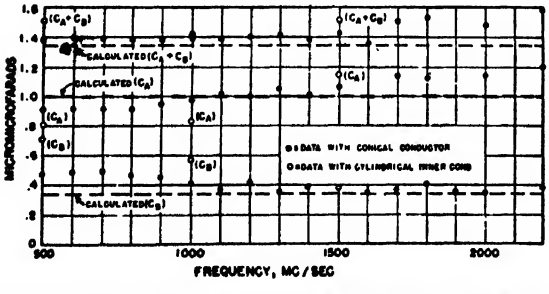

FIG. 11. Comparison of calculated and measured results for capacitances of the input network.

A similar procedure was followed in the experimental determination of the network for representation of the antenna input region in the present investigation. To produce known terminating susceptances at the reference radius r_1 chosen as the output reference of the network, hemispherical shorts to the spherical TEM mode were placed at a radius $r_2>r_1$, as indicated in Fig. 10. The positions of the current maxima on an input coaxial line were observed, giving the corresponding susceptances at the input reference. This procedure was repeated at each frequency with four different hemispherical shorts of nominal diameters 6, 9, 12, and 15 inches, the fourth pair of input-output data providing a check on the three pairs required for the calculation. Most of the measurements were made with

the inner conductor flared conically between r_1 and r_2 in order that a true spherical TEM mode might exist in this region and B_L might be computed in terms of the short position by uniform transmission line equations. It is true that this introduces a discontinuity not present on the antennas themselves, but it is believed that the effect will be small because of the smallness of the flare required. A few measurements were made for a check with the input conductor maintained cylindrical, but in these the data had to be reduced by the longer non-uniform line calculations. The test set-up for all measurements is as indicated in Fig. 10.

The admittance produced at r_1 by the length of shorted spherical TEM mode is

$$Y_L = jB_L = -j\left[\frac{1}{60 \ln \cot(\psi/2)}\right] \cot\frac{2\pi}{\lambda}(r_2 - r_1), \quad (20)$$

ψ = the cone angle, measured from the axis.

Once the admittance parameters are calculated from three pairs of input-output data by Eqs. (17)–(19), the elements of the pi-network may be found from the equations

$$\omega C_a = B_{11} - B_{12}, \quad (21)$$

$$\omega C_b = B_{22} - B_{12}, \quad (22)$$

$$\omega L = -1/B_{12}. \quad (23)$$

It has been mentioned that four hemispheres were constructed to give an additional pair of input-output data for a check, and that some check points were taken with the cylindrical inner conductors. The consistency check for the extra data was made by means of a graphical construction described by Weissfloch[10] (reactive transformation diagram). The three pairs required for the calculation from Eqs. (17)–(19) were selected as those having the greatest difference in admittance values, once unreliable points had been eliminated by the Weissfloch diagram.

The results for C_a and C_b (and for C_a+C_b) are shown in Fig. 11 compared with the dashed line showing the calculated result of Eqs. (15), (16). The comparison for the inductance L is shown in Fig. 12. Although agreement is not perfect, it is believed sufficient to check the principle used. Aside from the fact that the method of calculation was an approximate one, much of the difference is believed to be caused by the fact that the hemispheres could not be spun perfectly, so that they were more nearly spheroids with major and minor half-axes differing by as much as one-fourth inch. Uncertainty in reading the plunger position, although only of the order 0.1 mm, could also explain some of the deviation. A study of the equations revealed that the 0.1 mm deviation could account for as much as a three percent error in the elements of the circuit.

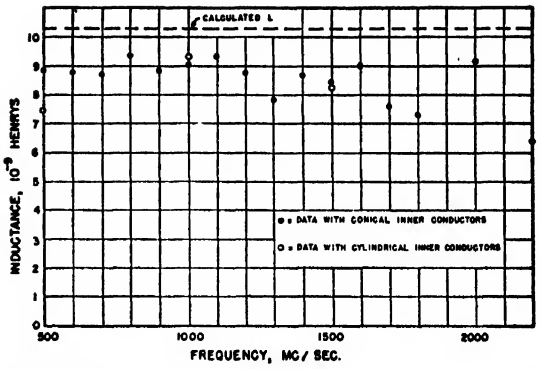

FIG. 12. Comparison of calculated and measured results for inductance of the input network.

NON-UNIFORM LINE REPRESENTATION OF THE ANTENNA

Schelkunoff's analysis of thin antennas of other than conical shape utilizes a perturbation solution which may be interpreted in terms of transformation of impedances along a non-uniform transmission system, as described earlier. As is shown in Appendix B, the Carson-Schelkunoff perturbation solution for slightly non-uniform lines may be described by stating a "perturbation" network to be connected at the input of the corresponding uniform line of average characteristic impedance and propagation constant. The $\mathfrak{A}\mathfrak{B}\mathfrak{C}\mathfrak{D}$ constants of the perturbation network are given in Eqs. (47) and (45) of Appendix B. For the antenna problem, each element of the antenna is represented by a section of the uniform spherical TEM mode, so the special forms of Eqs. (48)–(49) for a loss-free system with constant LC product at each reference on the system are applicable.

$$\mathfrak{A}_1(l) = 1 - \frac{M(l)}{K_0} \quad (24)$$

$$\mathfrak{B}_1(l) = -jN(l) \quad (25)$$

$$\mathfrak{C}_1(l) = j\frac{N(l)}{K_0^2} \quad (26)$$

$$\mathfrak{D}_1(l) = 1 + \frac{M(l)}{K_0}, \quad (27)$$

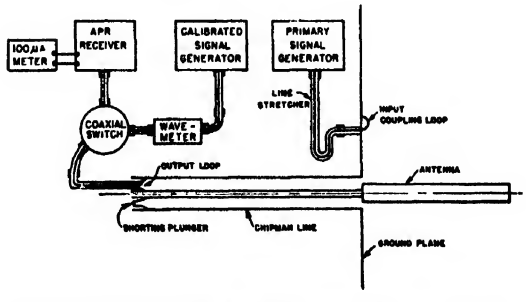

FIG. 13. Set-up for antenna impedance measurements.

where

$$M(l)=\beta\int_0^l [K_0-K(z)]\sin 2\beta z dz \tag{28}$$

$$N(l)=\beta\int_0^l [K_0-K(z)]\cos 2\beta z dz \tag{29}$$

$K(z)$ = the local characteristic impedance for a given reference z

$$K_0=\frac{1}{l}\int_0^l K(z)dz \tag{30}$$

β = phase constant, $\omega(LC)^{\frac{1}{2}}$.

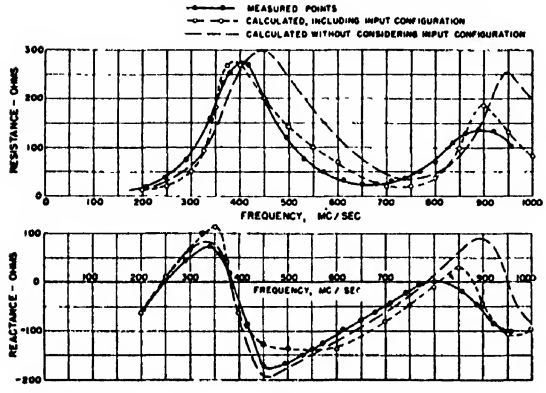

FIG. 14. Input impedance of cylindrical antenna.

For the cylindrical antenna, the equations for M, N, and K_0 given by Schelkunoff[11] must be modified slightly since it is desired to begin the nonuniform line not at the origin, but at a finite radius r_1. Thus

$$z\cong r-r_1.$$

Eq. (1) for the local characteristic impedance $K(z)$, approximated from that for the spherical TEM mode for this radius, becomes

$$K(z)\cong 60\ln\left[\frac{2r}{\rho(r)}\right]=60\ln\left[\frac{2(r_1+z)}{a}\right]. \tag{31}$$

Substitution of this value in Eqs. (28)–(30) yields

$$K_0=60\left[\frac{r_2}{l}\ln\frac{2r_2}{a}-\frac{r_1}{l}\ln\frac{2r_1}{a}-1\right] \tag{32}$$

$$M(l)=30\left\{\ln\frac{r_2}{r_1}+(1-\cos 2\beta l)\left[\frac{r_1}{l}\ln\frac{r_2}{r_1}-1\right]-\cos 2\beta r_1[Ci2\beta r_2-Ci2\beta r_1]-\sin 2\beta r_1[Si2\beta r_2-Si2\beta r_1]\right\} \tag{33}$$

$$N(l)=30\left\{\sin 2\beta l\left[\frac{r_1}{l}\ln\frac{r_2}{r_1}-1\right]+\cos 2\beta r_1[Si2\beta r_2-Si2\beta r_1]-\sin 2\beta r_1[Ci2\beta r_2-Ci2\beta r_1]\right\}. \tag{34}$$

For the pointed antenna of Fig. 6C, one transformation set may be obtained for the entire region from r_3 to r_1, or the problem may be broken into two cascaded non-uniform lines, separated at the beginning of the taper, $r=r_2$. Calculations were made both ways without much difference in the results, so the results will be given here only for the over-all antenna as a unit. The local characteristic impedance is

$$K(z)=\begin{cases}60\ln\left[\dfrac{2(r_1+z)}{a}\right] & r_1<z<r_2\\[2ex] 60\ln\left[\dfrac{2(r_1+z)l_2}{a(l-z)}\right] & r_2<z<r_3\end{cases}. \tag{35}$$

Substitution of this in Eqs. (28)–(30) yields

$$K_0=60\left[\frac{r_3}{l}\ln\frac{2r_3}{a}-\frac{r_1}{l}\ln\frac{2r_1}{a}-\frac{l_1}{l}\right] \tag{36}$$

$$M(l)=[M(l)]_{cyl}+30\left[\frac{l_2}{l}(1-\cos 2\beta l)+\cos 2\beta l S_1(2\beta l_2)-\sin 2\beta l Si(2\beta l_2)\right] \tag{37}$$

$$N(l)=[N(l)]_{cyl}+30\left\{\sin 2\beta l\left[\frac{l_2}{l}-S_1(2\beta l_2)\right]-\cos 2\beta l Si(2\beta l_2)\right\}, \tag{38}$$

where $[M(l)]_{cyl}$ and $[N(l)]_{cyl}$ denote the M and N for a cylinder extending from r_1 to r_3, computed from Eqs. (33) and (34) with r_3 substituted for r_2. $S_1(x)$ is the function tabulated by Terman,[12] equal to

$$\ln x+0.5772-Ci(x).$$

THE TERMINATING ADMITTANCE

The radiation admittance at the end of the antenna, representing the effect of TM modes inside and outside the antenna region on the TEM mode equivalent circuit, may be taken from Schelkunoff's approximate formulas.[13] For a monopole, they are

$$Y_R=\frac{R_a(\beta r_2)+jX_a(\beta r_2)}{K_0^2}, \tag{39}$$

[11] S. A. Schelkunoff, *Electromagnetic Waves* (D. Van Nostrand Company, Inc., New York, 1943), p. 291.

[12] F. E. Terman, *Radio Engineers Handbook* (McGraw-Hill Book Company, Inc., New York, 1943), p. 17.

[13] See reference 11, pp. 465 and 453.

where

$$R_a(\beta r_2)=15\{2S_1(2\beta r_2)+\cos 2\beta r_2 \times[C+\ln\beta r_2-2Ci2\beta r_2+Ci4\beta r_2] +\sin 2\beta r_2[Si4\beta r_2-2Si2\beta r_2]\} \quad (40)$$

$$X_a(\beta r_2)=15\{2Si(2\beta r_2)+\sin 2\beta r_2 \times[Ci4\beta r_2-\ln\beta r_2-C]-\cos 2\beta r_2 Si4\beta r_2\}. \quad (41)$$

$$C=0.5772.$$

The approximations referred to in the development of the above limit results to relatively thin antennas. Schelkunoff has mentioned a lower limit for K_0 of around 500 ohms (for a dipole antenna) in order for the results to be applicable. The antennas studied in this report are very close to this limit.

There is also a question of a possible added admittance at the end to account for the caps or other end effect.[14] It was believed that the theory of this end effect is insufficiently understood to justify its inclusion in the calculation. The experimental results actually showed no measurable difference between the capped antenna of Fig. 6b and the open-ended antenna of Fig. 6a—a result checking similar experiments by Brown and Woodward.[1] Of course this might mean only that the two antennas had similar end effects, and not that the end effect for either is negligible. The

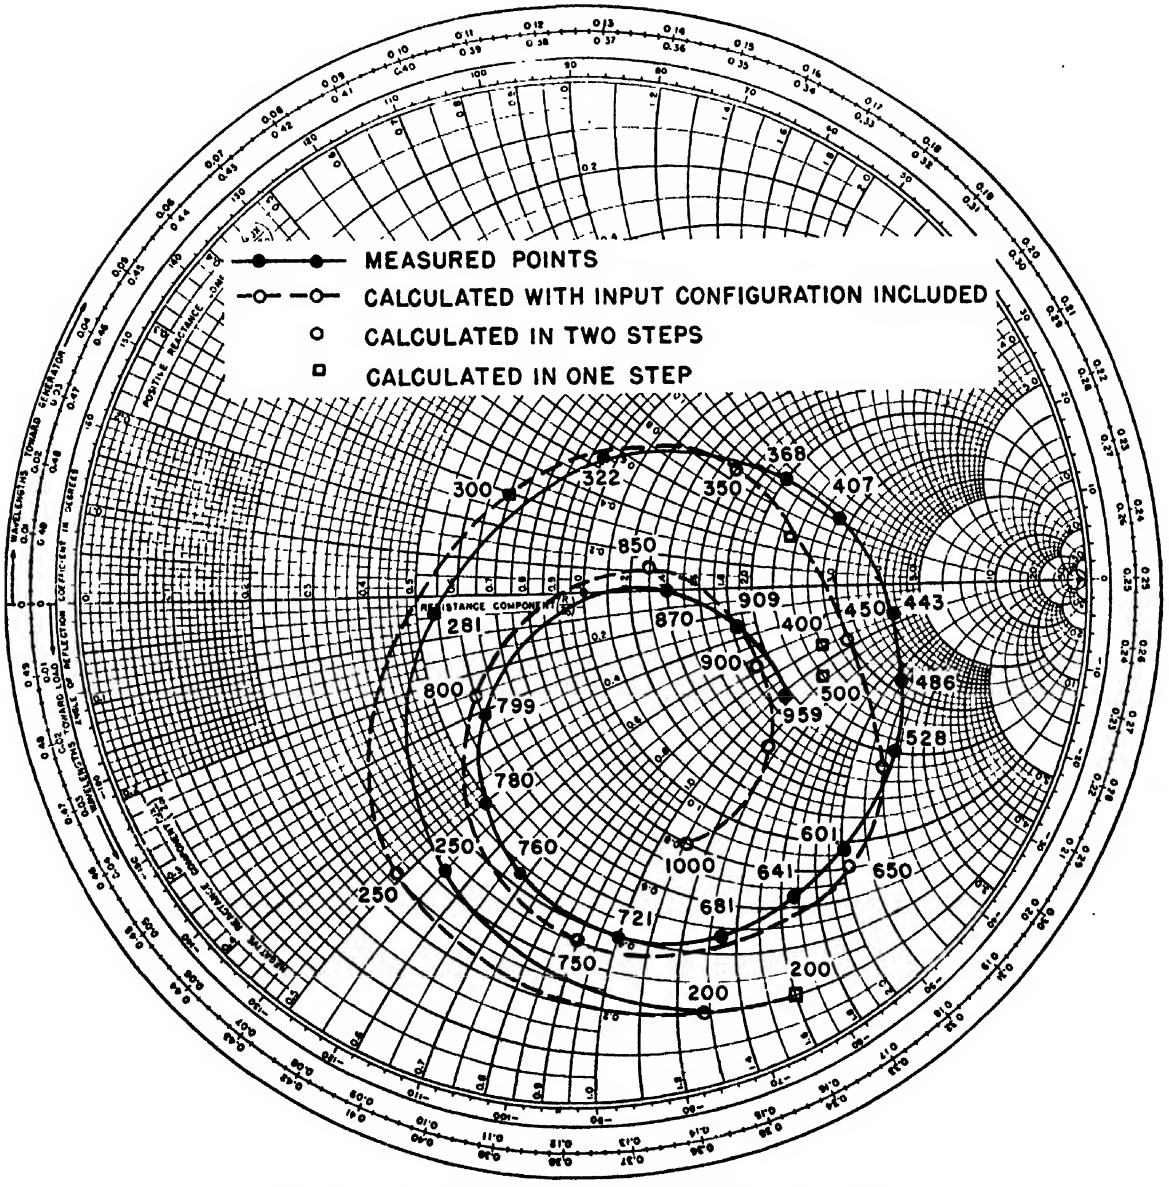

FIG. 15. Input impedance of pointed antenna referred to 66-ohm line.

[14] See reference 11, p. 465.

pointed antenna was chosen to minimize this end effect, but, since it represents a more non-uniform transmission system, the error in that stage of the analysis may be greater so that the net improvement is doubtful.

CALCULATED AND MEASURED IMPEDANCES FOR THE OVER-ALL ANTENNA

All parts of the equivalent circuit of Fig. 5 have now been described so that a calculation of the input impedance referred to the end of the antenna may be accomplished by straightforward, though lengthy, network and transmission line calculations.

The input impedance curves for the antennas sketched in Fig. 6 were measured over the range 200 to 1000 mc/sec. for comparison with the calculated values. The general set-up for the measurement is indicated in Fig. 13. The monopoles were extended horizontally from the side of a building on which there was a vertical ground plane consisting of a three-foot-square copper sheet set into a 20-foot-square section of one-fourth inch galvanized mesh. Each antenna was screwed into the one-fourth inch diameter inner conductor of the 66-ohm coaxial Chipman line.[15] Signal generator power was supplied to a semicircular loop, two inches in diameter, approximately one foot from the antenna. Received power was taken from a small loop (approximately a $\frac{1}{16}$-inch diameter semicircle) in the shorting plunger of the line by cable to an APR receiver with external meter used as a detector. The standing wave ratio (ratio of maximum current to minimum current as the shorting plunger is moved) was found by several methods, all of them utilizing comparison with an auxiliary signal generator having a calibrated attenuator. Position of the maximum current reference was also observed so that each point could be plotted directly on a Smith transmission line chart, and then translated to total impedance or admittance if desired.

Since no measurable difference was observed between the results for the capped and open-ended cylinders, only one comparison curve is shown for the cylindrical antennas. Figure 14 shows the measured curves of resistance and reactance *versus* frequency, compared with calculated values utilizing the methods of this paper, and also with curves calculated without consideration of the input configuration. These latter calculations simply extend the non uniform line to $r=0$, as explained in the discussion of Fig. 2. The comparison of calculated and measured results for the pointed antenna is shown directly in Smith chart form in Fig. 15.

In comparing the calculated and measured curves, it is concluded that the agreement, although not perfect, is greatly improved by the consideration of the input configuration. This is true for both the cylindrical and the pointed antennas. It is believed that much of the remaining disagreement is caused by the relatively large diameter-to-length ratios of the antennas used, which make certain aspects of the thin antenna theory used subject to error. The end effect at the outer end of the antenna is also an unknown and may be important. Of course there are also possible sources of error in the measurement procedure. Among these are the finite extent and conductivity of the ground plane, the presence of reflections from nearby buildings, the finite conductivity of the measurement line, the finite size of the coupling loops, and random instabilities occasionally present in the signal generators.

STUDIES WITH VARIOUS INPUT CONFIGURATIONS

The study described has utilized a given input configuration and different antennas. G. W. Zeoli[16] has recently applied the approach of this paper to the study of given antennas with different input configurations. Two different input configurations were used for a $\frac{1}{2}$-inch-diameter antenna 11 inches long, and two for a $\frac{1}{4}$-inch-diameter antenna 11 inches long. There was a considerable difference between the measured results for a given antenna with the different input configurations, and the amount of this difference was predicted reasonably well by the theoretical calculations. This in some ways gives a more satisfying check of the principles introduced here than the measurements cited in the preceding section. The agreement in Zeoli's results was best for the thin antennas, checking our belief that some of the deviations in Fig. 15 arise from the application of thin antenna theory to antennas which are on the borderline of its applicability.

Work has also been reported in the literature by King and co-workers[17, 18] on antennas fed by parallel-wire lines. A terminal zone is defined there also, and, although the method of attack is somewhat different from that of this paper, equivalent networks are obtained by averaging processes for representation of the terminal zone.

APPENDIX A. A QUASI-STATIC METHOD FOR OBTAINING EQUIVALENT CIRCUITS

It is assumed that the electric field distribution is represented well enough by that obtained from a static field map, and the region to be studied is divided by the flux tube boundaries into equal flux divisions, as indicated in Fig. 8. A capacitance C_n (equal for all subdivisions) and an inductance L_n (computed from Eq. (10) for axially symmetric regions) may be found. If the subdivision is represented by a symmetrical T equivalent circuit, the $\mathfrak{A}\mathfrak{B}\mathfrak{C}\mathfrak{D}$ constants are

$$\mathfrak{A}_n = \left(1 - \frac{\omega^2}{2\omega_n^2}\right)$$

[15] R. A. Chipman, J. App. Phys. 10, 27–38 (1939).

[16] G. W. Zeoli, "Impedance of antennas with various input configurations," Report No. 157, Contract NObsr-39401, Antenna Laboratory, University of California, August 22, 1949.

[17] R. King, J. App. Phys. 20, 832 (1949).

[18] R. King and K. Tomiyasu, Proc. I.R.E. 37, 1134 (1949).

$$\mathfrak{B}_n = j\omega L_n\left(1-\frac{\omega^2}{4\omega_n^2}\right)$$

$$\mathfrak{C}_n = j\omega C_n$$

$$\mathfrak{D}_n = 1-\frac{\omega^2}{2\omega_n^2},$$

where

$$\omega_n^2 = \omega^2 L_n C_n.$$

The N subdivisions are now cascaded and the overall $\mathfrak{ABCD}$ constants obtained by multiplying the individual matrices together. Multiplying from the right, the product of the last two matrices is taken, neglecting powers of (ω/ω_n) higher than the second.

$$\mathfrak{A}_{N-1,N} = 1-\frac{\omega^2 C_n}{2}(L_N+3L_{N-1})$$

$$\mathfrak{B}_{N-1,N} = j\omega(L_N+L_{N-1})$$

$$\mathfrak{C}_{N-1,N} = 2j\omega C_n$$

$$\mathfrak{D}_{N-1,N} = 1-\frac{\omega^2 C_n}{2}(3L_N+L_{N-1}).$$

Repetition of this process with the succeeding adjacent matrices reveals the law of formation, as follows:

$$\left.\begin{aligned}
\mathfrak{A} &= 1-\frac{\omega^2 C_n}{2}\sum_{k=1}^{N} L_k[2(N-k)+1]\\
\mathfrak{B} &= j\omega\sum_{k=1}^{N} L_k\\
\mathfrak{C} &= NC_n\\
\mathfrak{D} &= 1-\frac{\omega^2 C_n}{2}\sum_{k=1}^{N}(2k-1)L_k.
\end{aligned}\right\} \tag{42}$$

The above may be shown to be the constants for a pi-network as shown in Fig. 9 with L, C_a, and C_b given by Eqs. (5) and (7). The same formulas are applicable to a two-dimensional region, except that the formulas for inductance of the subdivisions (10) must be modified.

APPENDIX B. NETWORK FORMULATION OF NON-UNIFORM LINE THEORY

For a slightly non-uniform transmission system with local impedance per unit length given as $Z(z)=Z_0+\hat{Z}(z)$, and the local admittance per unit length given as $Y(z)=Y_0+\hat{Y}(z)$, Schelkunoff[19] has given the zero-order solution in his Eqs. (11-7), and the first-order solution, obtained by a perturbation calculation, in Eqs. (12-1). The zero- and first-order solutions may be added and put in matrix form as follows:

$$\begin{bmatrix} V(0)\\ I(0)\end{bmatrix} = \begin{bmatrix} \mathfrak{A}(l) & \mathfrak{B}(l)\\ \mathfrak{C}(l) & \mathfrak{D}(l)\end{bmatrix}\begin{bmatrix} V(l)\\ I(l)\end{bmatrix}, \tag{43}$$

where

$$\left.\begin{aligned}
\mathfrak{A}(l) &= [1-F_2(l)]\cosh\gamma_0 l + [F_1(l)+F_3(l)]\sinh\gamma_0 l\\
\mathfrak{B}(l) &= K_0\{[1-F_2(l)]\sinh\gamma_0 l + [F_1(l)+F_3(l)]\cosh\gamma_0 l\}\\
\mathfrak{C}(l) &= \frac{1}{K_0}\{[F_3(l)-F_1(l)]\cosh\gamma_0 l + [1+F_2(l)]\sinh\gamma_0 l\}\\
\mathfrak{D}(l) &= [1+F_2(l)]\cosh\gamma_0 l + [F_3(l)-F_1(l)]\sinh\gamma_0 l
\end{aligned}\right\} \tag{44}$$

$$\left.\begin{aligned}
F_1(l) &= \frac{1}{2}\int_0^l\left[\frac{\hat{Z}(z)}{K_0}-K_0\hat{Y}(z)\right]\cosh 2\gamma_0 z\,dz\\
F_2(l) &= \frac{1}{2}\int_0^l\left[\frac{\hat{Z}(z)}{K_0}-K_0\hat{Y}(z)\right]\sinh 2\gamma_0 z\,dz\\
F_3(l) &= \frac{1}{2}\int_0^l\left[\frac{\hat{Z}(z)}{K_0}+K_0\hat{Y}(z)\right]dz.
\end{aligned}\right\} \tag{45}$$

K_0 and γ_0 are the average characteristic impedance and propagation constant, respectively.

The matrix of Eq. (43) defined by (44), may be recognized as the product of two matrices.

$$\begin{bmatrix} \mathfrak{A}(l) & \mathfrak{B}(l)\\ \mathfrak{C}(l) & \mathfrak{D}(l)\end{bmatrix} = \begin{bmatrix} \mathfrak{A}_1(l) & \mathfrak{B}_1(l)\\ \mathfrak{C}_1(l) & \mathfrak{D}_1(l)\end{bmatrix} \times \begin{bmatrix} \cosh\gamma_0 l & K_0\sinh\gamma_0 l\\ \frac{1}{K_0}\sinh\gamma_0 l & \cosh\gamma_0 l\end{bmatrix}, \tag{46}$$

where

$$\left.\begin{aligned}
\mathfrak{A}_1(l) &= 1-F_2(l)\\
\mathfrak{B}_1(l) &= K_0[F_1(l)+F_3(l)]\\
\mathfrak{C}_1(l) &= \frac{1}{K_0}[F_3(l)-F_1(l)]\\
\mathfrak{D}_1(l) &= 1+F_2(l).
\end{aligned}\right\} \tag{47}$$

[19] See reference 11, Sections 7.11 and 7.12.

Thus the over-all transformation network for the non-uniform line may be broken into a section of uniform line of characteristic impedance K_0 and propagation constant γ_0, with a transforming network with constants given by Eqs. (47) in cascade with its input.

The non-uniform systems met with in this study are specialized in that they are loss free, and also have a constant LC product for each point along the line. The following may then be shown:

$$\frac{\hat{Z}}{K_0}+K_0\hat{Y}=0$$

$$\frac{\hat{Z}}{K_0}-K_0\hat{Y}=2j\omega(L_0C_0)^{\frac{1}{2}}\left[\frac{K(z)}{K_0}-1\right].$$

Substitution of these relations in Eqs. (61) gives

$$F_1(l)=\frac{N(l)}{jK_0}$$
$$F_2(l)=\frac{M(l)}{K_0} \qquad (48)$$
$$F_3(l)=0,$$

where

$$M(l)=\beta\int_0^l[K_0-K(z)]\sin 2\beta z dz$$
$$N(l)=\beta\int_0^l[K_0-K(z)]\cos 2\beta z dz. \qquad (49)$$

The $\mathfrak{A}_1$, $\mathfrak{B}_1$, $\mathfrak{C}_1$, $\mathfrak{D}_1$, constants of Eqs. (47) then become as given in the main body of the paper, Eqs. (24)–(27).

Microwave Techniques for the Measurement of the Dielectric Constant of Fibers and Films of High Polymers

T. M. Shaw and J. J. Windle
Western Regional Research Laboratory, Albany, California*
(Received March 27, 1950)

A resonant cavity method is described for the determination of the dielectric constant of polymeric solids in the form of fibers, films, and thin cylinders. Methods for investigating electrical anisotropy are outlined. In the case of fibers, for the electric field parallel to the fiber axis, the dielectric constant is determined directly. For the electric field perpendicular to the fiber axis, the problem arises of calculating the dielectric constant of the fiber from that of an air-fiber mixture. For the latter purpose the Lichtenecker equation was found to be applicable. Illustrative measurements of the dielectric constant of wool, Nylon, and Cellophane are presented and discussed briefly.

INTRODUCTION

THE development of sources of microwave energy has made possible the extension of dielectric-constant studies on solid polymers to frequencies in the region 3000 to 30,000 Mc (1 Mc$=10^6$ cycles per second) or more where new facts concerning the structure of polymers are to be expected. The keratins represent a group of polymers for which dielectric studies in the microwave range should be especially informative. Dielectric constants for wool keratin[1] and for horn keratin[2] have been reported for frequencies between about 500 c.p.s. and 13 Mc. At 13 Mc the dielectric constant was found to be 4.2. This value is considerably greater than the square of the index of refraction for visible light ($\sim$2.25) and has been interpreted as an indication of atomic or ionic polarization.[1] This should lead to a large variation in the dielectric constant with frequency in the microwave region. In order to investigate this possibility, suitable methods were sought for making dielectric constant measurements on the keratins in the microwave region.

Since the keratins of greatest interest are available only in limited forms, for example wool fibers, the generally used cavity resonator[3] and wave-guide procedures,[4,5] which employ relatively large accurately machined specimens, are not directly applicable. For this reason a modified cavity resonator technique has been developed for use with dielectric specimens in the form of fibers, films, and thin cylinders. The procedures and apparatus are described in the present paper. They have been used exclusively in the 3000-Mc frequency region but appear to be suitable for use at higher frequencies with only minor modifications.

THEORY

Figure 1 represents a cavity resonator. The cavity is circular in cross section and is closed with plane parallel ends perpendicular to the axis of the cylinder. As is well known, when a cavity is excited to resonance at the frequency f_0, in the fundamental or TM_{010} mode, the electric field in the cavity is directed parallel to the cylinder axis. The electric field possesses a single maximum at the axis and falls to essentially zero at the cylinder wall.

The usefulness of such a resonator for dielectric constant measurements derives from the fact that when a dielectric specimen is placed in the cavity the resonance frequency is changed; such change in frequency can be related quantitatively to the dielectric properties of the specimen.

The theory of the use of the resonator for the case of a smooth circular cylinder low loss[6] dielectric specimen placed along the cavity axis is well known.[3] For a specimen so small in diameter that insertion of the specimen in the cavity results in a negligible change in the electric and magnetic field distribution, the resonant frequency is given by the equation,

$$f=f_0-(\epsilon-1)f_0b^2/0.539a^2. \qquad (1)$$

In this equation f is the frequency of the resonator containing the dielectric specimen, f_0 is the frequency of the empty resonator, ϵ is the dielectric constant of the specimen, b is the radius of the dielectric cylinder, and a is the radius of the cavity resonator.

The frequency change (f_0-f) to be expected when a single wool fiber of a length equal to that of the cavity is used as a dielectric specimen is easily obtained by means of Eq. (1). Assuming as typical values, $\epsilon\sim4$, $b\sim10^{-3}$ cm, $a=4.5$ cm, $f_0=3000$ Mc, it is found that $(f_0-f)\sim0.001$ Mc. Although this small frequency change can be detected readily with standard microwave equipment, it is too small for accurate measurement purposes. Since changes in the temperature of the cavity and in the humidity of the air in the cavity can produce relatively large frequency changes it is necessary to work with specimens consisting of several thousand fibers. In this way only moderately constant temperature and humidity are required.[7]

A cylindrical bundle containing several thousand wool fibers is about 0.15 cm in radius. The theoretical calculations of Horner and co-workers[3] show that if Eq. (1) is applied to a cylinder of dielectric of about this size and with a dielectric constant of six or less, the frequency change will be accurate to within one percent. This is true because for a cylinder of dielectric of this diameter the variation of the intensity of the electric field across the cylinder cross section is negligible.

For convenience in calculations Eq. (1) may be expressed in terms of the volume of the dielectric specimen and the volume of the cavity resonator by replacing b^2 by its equivalent $v_s/\pi l$ and a^2 by its equivalent $v_c/\pi l$. The resultant equation is

$$f=f_0-(\epsilon-1)f_0v_s/0.539v_c. \qquad (1a)$$

In this equation it is understood of course that the volume v_s is that of a specimen extending the entire length of the cavity.

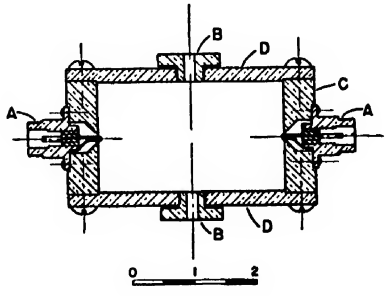

FIG. 1. Cross-sectional view of cylindrical cavity resonator. *A*, Type *N* cable connectors; *B*, plugs to permit specimen to be inserted along axis of resonator; *C*, cylinder wall, *D*, end plates perpendicular to cylinder axis.

Equation (1) and thus also (1a) was derived for a dielectric specimen consisting of a single circular cylinder. Since a bundle of fibers only approximates a circular cylinder in shape, tests were made to determine whether errors were introduced by applying Eq. (1a) to a specimen composed of a number of circular cylinders. Glass was chosen as a convenient test material rather than a polymer since it was desired to avoid possible effects due to anisotropy and to water absorption. Single glass cylindrical rods were prepared with radii ranging from about 0.02 to 0.05 cm. These rods were inserted in the cavity individually and in groups and the frequency change (f_0-f) determined. The results are shown in Table I. Constancy of the ratio $(f_0-f)/b^2$ shows that the frequency change (f_0-f) is a linear function of the volume of glass contained in a specimen irrespective of whether the glass is in the form of a single rod or a group of rods. Calculations showed that the external radius of the largest bundle of rods considered was within the limit for the size of a single cylinder set by Horner[3] if an accuracy of one percent or better is to be expected. Table I also shows that dielectric constants calculated from the various measurements are in good agreement. The statistical error (standard deviation) is slightly less than one percent which, considering the approximations made in the derivation, is all that can be expected from Eq. (1a) for specimens of this size and dielectric constant.

These results demonstrate that the exact form of the

[6] The equations given below apply strictly only to a hypothetical dielectric with a zero loss tangent, i.e., $\tan\delta=0$. Their application to the materials considered in the present paper is justified because $\tan\delta$ does not exceed 0.05 and only a negligible error is introduced. For a complete discussion see reference 5, p. 568.

[7] For the particular 3000-Mc cavity resonator used a one-degree rise in temperature produces a decrease in the resonant frequency of 0.058 Mc. A change in relative humidity from 25 percent to 50 percent will cause a frequency decrease of about 0.03 Mc.

boundary of the dielectric specimen is not important provided the specimen is confined to a region where the electric field is essentially constant as discussed above. Since the shape of the specimen is not important, it was assumed and subsequently verified with Teflon films and rods that the dielectric specimen may have any of the forms *A*, *B*, *C*, *E*, or *F* of Fig. 2 provided only that the specimen is continuous over the entire length of the cavity resonator and be composed of elements of solid the boundaries of which are tangential to the electric field. For all such specimens Eq. (1a) can be used to calculate the dielectric constant. The volume of the specimen is conveniently and accurately determined from its mass and density. This procedure is especially convenient for fiber specimens where the small size and large number of the fibers in a specimen makes accurate measurements of the fiber volume very difficult.

TABLE I. Summary of measurements of dielectric constant of Pyrex glass (No. 7740) rods.

Specimen numbers	Square of radius of rod b^2	Change in frequency (f_0-f)	$(f_0-f)/b^2$	Dielectric constant
	$(cm)^2$	Mc		
1	27.10×10^{-4}	3.82	1.410×10^3	4.66
2	26.80	3.83	1.430	4.70
3	22.40	3.18	1.420	4.68

Specimens of type *E* are of interest when it is desired to investigate the electrical anisotropy in polymer films.[8] The general treatment of *E* has been discussed. It remains only to remark that by rolling the film into a thin cylinder with the selected direction in the film parallel to the axis of the cylinder it is possible to determine the dielectric constant of the film with the electric field parallel to the direction chosen. By rolling the film into cylinders with the axis in other directions anisotropy can be investigated.

The type of specimen represented by *D* of Fig. 2 is perhaps the most important that must be considered. A solenoidal specimen of fibers of this type is used to determine the dielectric constant of the fibers with the electric field perpendicular to the fiber axis. Such measurements when combined with those on parallel bundles of fibers may be used to investigate the electrical anisotropy of fibers.[8]

A solenoidal specimen is obtained by winding fibers in the form of a helix with very small pitch about a central core. The core is made from a material of low dielectric constant and dielectric loss in order to minimize the correction to the frequency change to be made for the core. Polystyrene is satisfactory from this viewpoint but it is not satisfactory when it is necessary to heat the fibers such as is required in some instances to remove absorbed water. It was because of the latter limitation that quartz was usually used in the present work.

The dielectric constant which results when Eq. (1a) is applied to a solenoidal specimen is that of an *air-solid* mixture. The volume of the specimen v_s used in Eq. (1a) is calculated from the external diameters of the solenoid and its core and the length of the solenoid. The length is, of course, the same as that of the resonator. From these measurements the dielectric constant of the air-solid mixture (fibers plus air) is calculated. The justification for this procedure lies in the fact that the mixture of fibers and air occupies an essentially uniform electric field and the frequency changes due to the core and to the fiber-air mixture are additive.

To deduce the dielectric constant of the solid material (fibers) from that of the air-fiber mixture recourse must be had to a mixture law. For this purpose consideration has been given to only the equations of Lorentz[9] and of Lichtenecker,[10] for dielectric mixtures. For a two-component system the Lorentz equation is

$$(\epsilon_m-1)/(\epsilon_m+2)=v_f(\epsilon_\perp-1)/(\epsilon_\perp+2)+v_a(\epsilon_a-1)/(\epsilon_a+2). \quad (2)$$

In this equation ϵ_m is the dielectric constant of the air-fiber mixture, $\epsilon_\perp$ is the dielectric constant of the fiber substance measured with the electric field directed perpendicular to the fiber axis, ϵ_a is the dielectric constant of air and v_f and v_a are, respectively, the volume of the fiber substance and of air in 1 cc of the fiber-air mixture.

Similarly, for a two-component mixture the Lichtenecker equation may be written,

$$\log\epsilon_m=v_f\log\epsilon_\perp+v_a\log\epsilon_a, \quad (3)$$

and the symbols have the same meanings stated for Eq. (2).

Owing to the well-recognized theoretical limitations of mixture equations for dielectrics it was desired to ascertain only on a purely empirical basis whether one of these equations would give satisfactory values for $\epsilon_\perp$. The validity of the equations was tested by comparing the value of $\epsilon_{||}$ determined for glass fibers with $\epsilon_\perp$ for the same fibers as calculated by means of the mixture equa-

[8] A preliminary discussion of methods for measurement of electrical anisotropy in polymers at microwave frequencies was presented by the authors at the Seattle meeting of the American Physical Society, June 27–29, 1949; T. M. Shaw and J. J. Windle, Phys. Rev. 76, 586 (1949).

tions from measurements performed on solenoidal specimens. For glass fibers $\epsilon_{\parallel}$ should equal $\epsilon_{\perp}$ since well-annealed glass is isotropic. Table II summarizes the experimental data and calculations for a number of specimens of glass fibers. The table shows that the mean value of $\epsilon_{\perp}$ calculated with the aid of the Lichtenecker equation agrees with $\epsilon_{\parallel}$ within about two percent. This is considered to be satisfactory because of the likelihood of errors which can arise in the measurement of the external diameter of the solenoid. An error of one percent in diameter of the solenoid can cause an error of about two percent in $\epsilon_{\perp}$. It is significant in this regard that a low value of $\epsilon_{\perp}$ is to be associated with a low value in the diameter of the solenoid. This is the most likely direction for error since it is not possible to define exactly the outer boundary of the air-fiber mixture.

The values of $\epsilon_{\perp}$ obtained by means of Eq. (3) are higher than $\epsilon_{\parallel}$ by about 7 percent. Because the disagreement between $\epsilon_{\parallel}$ and $\epsilon_{\perp}$ obtained with the Lichtenecker equation is no greater than the experimental error it was adopted as satisfactory for calculating the dielectric constant of the fibers from measurements on an air-fiber mixture in the form of a solenoid. The table also shows that ϵ_m for the air-fiber mixture as well as $\epsilon_{\perp}$ is independent of the size of the solenoidal specimen. This constitutes further experimental proof that the electric field is essentially uniform over the cross section occupied by the solenoidal dielectric specimens.

EXPERIMENTAL

A cross-sectional view of the cavity resonator is shown in Fig. 1. The cavity dimensions are almost identical with those for a similar cavity described by Horner.[3] The present cavity was equipped with standard type *N* coaxial cable connectors which terminate in small coupling loops. These loops are inserted into the cavity through holes in the cylinder wall. The plane ends of the cavity are equipped with removable plugs in order to insert dielectric specimens. For non-hygroscopic specimens the removable plugs are simply drilled with holes large enough to accommodate the specimen. The effect of the holes and the specimen contained within them on the resonant frequency of the cavity is very small.[11] For hygroscopic specimens the removable plugs are designed to hold the specimen in place in the cavity and to allow the cavity to be evacuated.

When the cavity was used at temperatures other than room temperature a correction was made for the change in resonant frequency caused by expansion or contraction of the cavity. The correction required was determined experimentally to be 0.058 Mc per degree C by measuring the resonant frequency of the cavity over the temperature range 0 to 100°C.

A block diagram of the microwave equipment used to determine the frequency of the resonant cavity is shown in Fig. 3. The klystron oscillator is frequency modulated

by means of a saw-tooth wave derived from the oscilloscope sweep. The signal from the klystron is attenuated and fed simultaneously to the cavity resonator and to a wave meter. The rectified output of the cavity is combined with the rectified output from the wave meter in a balanced mixer transformer. The resultant signal is amplified and displayed on the oscilloscope. The frequency of the oscillator is adjusted until it is being swept over the frequency of the cavity resonator. When this is done, a typical resonance curve is obtained. The wave meter is adjusted until it is tuned to the same frequency as the cavity as indicated by the appearance of a double-humped pattern on the oscilloscope. By proper adjustment of the wave-meter output the pattern obtained on the oscilloscope is a very sensitive indication of the equality of frequency of the cavity and wave meter. The general usefulness of such patterns in the tuning of resonators has been discussed.[12] The same procedure is followed to determine the frequency f_0 of the empty cavity resonator and the frequency, f, of the cavity resonator when it contains a dielectric specimen.

The wave meter used to determine the frequency difference (f_0-f) is especially designed to facilitate the determination of small frequency differences. The wave meter consists of a section of rectangular wave guide tuned by means of movable plungers in the ends. Operation of the wave meter in the TE_{107} mode results in a relatively large displacement in plunger position for

a small frequency difference (f_0-f). The calibration for the wave meter was calculated from the dimensions of the wave guide. Rotation of the screw used to drive the tuning plunger by one turn changes the frequency by 2.756 Mc. The sensitivity of the measuring system is such that a change in frequency of 0.003 Mc can be detected easily.

Verification of the calculated calibration of the wave meter was accomplished indirectly by measuring the dielectric constants of a number of materials for which the dielectric constants at 3000 Mc are given in the literature.[13] Figure 4 is a graph comparing the values obtained by the present method with the values taken from the literature.[13] With the exception of the data for glasses, the values given in the literature and those determined by the methods described in this paper agree to within about one percent. For the glasses deviations up to about five percent were obtained. In view of the discrepancy in the low frequency dielectric constants for glasses reported by different sources, it was assumed that the deviations greater than one percent observed in the microwave dielectric constants are due to differences in composition of the specimens rather than to errors in measurement. This assumption is supported by the

measurements summarized in Table I which show that variations in the dielectric constant for various sizes of samples of a given glass are much smaller than the discrepancy between the literature values and the present determinations. For the data in Table I the standard deviation is less than one percent.

TYPICAL RESULTS

The dielectric constants of a number of natural and synthetic polymers have been measured by the methods outlined in this paper. The measurements presented below have been selected to illustrate a number of the types of specimen which have been studied.

The dielectric constant of dry wool fibers has been determined for the electric field parallel to the fiber axis ($\epsilon_{\parallel}$) and for the electric field perpendicular to the fiber axis ($\epsilon_{\perp}$). The fibers were arranged into bundles and solenoids as illustrated in Fig. 2 and dried at 100°C in a vacuum oven. The results are shown in Table III. The values of the dielectric constant for the individual specimens agree to within about plus or minus 3 percent. This variation is believed to be due to errors in the dimensions of the specimens. The wool fibers are not uniform and it is difficult to prepare specimens that are well defined geometrically. If methods can be perfected to prepare more uniform specimens, the variation in the dielectric constant can probably be reduced substantially.

The differences between the values of $\epsilon_{\parallel}$ and $\epsilon_{\perp}$ for wool shown in Table III are sufficiently great compared to the statistical errors that it appears likely wool is electrically anisotropic at 3000 Mc. This is interesting in view of the anisotropy reported for another keratin[2] (horn) at much lower frequencies and in view of the apparent lack of anisotropy in horn at 3000 Mc.[8] The validity of the conclusion that wool is electrically anisotropic is of course based on the applicability of the

Lichtenecker equations to mixtures of fibers and air as discussed earlier. If these equations are not valid for wool, then the conclusion of an anisotropy for wool would have to be modified. Further discussion of the anisotropy in wool and other related polymers will be reserved for discussion at a later time.

Table IV contains values of the dielectric constant (ϵ_{11}) of Nylon fibers. The agreement between the individual measurements of (ϵ_{11}) is better than was obtained for wool. This is probably a result of the fact that the Nylon fibers measured were in the form of a uniform continuous filament. This made it possible to prepare more uniform specimens than was possible with wool.

In Table V results are presented which illustrate an application to measurement of the dielectric constant of a polymer film. The material in this case is Cellophane. The ten specimens for which data are given were cut from a single sheet and rolled to form cylinders in the manner illustrated by E of Fig. 2. The individual values of the dielectric constant agree to within about plus or minus one percent, which indicates a high degree of uniformity in a single sheet of film. Similar measurements on specimens from a second sheet of film gave an average value for the dielectric constant of 3.89 compared to the value of 4.04 obtained with the first sheet. This difference in the dielectric constant of the two sheets probably represents a real difference in the Cellophane.

From the results presented it may be concluded that the resonant cavity method may be used to advantage for the determination of the dielectric constants of polymers either in the form of thin cylinders, fibers, or films. It thus appears to be especially useful in the study of the dielectric properties of natural polymers most of which are available only in highly specialized or limited forms such as, for example, fine fibers. The method appears to be capable of yielding accurate values of the dielectric constant even when used with rather small amounts of material.

A more complete discussion of the dielectric constants of wool and related polymers obtained by the methods described above will be given in a subsequent paper to be submitted to this journal.

It is with sincere regret that we announce the death on July 5, 1950 of Dr. Otto A. Beeck, Associate Editor of the *Journal of Applied Physics*.

Determination of Residual Stresses of Quenching Origin in Solid and Concentric Hollow Cylinders from Interferometric Observations

A. W. Sáenz
Applied Mathematics Branch, Mechanics Division, Naval Research Laboratory, Washington, D. C.
(Received August 10, 1949)

A theoretical procedure for the determination of the stresses of quenching origin in solid and concentric hollow cylinders has been derived. The method relies on interferometric data and the assumptions discussed in Section I, whose validity for the technically important case of glass is supported by a number of experimental investigations.

The results should be of interest for the analysis of stresses in quenched glass cylinders, so great in magnitude that the usual cutting techniques are precluded, because of the explosive characteristics of highly stressed objects of this material.

I. INTRODUCTORY REMARKS

An optical method for the determination of the pointwise distribution of stresses of thermoelastic or residual type due to quenching in transparent initially isotropic spheres and infinite cylinders was developed recently at the University of Michigan, and presented in an earlier paper.[1] In the former case, it was proved that the residual stresses could be measured by means of a Babinet compensator, provided the photoelastic law was valid for these stresses, while in the latter it was necessary to introduce special assumptions concerning the mechanism of quenching. To avoid the use of such hypotheses, a theoretical method for the determination of residual stresses of quenching origin in solid and concentric hollow cylinders from interferometric observations alone will be developed in this article. This extension of the use of the usual interferometric procedures[2] to three-dimensional stress fields will complete the work on spheres and cylinders mentioned previously. The method should be of particular interest for the case of glass.

The considerations in the following pages rest on three assumptions: (a) The directions of the principal stresses are assumed to be parallel to the cylindrical coordinates ρ, φ, and z. (b) The stress system resulting from quenching is assumed to be radially symmetrical, i.e., it is independent of φ and z. (c) The Maxwell-Neumann stress-optic law holds, i.e.,

$$\begin{aligned} n_P - n_0 &= C_1 P + C_2(Q+R), \\ n_Q - n_0 &= C_1 Q + C_2(P+R), \end{aligned} \qquad (1)$$

where P and Q are secondary principal stresses in the plane of the wave front, R is the stress normal to the wave front, n_P and n_Q are refractive indices for plane polarized waves with directions of vibration parallel to P and Q, respectively. As to the meaning of n_0 in Eq. (1), a few words are necessary at this point. In the case of stresses below the elastic limit induced by mechanical, thermal, or other means, the initial index of refraction of the material involved is equal to the final index, when the external forces are removed. This is the ordinary case treated in photoelasticity, and experiment shows that (1) is valid if n_0 is identified with the initial refractive index of the substance under examination. However, when residual stresses are being studied photoelastically, the index of refraction of the material is frequently history-dependent, the case of glass furnishing a good illustration of this statement.[3] To avoid these difficulties, the stress-optic law (1) will be assumed in this paper with the proviso that n_0 is now a constant on the same footing as C_1 and C_2. An experimental method to find this constant will be given in Section III.

How valid are the assumptions (a)–(c) for infinite cylinders which have been symmetrically quenched? It is clear that (a) and (b) hold for objects of this shape under the quenching conditions mentioned previously, from symmetry arguments. As to the third assumption, it is realized that this is a highly controversial subject at the present time. Notwithstanding, a number of experimental results strongly support the validity of the photoelastic law for residual stresses of quenching origin in glass, for the case when the initial temperature is low enough so that plastic deformations can be neglected. For example, the conditions of static equilibrium are obeyed by stresses in glass, calculated by photoelastic means,[4] and it is also known that the birefringence of quenched objects of this material is affected by cutting and goes to zero at the surface of the cut, which is a good indication that the optical effect can be expressed as a function of the stress alone. Of course, it will be necessary to carry out a more exhaustive experimental investigation before the above assertions can be generally accepted.

[1] R. C. O'Rourke and A. W. Sáenz, Quart. App. Math. (to be published). The distinction between thermoelastic and residual stresses due to quenching, which is made in that article and the present one, is that the former are transient, because of the fact that the initial temperature is below the softening temperature, while the latter are permanent in character and are produced by rapid cooling from temperatures above the softening point.

II. DETERMINATION OF σ_ρ, σ_φ, AND σ_z IN INFINITE SOLID AND CONCENTRIC HOLLOW CYLINDERS FROM INTERFEROMETRIC DATA

If a symmetrically quenched infinite cylinder is immersed in a liquid whose index of refraction matches its average index and a plane polarized beam of light is

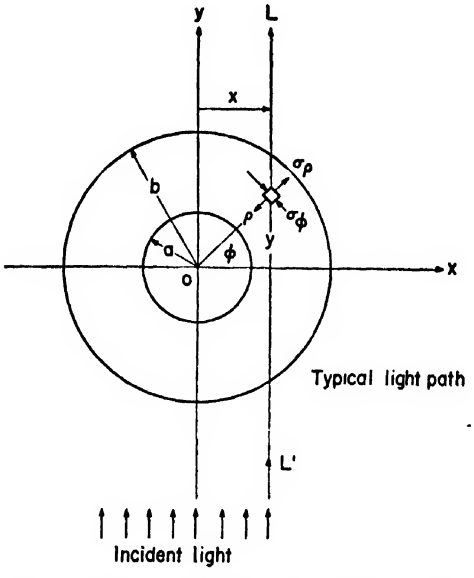

FIG. 1(a) Light normally incident on cylinder (z axis perpendicular to plane of paper).

made to fall normally on it, say along the y axis, as shown in Fig. 1(a), assumption (a) implies:

$$\left.\begin{aligned}\sigma_x&=\sigma_\rho\cos^2\varphi+\sigma_\varphi\sin^2\varphi\\ \sigma_y&=\sigma_\rho\sin^2\varphi+\sigma_\varphi\cos^2\varphi\\ \tau_{xz}&=0\\ \sigma_z&=\sigma_z\end{aligned}\right\}, \tag{2}$$

which means that the following identification can be made:

$$P=\sigma_z,\quad Q=\sigma_x,\quad R=\sigma_y \tag{3}$$

(nothing new would result by putting, instead of (3), $P=\sigma_x$, $Q=\sigma_z$) and, therefore, the directions of the principal stresses do not rotate in the plane of the wave front, so that the usual methods of calculating the phase retardations are correct in this case.

The absolute phase retardations R_P and R_Q along P and Q are, from (1), (2), and (3),

$$\left.\begin{aligned}R_P(x)&=\int_{-[b^2-x^2]^{\frac{1}{2}}}^{[b^2-x^2]^{\frac{1}{2}}}n_P\,dy\\ &=2\int_x^b\{C_1\sigma_z+C_2(\sigma_\rho+\sigma_\varphi)\}\frac{\rho\,d\rho}{[\rho^2-x^2]^{\frac{1}{2}}}\\ &\quad+2n_0[b^2-x^2]^{\frac{1}{2}}\end{aligned}\right\}, \tag{4a}$$

$$\left.\begin{aligned}R_Q(x)&=\int_{-[b^2-x^2]^{\frac{1}{2}}}^{[b^2-x^2]^{\frac{1}{2}}}n_Q\,dy\\ &=2\int_x^b\{C_1(\sigma_\rho\cos^2\varphi+\sigma_\varphi\sin^2\varphi)\\ &\quad+C_2(\sigma_z+\sigma_\rho\sin^2\varphi+\sigma_\varphi\cos^2\varphi)\}\frac{\rho\,d\rho}{[\rho^2-x^2]^{\frac{1}{2}}}\\ &\quad+2n_0[b^2-x^2]^{\frac{1}{2}}\end{aligned}\right\}, \tag{4b}$$

where x is the distance of a given ray LL' [Fig. 1(a)] from the origin 0, measured along the x axis. Equations (4) hold in the interval

$$a\leqq x\leqq b,\quad\text{with}\quad 0\leqq a<b, \tag{4'}$$

where a is the inner radius of the cylinder, taken equal to zero in the case of solid cylinders. Thus, there is no need to distinguish formally between solid and concentric hollow cylinders.

For the sake of completeness, a description of the measurement of $R_P(x)$ and $R_Q(x)$ will be sketched at this point, although it has no essential experimental novelty. A Mach-Zehnder interferometer, as modified by Favre[5] for photoelastic purposes, may be employed

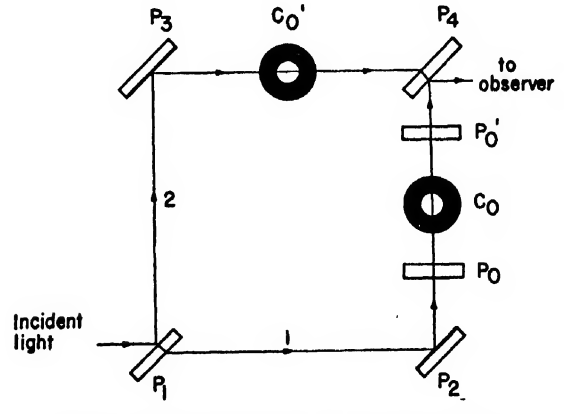

FIG. 1(b) Illustration of measurement of $R_P(x)$ and $R_Q(x)$ by a Mach-Zehnder interferometer.

[Fig. 1(b)]. The plates P_2 and P_3 are full-silvered mirrors, while P_1 and P_2 are half-silvered. The cylinder whose residual stresses are to be determined is placed at C_0, between the half-wave plates P_0 and P_0', in the path of ray 1, and a compensating cylinder of the same size and material is put at C_0', in the path of ray 2. The incident light is plane polarized and has its direction of vibration perpendicular to the plane of the paper [Fig. 1(b)], and the plates P_0 and P_0' permit one to rotate the plane of vibration so that it is parallel to either P or Q, i.e., to the z and x axes, respectively, at C_0

[5] See reference 2, pp. 245–253, where a careful description of the measurement of the absolute retardations along the P and Q axes is given.

and emerges vertical to the plane of the paper after having traversed P_0'. Thus the absolute retardations $R_P(x)$ and $R_Q(x)$ may be measured by Favre's method regardless of the fact that one is dealing with a three-dimensional stress system, because the secondary principal axes do not rotate along the light path for normal incidence.

Regarding $R_P(x)$ and $R_Q(x)$ as known for the interval (4'), it will be demonstrated that σ_ρ, σ_φ, and σ_z can be uniquely determined for all points of the cylinder examined, by inversion of the integral equations (4).

Subtracting (4b) from (4a) and putting $\cos\varphi = x/\rho$, one obtains:

$$R_P(x)-R_Q(x)\equiv r(x)$$

$$=2C\int_x^b\left\{(\sigma_z-\sigma_\varphi)+(\sigma_\varphi-\sigma_\rho)\frac{x^2}{\rho^2}\right\}\frac{\rho d\rho}{[\rho^2-x^2]^{\frac{1}{2}}} \quad (5)$$

where $C=C_1-C_2$ is the relative photoelastic constant and $r(x)$ is the relative retardation at the point x [Fig. 1(a)].

One can eliminate σ_φ from (5) by employing the equation of equilibrium

$$(d\sigma_\rho/d\rho)+[(\sigma_\rho-\sigma_\varphi)/\rho]=0. \quad (6)$$

If one carries out this substitution, integrates (5) partially to get rid of the term in $d\sigma_\rho/d\rho$, and demands that σ_ρ vanish at $\rho=b$, on account of the free boundary, one obtains:

$$r(x)=2C\int_x^b\frac{\sigma_z(\rho)\rho d\rho}{[\rho^2-x^2]^{\frac{1}{2}}}. \quad (7)$$

This is an integral equation of Abel type, index $\frac{1}{2}$,[6] whose only continuous solution is given by

$$\rho\sigma_z(\rho)=-\frac{1}{\pi C}\frac{d}{d\rho}\int_\rho^b\frac{r(x)xdx}{[x^2-\rho^2]^{\frac{1}{2}}},$$

which presents difficulties at $\rho=0$. To arrive at a more convenient expression for σ_z one integrates the last equation by parts[7] and uses the fact that $r(b)=0$, as can be seen from (5), so that the solution of the integral equation (7) becomes

$$\sigma_z(\rho)=-\frac{1}{\pi C}\int_\rho^b\frac{[dr(x)/dx]}{[x^2-\rho^2]^{\frac{1}{2}}}dx. \quad (8)$$

Digressing for a moment at this point, it can be seen that (7) expresses the remarkable fact that, as far as measurements of relative retardation for normal incidence of plane polarized light are concerned, a symmetrically quenched infinite cylinder acts as if only the axial stress σ_z were present. An interesting by-product of (7) and (8) is that σ_z can be determined by the Babinet compensator method, without recourse to more elaborate interferometric procedures.

Returning to the main discussion, one can also find similar expressions for σ_ρ and σ_φ in terms of optical data. With this purpose in mind, (4a) can be written as follows, using (7):

$$\left.\begin{aligned}\int_x^b\{\sigma_\rho(e)+\sigma_\varphi(e)\}\frac{\rho d\rho}{[\rho^2-x^2]^{\frac{1}{2}}}\\ =\frac{1}{2C_2}\{R_p(x)-2n_0[b^2-x^2]^{\frac{1}{2}}\\ -(C_1/C_2)r(x)\}\equiv F(x)\end{aligned}\right\}, \quad (9)$$

where $F(x)$ is known from interferometric observations.

Since (9) is again an Abel integral equation of index $\frac{1}{2}$, one can invert it uniquely in the same way as was done for (7), with the result

$$\sigma_\rho(\rho)+\sigma_\varphi(\rho)=-\frac{2}{\pi}\int_\rho^b\frac{dF(x)/dx}{[x^2-\rho^2]^{\frac{1}{2}}}. \quad (10)$$

From (6) and (10) one has, by repeated application of Dirichlet's formula for the inversion of order in repeated integrals,

$$\left.\begin{aligned}\sigma_\rho(\rho)=-\frac{2}{\pi}\int_\rho^b\frac{S(x)dx}{x^2[x^2-\rho^2]^{\frac{1}{2}}}\\ \text{where}\\ S(x)\equiv\int_x^b dF(x')/dx'\end{aligned}\right\}. \quad (11)$$

Finally, from (6) and (11) it follows that

$$\sigma_\varphi(\rho)=-\frac{2}{\pi}\frac{d}{d\rho}\left\{\rho\int_\rho^b\frac{S(x)dx}{x^2[x^2-\rho^2]^{\frac{1}{2}}}\right\}. \quad (12)$$

Equations (8), (11), and (12) furnish the principal stresses for solid and concentric hollow cylinders once n_0 has been measured. The integrations can be carried out by numerical or analytical methods, but it is felt that the latter are preferable for the most accurate results.[8] Since current interferometric methods in photoelasticity are capable of measuring absolute retardations down to a few percent of a wave-length, the present method seems quite promising with respect to accuracy. It is

[6] E. T. Whittaker and G. N. Watson, *Modern Analysis* (The Cambridge University Press, New York, 1945), p. 229.

[7] This and the succeeding partial integrations and inversions of the order of integration of repeated integrals are justified in virtue of the fact that the absolute retardations, $R_P(x)$ and $R_Q(x)$, as shown by physical considerations, are continuous in the closed interval (4') and possess derivatives which are also continuous in this interval, except at $x=b$, where they have singularities $O\{(b^2-x^2)^{-\frac{1}{2}}\}$.

[8] Analytical procedures were employed in conjunction with the fitting of the retardation curves by polynomials, using least squares, in a similar connection, with very satisfactory results. See Everett, Parsons, O'Rourke, and Sáenz, "Progress reports on stresses in insulators," Eng. Research Inst. Publ. (December, 1947), and also reference 4.

planned to carry out systematic experimental investigations with symmetrically quenched, unannealed glass cylinders to confirm this point.

III. MEASUREMENT OF n_0

Since it is necessary to know n_0 to calculate the stress distribution σ_ρ, σ_φ, and σ_z from the above integral formulas, a method for determining it will be presented at this point.

The following procedure can be used to measure n_0. One rotates the cylinder about the x axis by an angle α, so that the light strikes it obliquely, and determines the absolute retardations of the rays located in the central section S, as shown in Fig. 2. One also finds the value of the absolute retardations for waves whose planes of vibration coincide with the yz plane and are incident normally on the cylinder, as in Fig. 1(b). This information determines n_0 completely.

To prove this statement, one proceeds in the following way. In section S

$$\left.\begin{aligned} P' &= \sigma_z \cos^2\alpha + \sigma_\rho \sin^2\alpha \\ Q' &= \sigma_\varphi \\ R' &= \sigma_z \sin^2\alpha + \sigma_\rho \cos^2\alpha \end{aligned}\right\}, \tag{13}$$

where P' and Q' are the secondary principal stresses in the plane of the wave front in section S (Fig. 2), and R' is the stress normal to the wave front. Since it can be shown that no rotation of the secondary principal axes occurs along the light path LL' in S, the absolute retardations $R_P^{(\alpha)}$ and $R_Q^{(\alpha)}$ (the superscripts refer to the angle α of oblique incidence) corresponding to plane polarized waves whose planes of vibration are parallel to P' and Q', respectively, are given by

$$\left.\begin{aligned} R_{P'}^{(\alpha)} &= 2\sec\alpha\left\{\int_a^b [C_1(\sigma_z\cos^2\alpha+\sigma_\rho\sin^2\alpha) \right. \\ &\quad \left. + C_2(\sigma_\varphi+\sigma_z\sin^2\alpha+\sigma_\rho\cos^2\alpha)]d\rho + n_0(b-a)\right\} \\ R_{Q'}^{(\alpha)} &= 2\sec\alpha\left\{\int_a^b [C_1\sigma_\varphi + C_2(\sigma_\rho+\sigma_z)]d\rho \right. \\ &\quad \left. + n_0(b-a)\right\} \end{aligned}\right\}, \tag{14}$$

where the factor $\sec\alpha$ arises from the fact that the light paths are longer for oblique than for normal incidence.

The terms in (14) containing σ_φ vanish because of the relation

$$\int_a^b \sigma_\varphi(\rho)d\rho = b\sigma_\rho(b) - a\sigma_\rho(a), \tag{15}$$

which follows from (6). The right-hand side is zero for both solid and hollow cylinders since the boundaries are free from external stresses. From (14) and (15),

$$\left.\begin{aligned} n_0 = \frac{1}{2C(b-a)}\{ & C_2 R_{P'}^{(0)}(\cot^2\alpha - 1) + [-C_2 R_{P'}^{(\alpha)} \\ & + (C_1+C_2)R_{Q'}^{(\alpha)}\sin^2\alpha]\cot\alpha\csc\alpha\} \end{aligned}\right\}, \tag{16}$$

where $R_{P'}^{(0)}$ is the absolute retardation through the section S (Fig. 2) along the P' direction for normal incidence ($\alpha = 0$).

Equations (8), (11), (12), and (16) permit one to determine σ_ρ, σ_φ, and σ_z at all interior and boundary points of symmetrically quenched solid cylinders and concentric hollow cylinders from purely optical data.

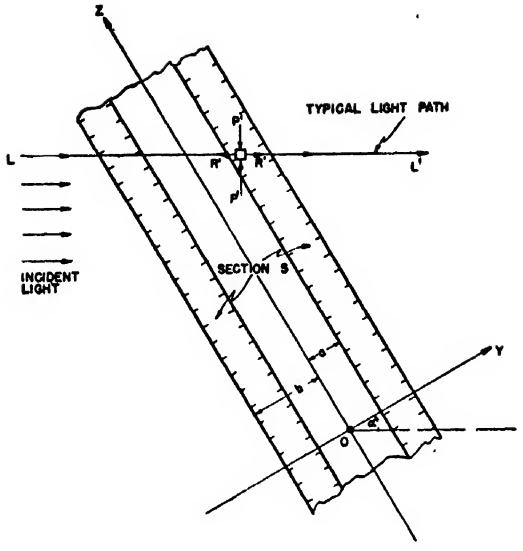

FIG. 2. Oblique incidence on central section S of cylinder (x axis and Q' perpendicular to plane of paper).

IV. CONCLUDING REMARKS

The method presented in the previous sections should be of particular interest for the analysis of residual stresses in glass objects which are so highly quenched that their explosive characteristics would prevent the use of cutting techniques for the measurement of these stresses. It also appears promising in the study of transient thermal stresses in cylinders, particularly for those cases when the temperature differences are so large that thermal and elastic constants of the material vary considerably, and the radiation at the surface does not follow the simple Newton law of cooling, so that the Stefan-Boltzmann law must be employed. Such thermal stresses cannot be determined readily by present photoelastic techniques.

Some Crossover Properties in the Electron Immersion Objective

L. JACOB*
The University, Manchester, England
(Received January 31, 1950)

It was earlier established that the lens field between the cathode and crossover can be represented by a simple function $V=A\sinh kz$, so that the main properties of the paraxial "crossover" (or minimum section of the beam) can be determined as a first approximation in terms of "A" and "k." The distance of the crossover works out at $8\pi/3k\sqrt{3}$; its potential is $A\exp(8\pi/3\sqrt{3})$; and the angle of the beam is simply proportional to "k." The radius of the crossover is then $2/k\exp[-(2\pi/3\sqrt{3})]\cdot\tan\theta$ for electrons of initial velocity "A," where θ is the angle of emission within the paraxial limit. The differential analyzer was also used to obtain the correct solution for the trajectory equation from the field plots for different systems, and shows that the simple theory gives an adequate approximation for design purposes.

I. INTRODUCTION

IT was only with the advent of the study of electron motions in E. S. Fields that their property of crossing over to form a minimum beam section was recognized. The optical counterpart has no practical significance, since focusing of the object is the chief aim, and in a sense it was hardly ever considered. In their observations on the focused spots of television C.R. tubes, Maloff and Epstein[1] concluded that the "object" which was imaged on the screen was a "crossover" produced by the first lens (immersion objective).

This is brought about in the following way. The electrons, which leave the cathode at all angles and with a range of initial velocities, are focused by the immersion lens and produce an image of the cathode. This is usually enlarged and inverted. The "principal rays" however, cross the axis at a point nearer the cathode; the plane perpendicular to the axis at this point contains the "crossover." The envelope of the beam at the crossover gives the minimum cross section of the beam, which is ultimately focused into the small spot on the screen.

The immersion objective consisted of an oxide emitting cathode C, a modulating electrode M, and an accelerator A (Fig. 1). The distance between C and M was varied keeping the position of A fixed, and the field distribution determined in the electrolytic tank. It has been shown[2] that a simple empirical formula $V=Ae^{kz}$ approximately describes the relation between the potential V at any point on the axis and the distance "z" from the cathode, for the region up to and somewhat beyond the modulating electrode, which was explored in the tank. Using this, an approximate theory of crossover properties is presented in what follows, which can be helpful in design. This indicates the importance of the geometrical arrangement of the electrodes.

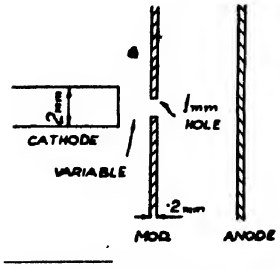

FIG. 1. Immersion objective.

II. THE CATHODE/CROSSOVER DISTANCE

For the purposes of the subsequent analysis, the simple relation $V=Ae^{kz}$ has been used. Here "k" is a geometrical scale factor which varies from geometry to geometry, while "A" is a voltage scale factor, which, for any one geometry and fixed field form, varies correspondingly with the over-all voltage applied to the system. In order to satisfy the boundary conditions at the cathode ($V=0$), the distribution in the region between the cathode and the nearest point of the experimental plot should be represented by $V=A(e^{kz}-e^{-kz})$. The extent of the linear part of the field given by the last expression is then assumed small in comparison with the exponential portion Ae^{kz} which includes the crossover region.

Electrons which are emitted normal to the cathode in the linear field remain normal till they enter the exponential region. Here, they experience the focusing effect. By assuming that the function $V=Ae^{kz}$ applies to this region, the electrons which leave the cathode at $z=0$ must enter the exponential field with a velocity of "A" volts. For paraxial systems this has a value of about 0.5 for a 30-v blackout, and is thus of significance in practice.

We begin with the paraxial form of the trajectory equation:

$$d^2r/dz^2+\tfrac{1}{2}(V'/V)dr/dz+\tfrac{1}{4}(V''/V)r=0 \qquad (1)$$

and, substituting $V=Ae^{kz}$, this yields

$$r=C\exp\{[-k/4+(k\sqrt{3}/4)\cdot i]z\}+D\exp\{[-k/4-(k\sqrt{3}/4)i]z\} \qquad (2)$$

as the complete solution. This gives the height "r" of the ray at any point

$$r=e^{-(k/4)z}\{M\cos(k\sqrt{3}/4)z+N\sin(k\sqrt{3}/4)z\}. \qquad (3)$$

To evaluate the constants M and N, we must put in the

[2] P. A. Einstein and L. Jacob, Phil. Mag. 39, 20 (1948).

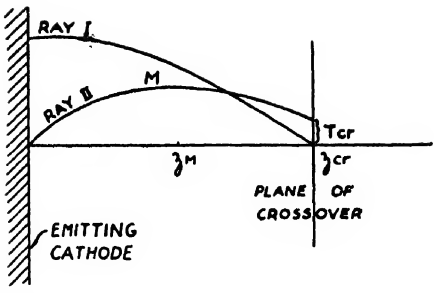

FIG. 2. Rays defining crossover and its plane.

boundary conditions. An electron starting at the top of the emitting area and moving parallel to the axis is deviated by the field so as to cut the axis at the crossover (Fig. 2); this gives one focal plane of the immersion objective. Now put $r=a$, the radius of the emitting area when $z=0$; hence $M=a$. Also $(dr/dz)_{z=0}=0$; hence

$$N=a/\sqrt{3}; \tag{4}$$

$$\therefore \quad r=ae^{-(k/4)z}\{\cos(k\sqrt{3}/4)z+(1/\sqrt{3})\sin(k\sqrt{3}/4)\cdot z\}. \tag{5}$$

Now, let this trajectory meet the axis in the crossover plane, at a distance z_{cr} from the cathode. Here, $r=0$.

$$\therefore \quad \cos(k\sqrt{3}/4)\cdot z_{cr}+(1/\sqrt{3})\sin(k\sqrt{3}/4)\cdot z_{cr}=0; \tag{6}$$

$$\therefore \quad z_{cr}=8\pi/3k\sqrt{3}. \tag{7}$$

Thus, the crossover distance from the cathode varies inversely as "k," the geometrical scale factor.

Actually, the value of the crossover distance determined from (7) will be a limiting value, since it corresponds to electrons with initial speeds of about 0.5 v. The most probable crossover corresponding with the most probable velocity of about 0.1 volt will lie somewhat closer to the cathode, but the difference is only some five percent and may be overlooked for this type of system. This "chromatic aberration" effect may however be important in systems where there is a wide spread in z_{cr} or of initial velocity; its effect will be most marked when crossover diameters are to be derived.

III. THE BEAM ANGLE AND POTENTIAL AT THE CROSSOVER

The immersion objective has the form of a "thick lens," i.e., consists of a series of contiguous refracting layers, so that an electron ray is continuously refracted all through the field. The direction in which it emerges and which defines the angle of the beam, as measured in a field free space outside the lens, is usually very different from the angle φ at which it crosses the axis at the crossover. The angle φ is derived by differentiating (5) and putting

$$z=z_{cr}=8\pi/3k\sqrt{3};$$

$$\therefore \quad \tan\varphi=-(ak/2)\exp(-2\pi/3\sqrt{3}). \tag{8}$$

This gives the angle at the crossover, in terms of the height at which the ray left the cathode normally, and the "k" of the field. For a constant emitting area of radius "a," the angle at the crossover is directly proportional to the factor "k" which defines the geometry of the system. It is, of course, also proportional to the diameter of the coated area.

For a given geometry, the beam angle is thus constant, independent of the total voltage on the system, because the factor "A" does not determine its value. This is a well known experimental law which is used in the Electron-optical voltmeter.[3]

The potential on the axis at the crossover is simply derived by substituting the value of z_{cr} from (7) in the equation $V=Ae^{kz}$ for the axial distribution. This yields a value $A\exp(8\pi/3\sqrt{3})$, which is thus proportional to A; hence, A is some constant fraction of the crossover voltage. Under the approximation used, it is also the initial velocity with which the electrons enter the exponential part of the field, as stated previously. If the total voltage on the system is increased "n" times, that at the crossover also increases "n" times, and the ratio of crossover potential to final potential is not altered. Hence, no change would be expected in the magnification of an image of the crossover, when the total voltage on the tube was varied in any way, apart from the effect on the space charge. Use can be made of this fact by finding

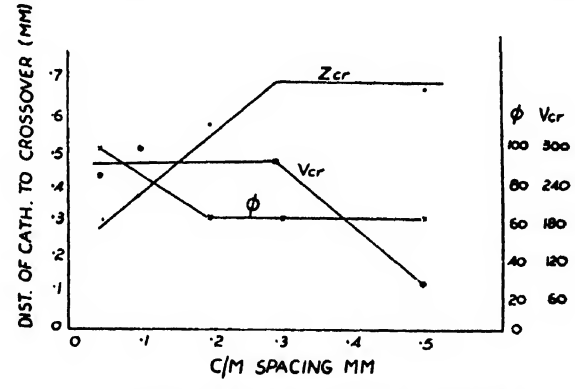

FIG. 3. Effect of spacing on crossover parameters.

the point at which the relationship no longer holds; the control of crossover size by space charge then steps in, and the magnitude involved can be assessed.

The variation of these crossover properties with C/M spacing is shown in Fig. 3. These were derived from the field plots for the different systems. They include crossover distance z_{cr}, angle at the crossover φ and its potential V_{cr} calculated from the above formulae using the constants determined from each geometry. The data has been converted to correspond with the case of a vacuum tube system run under the condition of constant anode voltage for each system. It will be seen that the potential at the crossover remains nearly constant except for the largest spacing. Also, the beam angle decreases and appears to reach a limiting value of 60° at

[3] L. Jacob, J. Inst. Elec. Eng. 91, 512 (1944).

this spacing. In an actual sealed off tube, the largest angle at the crossover is about 100°. In practice, using a fluorescent disk to measure the angle, the measured angles are only about 20°, i.e., one-fifth the calculated values. This arises from the fact that the angle is measured in a field-free space at the final anode voltage, while the angle at the crossover is situated in a space at a very much lower potential. Care should be taken to allow for this difference, when using measured values in any calculations which have to be made.

IV. THE EFFECT OF MODULATION ON CROSSOVER PROPERTIES

The field plotting technique can be readily applied to follow through the effect of modulating the beam, by applying negative potentials, V_m, to the modulator,

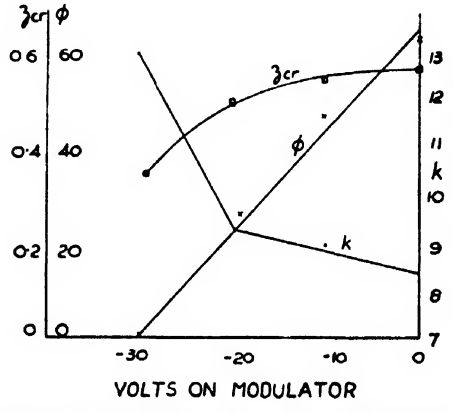

FIG. 4. Effect of modulation on crossover parameters.

with respect to the cathode. The family of curves obtained for negative voltages up to the blackout point follow the same exponential law as for $M=0$, but the value of "A" decreases while that of "k" increases in each case. A separate experiment in which the emitting area of the cathode was covered with a square gauze network showed clearly that one effect of the modulation was to reduce the radius of the emitting area of the cathode in proportion to the modulation swing. For example, if the system required -30 volts to black out the beam, then if -10 volts was applied to the modulating electrode, the emitting radius was restricted to 20/30 of its size when the modulator was at zero or cathode potential. Hence "a" in (8) decreases in proportion to the modulation, while "k" usually increases somewhat (Fig. 4).

The product "ak" which determines the angle is predominantly affected by the large variation in the emitting radius, and this is the controlling factor, so that the calculated angle φ varies almost linearly with V_m.

There is a further effect as regards the position of the crossover, z_{cr}, when the beam is modulated; it tends to move toward the cathode. This shift would be expected on purely qualitative grounds, since it is known that the equipotentials become more and more curved as the inter-electrode space becomes more negative. This, in turn produces larger deviations of the rays, i.e., shorter focal lengths; the crossover point will thus tend to move towards the cathode. With this type of system, the crossover remains on the side of the modulator remote from the cathode throughout the modulation range.

V. THE SIZE OF THE CROSSOVER

The intersection of the path of an electron which leaves the cathode at normal incidence and with zero velocity (at some height above its center) with the axis of the system defines the plane of the crossover for this velocity. All such electrons emerging at different heights will meet at this point under truly paraxial conditions. The upper limit to the size of the crossover will be defined by the group of electrons leaving the center of the cathode at an angle of 90°, and with the greatest velocity. The points at which these strike the plane of the crossover sets the limit to its boundary. The actual physical number involved here will be small since the emitter can be assumed to obey the Lambert cosine law. Further, for each direction of emission, the Maxwell distribution will determine the fraction of the total number with any assigned velocity; for example about 70 percent of the electrons are to be found with all velocities up to the most probable velocity of about 0.1 volt. It is therefore sufficient to examine the crossover sizes obtained for electron speeds of 0.1 volt as a working limit, since the area enclosed will embrace some 70 percent of all the electrons emitted by the source. Unfortunately, it was not possible to adhere to this value for the simple theory, since the initial electron velocity is fixed by the value of A, and this is about 0.5 v when the blackout voltage is 30 v. Even with this limitation, the theory is worth stating since it provides data for an upper limit to the size of the crossover. The size of the final image can be calculated from this, once the potential in the crossover plane is known.

In order to trace the rays which leave the center of the cathode at angles within the paraxial range, we use the original trajectory equation, but the constants will have different values because of the new boundary conditions. The initial linear field is again neglected here, but a rough calculation shows that by the time an electron has passed through it, its early parabolic path has now a slope within the paraxial range of the exponential focusing field, and the crossover height will not be affected by the height at which the ray starts. Since

$$r=e^{-(k/4)z}\{P\cos(k\sqrt{3}/4)z+Q\sin(k\sqrt{3}/4)z\}$$

from (3) the value of P is zero when $r=0$; for $z=0$.

$$\therefore\quad r=e^{-(k/4)z}\cdot Q\sin(k\sqrt{3}/4)z. \tag{9}$$

When $z=z_{cr}$, then $r=$radius of the paraxial crossover $=r_{cr}=\exp[-(k/4)z_{cr}]\cdot Q\cdot\sin(k\sqrt{3}/4)z_{cr}$. Now put $z_{cr}=8\pi/3k\sqrt{3}$

$$\therefore\quad r_{cr}=\exp[-(2\pi/3\sqrt{3})]\cdot Q\sin(2\pi/3). \tag{10}$$

This ray will pass through the periphery of the crossover. Before doing so, it may proceed to some point corresponding to z_M along the axis at which its height is maximum, while being focused toward its image on the axis. At this maximum height

$$(dr/dz)_{z=z_M}=0;$$

hence, from (9),

$$z_M=(4\pi/3k\sqrt{3})=z_{cr}/2. \tag{11}$$

This ray thus reaches its maximum height at a distance from the cathode equal to half the crossover distance. The height of the ray at this point is $\exp(-\pi/3\sqrt{3})\cdot Q\cdot\sqrt{3}/2$ and will obviously be governed, apart from its initial velocity "A," by the initial angle θ (assumed within the paraxial range) at which the electron leaves the cathode center, i.e., $(dr/dz)_{z=0}=\tan\theta$. Hence from (9),

$$Q=4\tan\theta/k\sqrt{3}; \tag{12}$$

$$\therefore\quad r=\exp[-(k/4)z]\cdot 4\tan\theta/k\sqrt{3}\cdot\sin(k\sqrt{3}/4)\cdot z. \tag{13}$$

This gives the height of the ray at any point in terms of the angle of ejection, and the geometry of the field

$$\therefore\quad r_{cr}=(2/k)\cdot\exp[-(2\pi/3\sqrt{3})]\cdot\tan\theta. \tag{14}$$

Hence, the paraxial crossover size is determined for electrons of initial velocity "A" by the ratio of $\tan\theta$ to "k." It might be supposed that there was no limit to the crossover size if θ took on the value of 90°. The theory would of course not hold for this case. Actually, the work with the differential analyzer described in the next section shows how quickly such rays are brought in by the field; the modulator hole does not appear to act in any way as a limiting stop. An examination of (14) indicates that the crossover size can be reduced only by a variation in geometry. In the standard C.R. tubes, "k" has already a value of about 10, and it is unlikely that it can be made much smaller by increasing the geometrical factor alone beyond this limit.

The aim in design should be to increase "k" to as large a value as possible, while at the same time insuring that the crossover is situated at a point in the field which has the lowest potential.

This should yield the minimum crossover image at the screen in theory; in practice, lens aberrations and space charge appear to be the controlling factors.

The maximum height of the trajectory was shown to be $\exp(-\pi/3\sqrt{3})\cdot Q\cdot\sqrt{3}/2$ and this occurs at a point approximately halfway to the crossover. All the rays leaving the center of the cathode will reach maximum height in the vicinity of this point; the peak height is found on substitution to be about 1.8 times the height of the crossover, independent of θ.

VI. TRAJECTORIES WITH THE DIFFERENTIAL ANALYZER

The crossover properties deduced from the simple theory can be helpful in design of systems, and the approximate form of the trajectory can also be traced out point by point for the paraxial case from (13).

In order to deal with electrons leaving the center of the cathode at angles *outside* the paraxial range, i.e., up to 90°, the differential analyzer was employed to solve the trajectory equation.

The general equation has been stated (1) as follows:

$$d^2r/dz^2+\{[1+(dr/dz)^2]/2(V+A)\}\cdot\partial V/\partial z\cdot dr/dz -\{[1+(dr/dz)^2]/2(V+A)\}\cdot\partial V/\partial r=0, \tag{15}$$

where V is the potential at any point on the axis and "A" is the initial electron velocity.

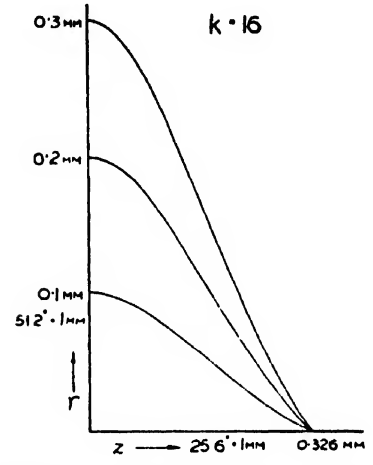

FIG. 5. Trajectories with differential analyzer.

This equation is not easily manageable unless paraxial conditions are imposed, e.g., $(dr/dz)\ll 0.1$, in which case it takes the form

$$d^2r/dz^2+\{V'/2(V+A)\}dr/dz +\{V''/4(V+A)\}\cdot r=0. \tag{16}$$

The differential analyzer solutions were, however, obtained from (16) which was taken in the simpler form of the two equations of motion, and before the time parameter "t" had been eliminated, i.e.,

$$m(d^2z/dt^2)=e(\partial V/dz), \tag{17}$$

$$m(d^2r/dt^2)=-er(\partial^2V/\partial z^2)/2. \tag{18}$$

If the electrons leave the cathode with initial velocity "A," then the results of the analyzer traces show that they follow approximately the same trajectory under the potential field $V=(Ae^{kz}-A)$, as those with zero velocity under a field $V=A(e^{kz}-e^{-kz})$. The value of "A" for cases of 30-v blackout is, as stated earlier, about 0.5 volt. This gives the diameter of the crossover calculated from (14) a practical significance. The analyzer traces were taken assuming the field to have the sinh-form all the way from the crossover to the cathode surface. The periphery of the crossover is then defined by the electrons which leave the center of the cathode at 90° and with the most probable velocity of 0.1 v.

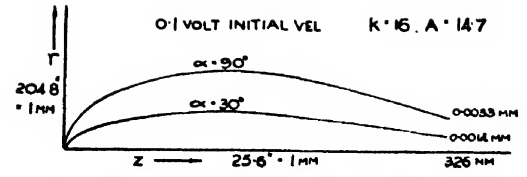

FIG. 6. Trajectories defining radius of crossover.

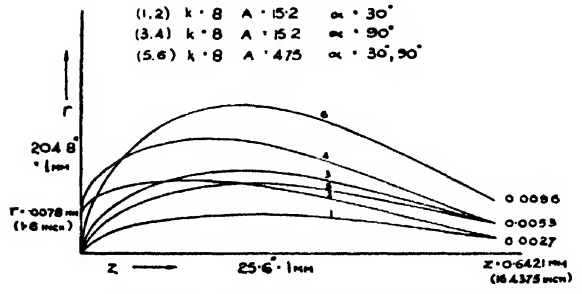

FIG. 7. Trajectories for 30° and 90° emission.

The electron distribution at the crossover assuming ideal focusing systems has already been treated by Langmuir[4] and will not be further discussed here.

In addition to the 90° trajectory, a further one of 30° was taken as a matter of interest, using the most probable velocity of 0.1 volt for the electrons leaving the center of the cathode. In order to find the crossover plane, it was necessary to trace electrons leaving the cathode normally at different heights above the axis. These are shown in Fig. 5 for a system with a value of $k=16$ and 5000 volts on the anode, and for an initial velocity of 0.1 volt. In order to keep within the paraxial region, the largest height of incidence used was 0.3 mm (emitting radius 0.5 mm). For the same system, the limiting value of the crossover radius is seen from Fig. 6 to be 0.0033 mm.

The size of the crossover will, for a given initial velocity, depend on the voltage applied to the system. If this is varied, the size is readily determined from the machine constants. For a 30-v blackout with this system and a 0.1 volt emission its value is 0.033 mm.

Figure 7 shows a series of trajectories for a system having $k=8$ and for various anode voltages, for angles

[4] D. B. Langmuir, Proc. I. R. E. 25, 977 (1937).

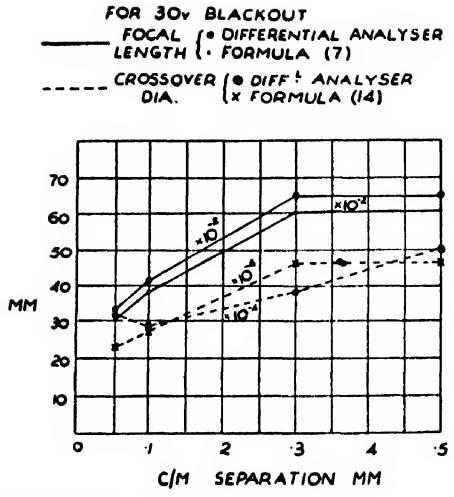

FIG. 8. Comparison between differential analyzer and simple theory.

of 30° and 90°. It will be observed from the pairs (1) and (2), and also (3) and (4), which relate to rays leaving the cathode surface with the same direction and velocity, but at different heights, that they are focused to the same point in the crossover plane, which is to be expected under these conditions. It should also be noticed that the trajectories from the center of the cathode reach a maximum height at a point roughly halfway to the crossover, and this is usually about twice the crossover height, as shown earlier.

The focal length of the lens formed by the immersion objective system is seen from Fig. 8 to increase with the C/M separation. The value calculated by formula (7) is shown to be a good approximation when compared with the traced value on the analyzer. The same figure shows how the crossover diameter varies as the cathode is moved away from the modulator keeping the blackout voltage constant at the value of 30 v. The approximation obtained from (14) is shown to be quite good, even though no rays are included which are inclined at an angle greater than 17°.

In conclusion, I wish to thank the Director of the National Physical Laboratory for his kindness in placing the facilities of the differential analyzer (housed in this University) at my disposal, and Messrs. Michel and Butler for helpful discussions during its operation.

Single Crystal Copper Surfaces*

T. N. Rhodin, Jr.
Institute for the Study of Metals, University of Chicago, Chicago, Illinois
(Received February 20, 1950)

Some surface structure characteristics of a metal single crystal are considered and the conclusions are applied to the preparation of single crystal plates of copper. A successful preparation is described as well as suitable methods for evaluating the effectiveness of the preparation. Using physical microadsorption isotherms of nitrogen at 78.1°K, electron diffraction, and x-ray diffraction methods, the conclusion is tentatively asserted that the surfaces are essentially planar on a molecular scale, and that the surface atoms are arranged in an approximately undistorted lattice.

I. INTRODUCTION

It has become a question of great interest to ascertain the relationship between the physical and chemical properties of a metal interface and that particular crystallographic arrangement characteristic of the atoms in the interface area between the metal and its environment. The environment could be a fluid or solid such as another grain of the same metal. Although these remarks apply equally well to any such interface in general, let us for convenience limit consideration to a single crystal-gas interface. The surface of the metal crystal may, in a region where the macroscopic surface has a given orientation, approximate the ideal crystal plane of the corresponding orientation—that is to say, a surface formed from an infinite crystal lattice by removing all atoms whose centers lie on one side of the plane. This would give steps and risers of atomic dimensions only.[1] The surface may, on the other hand, have a hill and valley structure on a scale larger than atomic dimensions,[2,3] so that the planar arrangement of the microscopic surface may well differ from that of the macroscopic surface as illustrated in Fig. 1. Thermodynamic considerations prescribe that the surface structure with the lowest free energy will be the true one providing that the surface be in equilibrium with its vapor for a sufficiently long time. However, as is so often the case for the solid state, since the structure actually obtained after a finite time will depend on the rate of approach of the system to an equilibrium state, the conditions experimentally obtained at room temperature may differ considerably. Hence, although there is much evidence[4] for the unlikelihood of hill and valley structures and for the validity of the hypothesis that surfaces are atomically smooth if the temperature is sufficiently high, such observations do not necessarily apply to metal surfaces prepared at low temperatures. Yet the definition of surface structure is a critical prerequisite to surface studies and it is exceedingly difficult to do so, when room temperature surface polishing techniques tend to distort mechanically the structure of the surface layers.[5] On the other hand, if the surface distortion were minimized the surface orientation of sufficiently planar surfaces would be that of the matrix atoms. The preparation of copper surfaces of this type suitable for surface chemistry studies using a sensitive quartz vacuum microbalance was systematically investigated without resorting to high temperature equilibrium conditions. Weight increments caused by surface effects such as adsorption or oxidation are often small and, even for an exceedingly sensitive instrument, it is desirable for the samples to possess a high surface to volume ratio; in other words, the optimum geometry of the sample is that of a very thin plate. It is difficult enough to satisfy the conditions of planarity and undistorted surface structure under the most favorable conditions but special considerations are required when this third condition is added. Recently a systematic study of these considerations, applicable to thin single crystal plates of copper, was completed. A concise report of the results seems desirable.

II. PROCEDURE AND RESULTS

The original source of the crystal plates was a cylindrical single crystal of copper (6 in.×1¼ in.) grown by

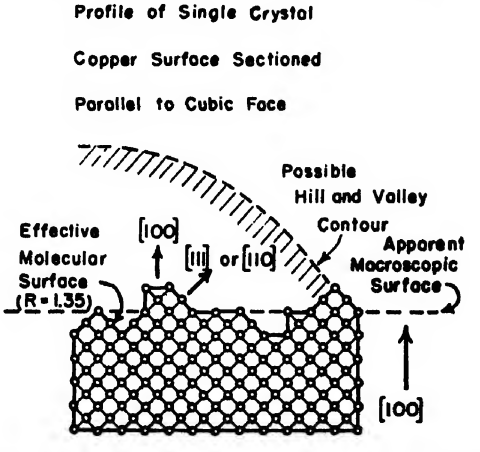

Fig. 1. Profile of single crystal copper surface sectioned parallel to cubic face (schematic). (Arrows indicate crystallographic directions normal to crystal face.)

the standard Bridgman method. The orientation and symmetry of the crystal was determined by the Laue method, using back reflection x-rays. Testing the crystal at various spots by this method indicated an over-all variation of lattice orientation of two degrees or less. The copper was 99.995 percent pure with traces of iron, silicon, and aluminum. Sections ($\frac{3}{4}$ in$\times\frac{1}{2}$ in.) were cut from the crystal very slowly with an alundum cutting wheel at a proper angle so as to expose the macroscopic face along a predetermined low index plane. The proper transfer of the crystal from the Laue camera set-up to the cutting wheel was insured by the use of an (some of the techniques roughly resemble those used by A. T. Gwathmey and A. F. Benton, J. Phys. Chem. 44, 35 (1940)) interchangeable jig arrangement schematically indicated in Figs. 2 and 3, respectively. The crystal was so arranged in the jig to permit one to orient the pole of the desired plane by simple rotations about two axes, one parallel to the cylinder axis and one normal to it, as indicated by items 5 and 6 in Fig. 2. Mounting the section in Lucite with one face exposed permitted one to polish it mechanically by the usual methods, finishing up with Buehler powder No. 3 on the polishing wheel. Upon reversal in the mount the second face was likewise polished until the thickness of the sample had been reduced to 0.040 in. This preliminary mechanical polish was necessary to insure uniform removal of material by the relatively prolonged electropolishing that followed. The plate was thereupon floated off the mount in benzene and the thickness reduced 75 percent to 0.010 in. by a carefully tedious process of electropolishing so as to insure removal of the distorted layers. The technique in this stage was a standard one except that the rate of removal of material was kept very small. A solution of orthophosphoric acid and ethyl alcohol was used in the usual proportions with an etching current of less than 0.01 ampere at about a potential of 2.0 volts for several periods of 20 minutes each until sufficient material had been removed. The long treatments tended to develop a wavy surface, but on such a large scale that it did not contribute to the molecular roughness. The final appearance was mirror bright and planar. No pitting nor selective attack of the surface was observed by microscopic observation at 1000 diameters.

The effectiveness of the preparation was tested in two ways. The planarity of the final surfaces on a molecular scale was determined from microadsorption isotherms of nitrogen at 78.1°K using a very sensitive microbalance technique described in detail elsewhere.[6] In brief, the amount of physically adsorbed gas as a function of pressure was measured and the weight of adsorbed gas corresponding to a monolayer coverage of the surface by a close packed layer of adsorbed gas molecules was calculated from the adsorption isotherms by the Brunauer-Emmett-Teller equation[7] and checked by the Harkins-Jura method.[8] Using the proper value for the cross-sectional area of an adsorbed nitrogen molecule a simple calculation yields the value of the effective surface area available for nitrogen molecule adsorption, that is to say, the molecular surface area. The ratio of this surface area to that calculated from the macroscopic dimensions of the sample gives a precise value for the roughness of the surface. For example, if (R) is the roughness factor, the percent roughness of the surface on

a molecular scale may be expressed as $100(R\text{-}1)$. Since it is reasonable to assume for a metal surface that irregularities will tend to be more or less spread out over the whole surface, surfaces with roughness factors near unity will be essentially planar. Such was the case for the surfaces prepared as described, where most of the R values ranged from 1.2 to 1.5.

The perfection of the surface structure was examined directly by both glancing angle electron diffraction and transmission and back-reflection of x-rays. No definable diffraction pattern was obtainable from the electron diffraction examinations, although the surface had been carefully cleaned by distilled water and alcohol rinses followed by a 400 C. hydrogen reduction and outgassing pre-treatment. Back-reflection x-ray patterns indicated a maximum lattice distortion of two degrees averaged over approximately the outer 5000 layers of copper atoms. In order to define better the structure of the surface layers, transmission x-ray examinations were made of a small section in the center of a crystal plate which was systematically reduced in thickness by successive electropolishing treatments. The ultimate thickness examined appeared to be less than 10^{-4} cm with no indication that the observed distortion was not more or less characteristic of the whole thickness of the plate.

III. DISCUSSION

If one assumes that the surfaces used for electron diffraction examination were adequately clean, the inability to observe coherent reflection patterns may just indicate the absence of suitable projections on the surface for the electrons to penetrate without being totally scattered. This might be conceivably true for surfaces approximately planar on a molecular scale. In addition, x-ray reflection and transmission patterns, indicating a maximum variation in lattice perfection of two degrees, may be considered to indicate a relatively undistorted surface layer providing one accepts the admittedly inconclusive indication that the observed small distortion is not intensively concentrated in the surface layers. It cannot be denied that the results do not preclude the possibility that a highly distorted outermost layer, too thin to contribute to the x-ray pattern, may exist. In addition, well-defined reflection patterns have been obtained for glancing angle electron reflection from planar surfaces of mica and from thin films of dielectrics formed by condensation on to mica substrates.[9] However, the existence of this effect for unetched single crystal metal surfaces has yet to be established and the present inability to observe it remains an open question.

In the final analysis the fact that atoms are arranged in a particular crystallographic plane on the surface may be best indicated by some physical chemical effect on a molecular scale, the magnitude of which can be measured and the extent of which is sensitively dependent on the particular crystallographic face involved. Two such effects, namely, low temperature oxidation, and low temperature physical adsorption of gases have been investigated in this laboratory. In both cases the magnitude of the energy terms involved, e.g., the activation energy for oxidation and the heat of physical adsorption have been observed to depend on the crystallographic direction of the macroscopic surface as if most of the surface atoms were arranged in a characteristic well-ordered surface lattice.[10] Since both phenomena occur by a molecular mechanism, there is reason to believe that there exists a precise and reproducible dependence on the surface structure. Although a detailed discussion of these effects is out of place here, the fact that they have been observed is cited as evidence for the assumption that the surface structures of the samples prepared, as previously described, correspond to a considerable extent to that of a fairly well-ordered surface lattice.

IV. CONCLUSIONS

It is believed that thin relatively undistorted single crystal plates of copper can be prepared from large single crystals. A suitable process of mounting and electropolishing is described, as well as a sample holder to facilitate orientation determination and sectioning. There is evidence to believe that the surfaces are essentially planar and that the surface atoms exist in an orientation corresponding to a considerable extent to that characteristic of parallel crystallographic planes in the matrix of the crystal.

Theory of the Parallel Plane Diode

A. H. Taub and Nelson Wax
University of Illinois, Urbana, Illinois
(Received March 10, 1950)

Transient and steady state solutions of the parallel plane diode are obtained. The limitations on a single valued velocity theory are investigated. These general results are applied to the space charge limited diode with the a.c. components small compared to the d.c. Power consumption is discussed and it is shown that hitherto neglected terms are of importance.

I. INTRODUCTION

THE parallel plane diode has been the subject of a large number of investigations, both theoretical and experimental.[1–6] A good deal of attention has been centered on problems concerning the behavior of the plane diode when both space charge and time-varying fields are present. These latter studies usually[4–6] have employed perturbation techniques: the time-varying quantities were assumed to be first-order corrections on the static quantities.

It is the purpose of this paper to discuss the theory of the plane diode when a time dependent current density flows between the cathode and plate. The following assumptions are made throughout: (1) The diode consists of an infinite plane cathode parallel to an infinite plane anode (edge effects are ignored). (2) The magnetic effects of the moving electrons are neglected.

Under these assumptions the fundamental equations are reduced to dimensionless form in II. The transient behavior of the diode is treated in III, and it is shown that the differential equations of the system may be solved by quadratures if the initial position, x^0, and velocity, v^0, of every electron is known at the time, $t=0$, when the current starts to flow. The steady state behavior is discussed in IV; the equations may be integrated directly again when ξ, the time of emission of an electron from the cathode, and t, the time, are chosen as independent variables. The necessary and sufficient condition that the electron trajectories shall not intersect is obtained as an immediate consequence of this formulation. The electron transit time and the plate voltage are given as functions of ξ and t, in V and VI, respectively. The treatment in these, and in subsequent sections, is restricted to a small signal analysis of the space charge limited diode. Fourier expansions for all the quantities which were discussed in earlier sections are given in VII, and these expansions are used in VIII to obtain an expression for the average power consumption of the diode per unit area. It is shown that the notion of complex impedance as used by previous workers is insufficient alone to account for all the power consumed by the diode.

All dimensional equations are in m.k.s. units.

II. THE FUNDAMENTAL EQUATIONS

The plane diode is described by the following three differential equations. The equation of motion of an electron in the diode is

$$(d^2x'/dt'^2)=(e/m)E', \tag{2.1}$$

where x' is the distance of the electron from the cathode, t' the time, E' the electric field intensity, and e/m the charge to mass ratio of an electron.

The equation of conservation of charge is

$$\partial(\rho'v')/\partial x'+\partial\rho'/\partial t'=0 \tag{2.2}$$

with ρ' the charge density and v' the velocity of the electrons associated with ρ'. $v'=dx'/dt'$.

Poisson's equation takes the form

$$\partial E'/\partial x'=\rho'/\epsilon_0. \tag{2.3}$$

ϵ_0 is the dielectric constant of free space $=1/36\pi\times10^{-9}$ farad per meter.

The total current density, I, is defined by

$$I=\rho'v'+\epsilon_0(\partial E'/\partial t'). \tag{2.4}$$

The first term in the right-hand member of Eq. (2.4) is the conduction current density and the second is the displacement current density. It is of particular note that I is a function of t' alone, and not of x'. This result may be obtained by substituting ρ', from Eq. (2.3), into Eq. (2.2) and using the definition for I (see Eq. 3.14).

If I is a periodic function of t', with period τ, then one can introduce the dimensionless set of variables

$$x=x'/a, \tag{2.5}$$

and

$$t=t'/\tau, \tag{2.6}$$

[4] H. W. König, Hochfrequenztech. u. Elektroakustik 62, 76 (1943).
[5] F. Gray of the Bell Telephone Laboratories Inc. has obtained the general solution of the diode equations by a different method in an unpublished memorandum dated 11/11/41. This material was presented as an invited paper "The general solution for an electron stream in a parallel plane diode" at the 266th meeting of the Am. Phys. Soc. June 15–16, 1945. Gray did not interpret his solutions in the fashion presented here. König (reference 4) has used an approach which is similar to, but more restricted than, Gray's in discussing the system of differential equations (2.11)–(2.13).
[6] H. W. König, *Laufzeittheorie der Elektronenrohren* (Verlag. Julius Springer, Vienna, 1948), Vol. 1.

where a is the distance between the cathode and plate of the diode.

The total current density may now be written as

$$I = I_0[1+\mu f(t)] = I_0 h(t). \tag{2.7}$$

I_0 and μ are constants, and $f(t)$ is an arbitrary periodic function of period one in t (τ in t'), and of maximum absolute value one. I_0 is thus the direct current density, and μI_0 is the maximum amplitude of the time dependent current density.

The dimensionless quantities v, E, and ρ are defined by

$$v = (\tau/a)v', \tag{2.8}$$

$$E = (\epsilon_0/\tau I_0)E' \tag{2.9}$$

and

$$\rho = (a/\tau I_0)\rho', \tag{2.10}$$

respectively. Equations (2.1) to (2.3) may be written in dimensionless form as

$$d^2x/dt^2 = (6/\kappa^3)E, \tag{2.11}$$

$$\partial(\rho v)/\partial x + \partial\rho/\partial t = 0, \tag{2.12}$$

and

$$\partial E/\partial x = \rho, \tag{2.13}$$

respectively. $\kappa^3 = (6am\epsilon_0/eI_0\tau^3)$ is a dimensionless constant.

III. THE TRANSIENT CASE

Let the position x^0 and the velocity v^0 of every electron be known, in the region between cathode and plate, at the time $t=0$, the instant at which the known current I starts to flow. At time $t=t_1$ the electron which emerged from the cathode at $t=0$ will be collected at the plate. It is the object of this section to study the behavior of those electrons which were in the anode-cathode region, at $t=0$, in the time interval $0 \leq t \leq t_1$.

If x^0 is known, then ρ^0, the density distribution of the electrons at $t=0$, is known. Note that $v^0 = v^0(x^0)$ and $\rho^0 = \rho^0(x^0)$. The subsequent position of any electron may be represented by

$$x = x(x^0, t), \tag{3.1}$$

where x^0 is its position at $t=0$.

Equation (3.1) together with the equation

$$t = t \tag{3.2}$$

may be considered as a transformation of coordinates from the variables x, t to the variables x^0, t. The velocity of every electron may be considered to be a function of both x^0 and t. Indeed Eq. (3.1) is the solution of

$$dx/dt = v(x^0, t). \tag{3.3}$$

Furthermore, if one fixes one's attention on any individual electron, then one has, using Eqs. (3.1) and (3.3), that

$$dx/dt = \partial x/\partial t = v(x^0, t), \tag{3.4}$$

since x^0 is fixed for each electron.

The matrix, M, of the Jacobian of the transformation defined by Eqs. (3.1) and (3.2) is

$$M = \begin{Vmatrix} \partial x/\partial x^0 & \partial x/\partial t \\ 0 & 1 \end{Vmatrix} = \begin{Vmatrix} \partial x/\partial x^0 & v \\ 0 & 1 \end{Vmatrix}. \tag{3.5}$$

The matrix, M', of the Jacobian of the inverse transformation (i.e., the transformation which gives x^0 and t in terms of x and t) is

$$M' = \begin{Vmatrix} \partial x^0/\partial x & \partial x^0/\partial t \\ 0 & 1 \end{Vmatrix} = \begin{Vmatrix} \dfrac{1}{\partial x/\partial x^0} & -\dfrac{v}{\partial x/\partial x^0} \\ 0 & 1 \end{Vmatrix}. \tag{3.6}$$

Thus, for any function $F(x, t)$ one has

$$\frac{\partial F}{\partial x} = \frac{\partial F}{\partial x^0}\frac{\partial x^0}{\partial x} = \frac{\partial F}{\partial x^0}\frac{1}{\partial x/\partial x^0} \tag{3.7}$$

and

$$\frac{\partial F}{\partial t} = -\frac{v}{\partial x/\partial x^0}\frac{\partial F}{\partial x^0} + \frac{dF}{dt}. \tag{3.8}$$

The notation dF/dt used in Eq. (3.8) is to denote the derivative of F with respect to t keeping x^0 constant, i.e., following a particular electron along its path. Furthermore,

$$\frac{dF}{dt} = \frac{\partial F}{\partial t} + v\frac{\partial F}{\partial x}, \tag{3.9}$$

when the variables x and t are used.

The equation of the conservation of charge is equivalent to the statement,

$$\frac{\partial x}{\partial x^0} = \frac{\rho^0(x^0)}{\rho}, \tag{3.10}$$

if x is a unique function of x^0 and conversely that x^0 is a unique function of x. One assumes, in writing Eq. (3.10), that M, and therefore M', are non-singular. This implies that electron trajectories cannot cross or touch each other.

The Poisson equation now takes the form

$$\partial E/\partial x^0 = \rho^0(x^0), \tag{3.11}$$

and the equation of motion remains unchanged

$$d^2x/dt^2 = (6/\kappa^3)E. \tag{3.12}$$

The general solution of Eq. (3.11) is

$$E = \int_0^{x^0} \rho^0(\eta)d\eta + g(t) + E_0, \tag{3.13}$$

where E_0 is the electric field intensity at $x^0=0$ and $g(t)$ is an arbitrary function of time. The particular solution

for the diode may be obtained by noting that

$$\frac{dE}{dt}=\frac{\partial E}{\partial x}v+\frac{\partial E}{\partial t}=\rho v+\frac{\partial E}{\partial t}=\frac{I}{I_0}=\frac{dg}{dt}=h(t). \quad (3.14)$$

$h(t)$ is a function of t alone, as was mentioned previously. Thus

$$E=\int_0^t h(t')dt'+\int_0^{x^0}\rho^0(\eta)d\eta+E_0 \quad (3.15)$$

for the diode. Equation (3.12) may be integrated directly. One has

$$\frac{\kappa^3}{6}v=\int_0^t\int_0^{t'}h(t'')dt''dt'+t\left(\int_0^{x^0}\rho^0(\eta)d\eta+E_0\right)+\frac{\kappa^3}{6}v^0(x^0), \quad (3.16)$$

where $v^0(x^0)=v(x^0,0)$, and

$$\frac{\kappa^3}{6}x=\int_0^t\int_0^{t'}\int_0^{t''}h(t''')dt'''dt''dt'+\frac{t^2}{2}\left(\int_0^{x^0}\rho^0(\eta)d\eta+E_0\right)+\left[tv^0(x^0)+x^0\right]\frac{\kappa^3}{6}. \quad (3.17)$$

ρ may be obtained from Eqs. (3.17) and (3.10) if desired.

The above solution was obtained under the assumption that M is non-singular. However those electrons which were at the cathode, $x^0=0$, at $t=0$ have orbits which differ; $x^0=0$ is a singular point, therefore, and the solution is inapplicable for electrons emitted when $t>0$. Equations (3.15) to (3.17) are valid only when $0<x^0\leq 1$. The orbit of the electron emitted at $t=0$ can be obtained by a limiting operation:

$$x(t)=\lim_{x^0\to 0}x(x^0,t). \quad (3.18)$$

IV. THE STEADY STATE CASE

Those electrons which are emitted from the cathode for $t>0$ were not under consideration in the previous section but will be studied now. The transformation given by Eqs. (3.1) and (3.2) proved to be singular at the cathode, and it is necessary to use some other variable rather than the initial positions of the electrons, to distinguish them. If the dimensionless variable ξ is chosen, corresponding to the time when an electron is emitted from the cathode, then any electron's orbit is described by

$$x=x(\xi,t). \quad (4.1)$$

One uses the equation

$$t=t \quad (4.2)$$

again, and the pair of equations, (4.1) and (4.2), yield an analogous transformation to Eqs. (3.1) and (3.2). All the preceding formulas apply when x^0 is replaced by ξ.

Equation (3.15) becomes

$$E(\xi,t)=\int_\xi^t h(t')dt'+E_0(\xi), \quad (4.3)$$

where $E_0(\xi)$ is the electric field intensity at the cathode ($t=\xi$). Similarly

$$\frac{\kappa^3}{6}v(\xi,t)=\int_\xi^t\int_\xi^{t'}h(t'')dt''dt'+(t-\xi)E_0(\xi)+v_0(\xi)\kappa^3/6=\int_\xi^t(t-t')h(t')dt'+(t-\xi)E_0(\xi)+v_0(\xi)\kappa^3/6 \quad (4.4)$$

is the solution for $v(\xi,t)$ when $v_0(\xi)$ is the velocity with which electrons are emitted from the cathode.

The orbit is given by

$$\frac{\kappa^3}{6}x(\xi,t)=\int_\xi^t\int_\xi^{t'}\int_\xi^{t''}h(t''')dt'''dt''dt'+\frac{(t-\xi)^2}{2}E_0(\xi)+(t-\xi)v_0(\xi)\kappa^3/6=\int_\xi^t\frac{(t-t')^2}{2}h(t')dt'+\frac{(t-\xi)^2}{2}E_0(\xi)+(t-\xi)v_0(\xi)\kappa^3/6 \quad (4.5)$$

since $x(\xi,\xi)=0$; namely, this corresponds to the cathode.

The matrix of the transformation given by Eqs. (4.1) and (4.2) is non-singular if and only if

$$\partial x/\partial\xi\neq 0. \quad (4.6)$$

Equations (4.6) and (4.5) lead to the condition† that

$$-\frac{(t-\xi)^2}{2}\left[h(\xi)-\frac{dE_0(\xi)}{d\xi}\right]+(t-\xi)\left[\frac{\kappa^3}{6}\frac{dv_0(\xi)}{d\xi}-E_0(\xi)\right]-\frac{\kappa^3}{6}v_0(\xi)\neq 0 \quad (4.7)$$

for all t and ξ with $t\neq\xi$, since at the cathode all orbits intersect. If $E_0(\xi)$ and $v_0(\xi)$ are constant in time then (4.7) becomes

$$\frac{\kappa^3}{6}v_0(\xi)+\frac{(t-\xi)^2}{2}h(\xi)+(t-\xi)E_0(\xi)\neq 0. \quad (4.8)$$

† J. Müller (reference 2) has obtained this as a sufficient condition by different methods.

The subsequent discussion will apply only to the space charge limited diode, for which

$$E_0(\xi)=v_0(\xi)\equiv 0. \tag{4.9}$$

One has then that orbits will not intersect away from the cathode ($t\neq\xi$) if and only if

$$I(\xi)\neq 0. \tag{4.10}$$

Whenever the current density is represented by Eq. (2.7) then it follows from (4.10) that

$$\mu<1 \tag{4.11}$$

is the necessary and sufficient condition that any two electron orbits shall not have a point in common in the space between cathode and plate.

The inequality (4.11) will be assumed throughout the remainder of this paper.

The space charge density distribution for the space charge limited diode is, from Eq. (2.13),

$$\rho(\xi,t)=\frac{\partial E}{\partial x}=\frac{\partial E}{\partial \xi}\Big/\frac{\partial x}{\partial \xi}=-h(\xi)\Big/\frac{\partial x}{\partial \xi}, \tag{4.12}$$

or

$$\rho(\xi,t)=\frac{2\kappa^3}{6(t-\xi)^2}. \tag{4.13}$$

Whenever ξ is known as a function of x and t, then ρ can be given in terms of these variables. The dependence of ξ on x and t is obtained from the inversion of Eq. (4.5), an operation which is feasible, generally, by using graphical or numerical methods.

V. TRANSIT TIME

The time which is required for an electron to travel the distance between cathode and plate is defined as the transit time. Let ξ_1 be the time at which an electron emerges from the cathode, and t the time at which it arrives at the plate; then

$$\frac{\kappa^3}{6}=\int_{\xi_1}^{t}\frac{(t-t')^2}{2}h(t')dt', \tag{5.1}$$

since $x=1$ is the coordinate of the plate, by Eq. (2.5). Equation (5.1) determines ξ_1, when $h(t)$ is known.

By definition the transit time T is

$$T=t-\xi_1. \tag{5.2}$$

If $h(t)$ is of the form given by Eq. (2.7) then Eq. (5.1) becomes

$$\kappa^3=(t-\xi_1)^3+3\mu\int_{\xi_1}^{t}(t-t')^2f(t')dt'. \tag{5.3}$$

Furthermore, if one considers the static diode, in which the current is constant, then Eq. (5.3) reduces to the Child-Langmuir solution

$$T=\kappa. \tag{5.4}$$

It is necessary to invert Eq. (5.1) for ξ_1 in order that T be known explicitly. One important property of T may be deduced without performing the inversion: if $h(t)$ is periodic then T will be periodic and of the same period.

The dimensionless period is unity and therefore

$$\begin{aligned}\frac{\kappa^3}{6}&=\int_{\xi_1(t+1)}^{t+1}\frac{(1+t-t')^2}{2}h(t')dt'\\&=\int_{\xi_1(t+1)-1}^{t}\frac{(t-t'')^2}{2}h(t''+1)dt''\\&=\int_{\xi_1(t+1)-1}^{t}\frac{(t-t'')^2}{2}h(t'')dt''\\&=\int_{\xi_1(t)}^{t}\frac{(t-t')^2}{2}h(t')dt'.\end{aligned} \tag{5.5}$$

It follows that

$$T(t+1)=t+1-\xi_1(t+1)=t-\xi_1(t)=T(t). \tag{5.6}$$

ξ_1, and hence T, may be obtained explicitly when μ is small. One expands ξ_1 in a MacLaurin series

$$\xi_1=\xi_0+\mu\left(\frac{d\xi_1}{d\mu}\right)_0+\frac{\mu^2}{2!}\left(\frac{d^2\xi_1}{d\mu^2}\right)_0+\cdots, \tag{5.7}$$

where the derivatives are evaluated at $\mu=0$, as is denoted by the subscript zero.

$$\xi_0=t-\kappa. \tag{5.8}$$

All the derivatives may be obtained from Eq. (5.3). For example, the first derivative is

$$\frac{d\xi_1}{d\mu}=\frac{\int_{\xi_1}^{t}(t-t')^2f(t')dt'}{(t-\xi_1)^2[1+\mu f(\xi_1)]} \tag{5.9}$$

with

$$\left(\frac{d\xi_1}{d\mu}\right)_0=\frac{\int_{\xi_0}^{t}(t-t')^2f(t')dt'}{\kappa^2}. \tag{5.10}$$

VI. THE PLATE VOLTAGE

At any fixed instant of time an electric field intensity exists at every point between cathode and plate. Minus one times the integral of this intensity with respect to distance, between two points, is defined as the voltage difference between these points for the fixed time under

consideration. Thus the plate voltage is, by definition,

$$V'(t')=-\int_0^a E'(x', t')dx'$$
$$=-\frac{a\tau I_0}{\epsilon_0}\int_0^1 E(x, t)dx=\frac{a\tau I_0}{\epsilon_0}V(t), \quad (6.1)$$

where the integrals are evaluated for the fixed time, t.

The dimensionless plate voltage, $V(t)$, may be written as

$$V(t)=\frac{3}{\kappa^3}\int_{\xi_1(t)}^t E(\xi, t)(t-\xi)^2h(\xi)d\xi. \quad (6.2)$$

As before, $V(t)$ will be periodic with the same period as $h(t)$, if $h(t)$ is periodic. One has

$$V(t+1)=\frac{3}{\kappa^3}\int_{\xi_1(t+1)}^{t+1} E(\xi, t+1)(t+1-\xi)^2h(\xi)d\xi$$
$$=\frac{3}{\kappa^3}\int_{\xi_1(t+1)-1}^t E(\eta+1, t+1)$$
$$\times(t-\eta)^2h(\eta+1)d\eta=V(t). \quad (6.3)$$

Use has been made of the periodicity of the transit time, and of the equation

$$E(\xi+1, t+1)=E(\xi, t), \quad (6.4)$$

which can be verified readily by referring to Eq. (4.3) and noting the $E_0(\xi)=0$.

Equation (6.2) is an expression for the voltage in terms of the known current density. The inverse relation is desired in many problems, that is, the dependence of the current on the voltage. Unfortunately the inversion of Eq. (6.2) involves the inversion of Eq. (5.1), which presents considerable analytical difficulty if the current density is an arbitrary function of time. These difficulties may disappear under some circumstances, but this problem will not be treated. The current density is assumed to be known.

The MacLaurin expansion for $V(t)$ is

$$V(t)=V_0+\mu\left(\frac{dV}{d\mu}\right)_0+\frac{\mu^2}{2!}\left(\frac{d^2V}{d\mu^2}\right)_0+\cdots \quad (6.5)$$

with

$$V_0=\frac{3}{\kappa^3}\int_{\xi_0}^t(t-\xi)^3d\xi=\frac{3\kappa}{4}. \quad (6.6)$$

The subscript notation is the one employed before, in Section V. The first derivative can be calculated by using Eqs. (6.2) and (5.9). One obtains

$$\frac{\kappa^3}{3}\frac{dV}{d\mu}=\int_{\xi_1}^t(t-\xi)^2\left[\frac{dE}{d\mu}h(\xi)+E\frac{dh}{d\mu}\right]d\xi$$
$$-E(\xi, t)\int_{\xi_1}^t(t-\xi)^2\frac{dh}{d\mu}d\xi. \quad (6.7)$$

This may be simplified by integrating by parts twice. The result is

$$\frac{\kappa^3}{6}\frac{dV}{d\mu}=\int_{\xi_1}^t[1+\mu f(\xi)]\int_\xi^t(t-t')$$
$$\times\int_{t'}^t f(t'')dt''dt'd\xi, \quad (6.8)$$

with

$$\frac{\kappa^3}{6}\left(\frac{dV}{d\mu}\right)_0=\int_{\xi_0}^t\int_\xi^t\int_{t'}^t(t-t')f(t'')dt''dt'd\xi$$
$$=\int_{\xi_0}^t\int_\xi^t(t-t')\mathcal{E}(t', t)dt'd\xi, \quad (6.9)$$

where

$$\mathcal{E}(\xi, t)=\int_\xi^t f(t')dt'.$$

The second derivative is given ultimately by

$$\frac{\kappa^3}{6}\frac{d^2V}{d\mu^2}=\frac{2}{(t-\xi_1)^2}\left[\int_{\xi_1}^t(t-t')\int_{t'}^t f(t'')dt''\right]^2$$
$$-\int_{\xi_1}^t(t-\xi)\mathcal{E}^2(\xi, t)d\xi, \quad (6.10)$$

with

$$\frac{\kappa^3}{6}\left(\frac{d^2V}{d\mu^2}\right)_0=\frac{2}{\kappa^2}\left[\int_{\xi_0}^t(t-\xi)\mathcal{E}(\xi, t)d\xi\right]^2$$
$$-\int_{\xi_0}^t(t-\xi)\mathcal{E}^2(\xi, t)d\xi. \quad (6.11)$$

Higher derivatives may be obtained in a similar fashion.

VII. FOURIER EXPANSIONS

Fourier expansions are given in this section for the electric field intensity, the position of an electron, various derivatives of the voltage, and for an auxiliary function of some usefulness in later discussions, when the Fourier series for the current density is known.

It should be remarked first that there is no loss in generality in taking $f(t)$ a periodic function of period one and zero mean. One may write then

$$f(t)=\sum_{-\infty}^{\infty}f_ne^{i\omega_nt}=\sum_{n=1}^{\infty}a_n\cos\omega_nt+b_n\sin\omega_nt \quad (7.1)$$

with $\omega_n=2\pi n$ and $f_0=0$. Since $f(t)$ is a real function of the real variable t, then f_n and f_{-n} are conjugate complex quantities, and the a_n and b_n are real.

Equation (4.3) becomes

$$\mathcal{E}(\xi, t)=\sum_{-\infty}^{\infty}\frac{f_n}{i\omega_n}(e^{i\omega_nt}-e^{i\omega_n\xi}). \quad (7.2)$$

The position x is given by

$$\frac{\kappa^3}{6}x(\xi,t)=\frac{(t-\xi)^3}{6}+\mu\sum_{-\infty}^{\infty}\frac{if_n}{\omega_n}e^{i\omega_n t}\left[\frac{(t-\xi)^2}{2}e^{-i\omega_n(t-\xi)}-\frac{i}{\omega_n}(t-\xi)e^{-i\omega_n(t-\xi)}+\frac{1}{\omega_n^2}(1-e^{-i\omega_n(t-\xi)})\right]. \quad (7.3)$$

It is convenient to introduce the function $G(\xi, t)$, defined by

$$G(\xi,t)=\int_\xi^t\int_{t'}^t(t-t')f(t'')dt''dt'=\int_\xi^t(t-t')\mathcal{S}(t',t)dt'. \quad (7.4)$$

Its Fourier series is

$$G(\xi,t)=\sum_{-\infty}^{\infty}-\frac{if_n}{\omega_n}e^{i\omega_n t}\left[\frac{(t-\xi)^2}{2}-\frac{i(t-\xi)}{\omega_n}\times e^{-i\omega_n(t-\xi)}+\frac{1}{\omega_n^2}(1-e^{-i\omega_n(t-\xi)})\right] \quad (7.5)$$

with

$$G(\xi_0,t)=\sum_{-\infty}^{\infty}B_n e^{i\omega_n t}, \quad (7.6)$$

$$B_n=-\frac{if_n}{\omega_n}\left[\frac{\kappa^2}{2}-\frac{i\kappa}{\omega_n}e^{-i\omega_n\kappa}+\frac{1}{\omega_n^2}(1-e^{-i\omega_n\kappa})\right]. \quad (7.7)$$

It follows from Eqs. (7.4) and (6.9) that

$$\frac{\kappa^3}{6}\left(\frac{dV}{d\mu}\right)_0=\int_{\xi_0}^t G(\xi,t)d\xi=\sum_{-\infty}^{\infty}-\frac{if_n}{\omega_n}e^{i\omega_n t}\left[\frac{\kappa^3}{6}+\frac{\kappa}{\omega_n^2}(1+e^{-i\omega_n\kappa})+\frac{2i}{\omega_n^3}(1-e^{-i\omega_n\kappa})\right]. \quad (7.8)$$

The Fourier series for the second derivative will not be given in detail. As can be seen from Eq. (6.11) and the definition for $G(\xi, t)$ given above, the second derivative contains the square of the series for $G(\xi, t)$ and an additional series. This last expansion may be written as

$$\int_{\xi_0}^t(t-\xi)\mathcal{S}^2(\xi,t)d\xi=\sum_{-\infty}^{\infty}G_n e^{i\omega_n t}, \quad (7.9)$$

where

$$G_n=\sum_{-\infty}^{\infty}-\frac{f_r f_{n-r}}{\omega_n\omega_{n-r}}\left\{\frac{\kappa^2}{2}-i\kappa\left[\frac{e^{-i\omega_r\kappa}}{\omega_r}+\frac{e^{-i\omega_{n-r}\kappa}}{\omega_{n-r}}-\frac{e^{-i\omega_n\kappa}}{\omega_n}\right]-\left[\frac{e^{-i\omega_r\kappa}-1}{\omega_r^2}+\frac{e^{-i\omega_{n-r}\kappa}-1}{\omega_{n-r}^2}-\frac{e^{-i\omega_n\kappa}-1}{\omega_n^2}\right]\right\}. \quad (7.10)$$

VIII. AVERAGE POWER

The power exchange between the d.c. and the a.c. components is of considerable interest. Earlier workers have shown that a negative resistance may occur if the diode is operating in a proper regime,[2-4,6] and a few self-excited oscillators have been built which make use of this phenomenon.[2-3] This section will be concerned with these questions.

The general expressions given above enable one to compute power for all $0\leq\mu<1$. As has been mentioned before, the analytic treatment is difficult when μ is not small. Attention will be restricted, therefore, to a small signal analysis.

The instantaneous power per unit area P' is defined as

$$P'=V'(t')I(t') \quad (8.1)$$

or

$$P'=\frac{a\tau I_0^2}{\epsilon_0}V(t)[1+\mu f(t)]=\frac{a\tau I_0^2}{\epsilon_0}P(t). \quad (8.2)$$

The average power per unit area, $\langle P'\rangle$, is the time average of P' over a cycle, and is given by

$$\langle P'\rangle=\frac{1}{\tau}\int_0^\tau P'(t')dt'=\frac{a\tau I_0^2}{\epsilon_0}\int_0^1 P(t)dt=\frac{a\tau I_0^2}{\epsilon_0}\langle P\rangle. \quad (8.3)$$

The MacLaurin series expansion for $\langle P\rangle$ is

$$\langle P\rangle=\langle P\rangle_0+\mu\left(\frac{d\langle P\rangle}{d\mu}\right)_0+\frac{\mu^2}{2!}\left(\frac{d^2\langle P\rangle}{d\mu^2}\right)_0+\cdots, \quad (8.4)$$

with the usual subscript notation.

The use of Eqs. (8.3), (6.9), and (6.11) yields the set of equations

$$\langle P\rangle=\frac{3\kappa}{4}, \quad (8.5)$$

$$\left(\frac{d\langle P\rangle}{d\mu}\right)_0=\int_0^1\left(\frac{dV}{d\mu}\right)_0dt+\int_0^1 V_0 f(t)dt=0, \quad (8.6)$$

$$\left(\frac{d^2\langle P\rangle}{d\mu^2}\right)_0=\int_0^1\left(\frac{d^2V}{d\mu^2}\right)_0dt+2\int_0^1\left(\frac{dV}{d\mu}\right)_0 f(t)dt. \quad (8.7)$$

Equation (8.6) states that the first-order correction to the d.c. power is zero. The second-order correction con-

tains two integrals which are, as will be shown, of comparable magnitude under certain conditions of diode operation. The first integral is the contribution to the power arising from the second-order correction to the voltage; it appears to have been neglected in previous discussions of diode theory. The second integral is the only contribution to the power which has been discussed in the literature. It may be interpreted as the diode "resistance" times the mean of the square of the alternating current.

The first integral is given by

$$\int_0^1 \left(\frac{d^2V}{d\mu^2}\right)_0 dt = 24\kappa \sum_{r=1}^{\infty} \frac{f_r f_{-r}}{\theta_r^4} \times\left[1-\frac{\theta_r^2}{4}+\frac{2}{\theta_r^2}(1-\cos\theta_r)-\frac{2\theta_r\sin\theta_r}{\theta_r^2}\right], \quad (8.8)$$

and the second by

$$\int_0^1 \left(\frac{dV}{d\mu}\right)_0 f(t)dt = 12\kappa \sum_{r=1}^{\infty} \frac{f_r f_{-r}}{\theta_r^4} \times[2(1-\cos\theta_r)-\theta_r\sin\theta_r], \quad (8.9)$$

where $\theta_r=\omega_r\kappa$.

Substituting Eqs. (8.8) and (8.9) into Eq. (8.7), one obtains

$$\left(\frac{d^2\langle P\rangle}{d\mu^2}\right)_0 = 24\kappa \sum_{r=1}^{\infty} \frac{f_r f_{-r}}{\theta_r^4}\left[1-\theta_r\sin\theta_r\left(1+\frac{2}{\theta_r^2}\right)+2(1-\cos\theta_r)\left(1+\frac{1}{\theta_r^2}\right)-\frac{\theta_r^2}{4}\right]. \quad (8.10)$$

The dimensionless quantity $\langle P\rangle$ is, therefore, to second-order

$$\langle P\rangle = \frac{3\kappa}{4}+12\mu^2\kappa \sum_{r=1}^{\infty} \frac{f_r f_{-r}}{\theta_r^4}\left[1-\theta_r\sin\theta_r\left(1+\frac{2}{\theta_r^2}\right)+2(1-\cos\theta_r)\left(1+\frac{1}{\theta_r^2}\right)-\frac{\theta_r^2}{4}\right], \quad (8.11)$$

or the average power per unit area is

$$\langle P'\rangle = \left(\frac{6a^4 I_0^5}{\epsilon_0^2}\frac{m}{e}\right)^{\frac{1}{2}}\left\{\tfrac{3}{4}+12\mu^2\sum_{r=1}^{\infty}\frac{f_r f_{-r}}{\theta_r^4} \times\left[1-\theta_r\sin\theta_r\left(1+\frac{2}{\theta_r^2}\right)+2(1-\cos\theta_r)\left(1+\frac{1}{\theta_r^2}\right)-\frac{\theta_r^2}{4}\right]\right. \quad (8.12)$$

Llewellyn[3] has treated the case $f_r=0$, $r\neq 1$ and obtained the reduced form of Eq. (8.10), aside from constants, as the expression for the "resistance" of the diode. However, Eq. (6.11) shows that the "resistance" (the real part of the complex impedance at a single frequency) times the mean of the square of the single frequency alternating current does not give the power at this frequency. The additional terms are given by Eq. (8.8).

For a given frequency the ratio λ of the total second-order correction to the power to the "resistance" term is given by one of (8.12) to one of (8.10). Thus,

$$\lambda = \frac{1-\theta_r\sin\theta_r[1+(2/\theta_r^2)]+2(1-\cos\theta_r)[1+(1/\theta_r^2)]-\theta_r^2/4}{2(1-\cos\theta_r)-\theta_r\sin\theta_r}. \quad (8.13)$$

For small values of θ_r this becomes

$$\lambda = \tfrac{5}{6}+O(\theta_r^2) \quad (8.14)$$

and the large values of θ_r

$$\lambda = O(\theta_r), \quad (8.15)$$

where $O(x)$ refers to the usual order of greatness.[7] Thus the terms neglected in the Llewellyn treatment dominate the "resistance" term in the expression for the power for large θ_r. Even for small θ_r the correction is about 16 percent.

High Frequency Impedance of Low Pressure Gaseous Diodes

CHAI YEH
*Department of Electrical Engineering, University of Kansas, Lawrence, Kansas**

E. L. CHAFFEE
Cruft Laboratory, Harvard University, Cambridge, Massachusetts
(Received March 20, 1950)

A simple theory of the lagging effect of the positive ions in neutralizing the space charge near the cathode of a gaseous diode is developed. By means of bridge measurement up to a frequency of 350 or 1000 kc per second, depending upon the type of tube used, the theory is checked experimentally in terms of the high frequency impedance of the diodes. Several constants of interest, such as the transit time and the lifetime of a positive ion, its effectiveness in neutralizing space charge, etc., can be deduced from the theoretical and experimental investigations.

I. INTRODUCTION

WHEN a conducting path of electricity possesses quantities which cause a lag and lead of an alternating current with respect to the voltage, the effect is ordinarily expressed in terms of inductive or capacitive reactance. This characteristic of a conductor may result from the inertia of the carriers of the charge wholly irrespective of any ordinary inductance or capacitance which the circuit may contain. Llewellyn[1] has treated the effects of the inertia of the electron at very high frequencies in modifying the conduction characteristics of high vacuum tubes. A similar inertia effect may be observed at low frequencies in the conduction through a gaseous vacuum tube. The reactance of the conduction path in this case results from the inertia of the positive ions. An interesting case of this type of conduction with inertia effects is described in this paper. A simple theory of the effect will first be presented and then experimental measurements on several soft tubes will be given to show that the theory at least approximately describes the effects observed. Certain fundamental quantities pertaining to the conduction process can be approximately determined from the experimental results.

The case to be treated is that of a cylindrical diode containing a trace of gas. The d.c. polarizing potential is adjusted to be slightly greater than the ionization potential of the gas and a small superimposed a.c. voltage is applied. The object is to find the equivalent a.c. resistance and reactance of the diode as a function of frequency.

The conditions assumed in the analysis are as follows: The static characteristic curve of the soft diode is of the type shown in Fig. 1, where $\bar{E}_i$ is the ionization potential. The increase in current above the normal space-charge limited current when the impressed potential exceeds $\bar{E}_i$ is assumed to be due to the partial neutralization of space charge near the cathode by positive ions. The current carried by positive and negative ions is assumed negligible.

The instantaneous anode current i at time t is not only a function of the instantaneous anode potential e but is also a function of the applied anode potential at a previous time $t-\tau$ denoted by $e_{t-\tau}$. The reason for the latter effect is that positive ions produced near the anode at time $t-\tau$ requires time τ to reach the space near the cathode where they neutralize some of the negative space charge. Expressed analytically,

$$i=f(e, e_{t-\tau}). \tag{1}$$

Equation (1) can be expressed in terms of n, the number of positive ions existing at time t in the cathode space. Then

$$i=F(e, n). \tag{2}$$

Since n does not depend upon e but is a function of $e_{t-\tau}$, e and n can be considered as independent variables. Then the differential of Eq. (2) is

$$di=(\partial i/\partial e)_n de+(\partial i/\partial n)_e dn=Kde+Gdn, \tag{3}$$

where $K\equiv(\partial i/\partial e)_n$, and is the slope of the $i-e$ curve for a constant number of positive ions, and $G\equiv(\partial i/\partial n)_e$, and is the effectiveness of partial neutralization of space charge by the positive ions at constant e.

II. CALCULATION OF THE NUMBER OF POSITIVE IONS

The evaluation of the current by Eq. (3) requires a knowledge of the number of positive ions, n at time t.

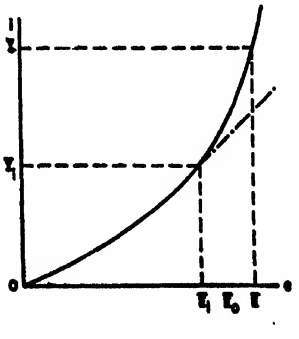

FIG. 1. Static characteristic curve of a gaseous diode. The dot-dash extension indicates the space-charge limited case in a high vacuum tube.

* Formerly, Cruft Laboratory, Harvard University, Cambridge, Massachusetts.

[1] F. B. Llewellyn, Proc. I. R. E. 21, 1532 (1933), 22, 947 (1934), 23, 112 (1935).

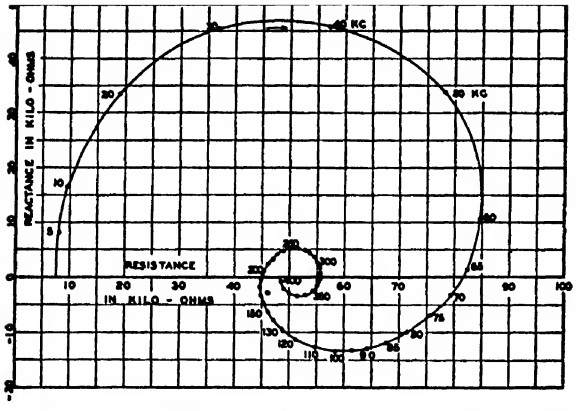

FIG. 2. Theoretical impedance curve of Type I, $B<K$, calculated with the following constants: $\bar{I}=0.2$ ma, $\bar{E}_0=1$ volt, $K=0.1955\cdot10^{-4}$ mhos, $P=0.1445\cdot10^{6}$ 1/volt²-sec., $\beta=0.401\cdot10^{5}$ 1/sec., $\tau=3.960\cdot10^{-6}$ sec. Frequency scale is spotted along the curve.

An expression for n will now be derived. Assume a cylindrical diode having an anode of radius a at potential e. The diode is assumed to contain a trace of gas which has an ionization potential $\bar{E}_i$. If $\bar{E}_i$ is slightly less than e, ionization occurs in a thin cylindrical space adjacent to the anode. The gas pressure is such that the mean free path of electrons is large compared with a.

Let $S(e_r)$ be the ionization coefficient at potential e_r, defined as the number of ions produced by one electron in traveling one centimeter at one-mm pressure. Then the number of ions produced by current i in time dt is

$$dN=(pi/10\epsilon)dt\int_{r_i}^{a}S(e_r)dr, \tag{4}$$

where p is the pressure in mm of mercury, i is the current in amperes, ϵ is the electronic charge in absolute e.m.u., and r_i is the radius corresponding to $\bar{E}_i$.

We shall assume a linear relation between e_r and r near the anode in the form $e_r=[(r-a)/g-1]e$, so that $dr=(g/e)de_r$. Furthermore, we shall assume a linear relation between $S(e_r)$ and e_r of the form $S(e_r)=b(e_r-\bar{E}_i)$. This latter relation is quite accurate for values of e_r not exceeding $2\bar{E}_i$. Using these relations, Eq. (4) becomes

$$dN=M(i/e)\cdot(e-\bar{E}_i)^2dt, \tag{5}$$

where

$$M=pgb/20\epsilon. \tag{6}$$

M is a constant for any given tube at constant pressure.

Equation (5) gives the number of positive ions produced in time dt near the anode. We shall indicate the mean transit time of a positive ion in traveling from anode to cathode by τ. Although some positive ions may strike the cathode, others miss the cathode and oscillate about it. We must therefore recognize a mean lifetime of positive ions in the cathode space. The decay of any elementary group dN in time t when near the cathode may be expressed by the relation

$$dn=dNe^{-\beta t}, \tag{7}$$

where β is the reciprocal of the mean lifetime of a positive ion as defined by Kingdon.[3] Multiplying Eq. (5) by (7) in which $t-\tau-\lambda$ is substituted for t, we have for the number of positive ions at time t,

$$n=\int_{-\infty}^{t-\tau}M(e_\lambda-\bar{E}_i)^2(i_\lambda/e_\lambda)e^{-\beta(t-\tau-\lambda)}d\lambda. \tag{8}$$

Now assume that $\bar{E}$ and $\bar{I}$ are the d.c. anode potential and anode current, where $\bar{E}$ is assumed to be just greater than $\bar{E}_i$. Let a small a.c. potential of angular frequency ω be superimposed on $\bar{E}$. Then

$$\begin{aligned}e&=\bar{E}+\Delta E\sin\omega t,\\ i&=\bar{I}+\Delta I\sin(\omega t-\phi).\end{aligned} \tag{9}$$

Substituting expressions (9) for e_λ and i_λ in (8) and

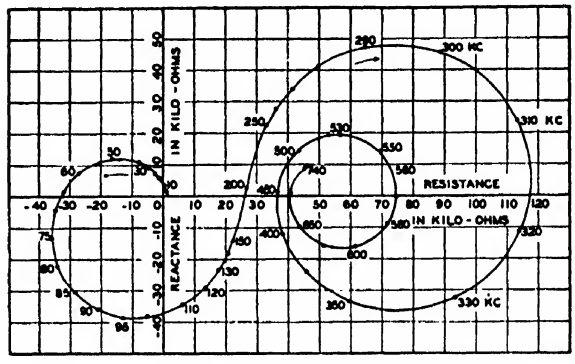

FIG. 3. Theoretical impedance curve of Type II, $B>K$, calculated with the same set of constants as the Type I curve except with $\bar{I}=1.5$ ma. The constants used in these calculations were actually determined from experimental data. The results check with each other very well up to 150 kc. Measurements at higher frequencies are lacking due to experimental difficulties.

integrating, we obtain n in the form $N+\Delta n$ plus high order terms. Retaining terms of fundamental frequency only and neglecting terms of the higher order of ΔE and ΔI, gives

$$\Delta n=\frac{\bar{E}_0M}{\bar{E}(\omega^2+\beta^2)^{\frac{1}{2}}}\{\Delta E\bar{I}(2-\bar{E}_0/\bar{E})\sin[\omega(t-\tau)-\theta]+\bar{E}_0\Delta I\cos[\omega(t-\tau)-\theta-\phi]\}, \tag{10}$$

where $\bar{E}_0=\bar{E}-\bar{E}_i$, $\theta=\tan^{-1}\omega/\beta$.

III. ALTERNATING CURRENT IMPEDANCE

We can now substitute (10) in (3) and equate to zero the coefficients of $\sin\omega t$ and $\cos\omega t$. Since $\sin\phi=X/Z$ and $\cos\phi=R/Z$, the values of R and X can be found and are

$$R=\frac{(K-BA)+(B-AK)\cos\delta}{K^2+B^2+2KB\cos\delta}, \tag{11}$$

$$X=\frac{(B+AK)\sin\delta}{K^2+B^2+2KB\cos\delta}, \tag{12}$$

[3] K. H. Kingdon, Phys. Rev. 21, 408 (1923).

$$Z^2=R^2+X^2=\frac{A^2-2A\cos\delta+1}{K^2+B^2+2KB\cos\delta}, \tag{13}$$

where

$$A=\frac{MG\bar{E}_0^2}{\bar{E}(\omega^2+\beta^2)^{\frac{1}{2}}}=\frac{P\bar{E}_0^2}{(\omega^2+\beta^2)^{\frac{1}{2}}}, \quad P=\frac{MG}{\bar{E}}, \tag{14}$$

$$B=\frac{MG\bar{E}_0\bar{I}}{\bar{E}(\omega^2+\beta^2)^{\frac{1}{2}}}\left(2-\frac{\bar{E}_0}{\bar{E}}\right)=\frac{P\bar{E}_0\bar{I}}{(\omega^2+\beta^2)^{\frac{1}{2}}}\left(2-\frac{\bar{E}_0}{\bar{E}}\right) \tag{15}$$

and

$$\delta=\omega\tau+\theta=\omega\tau+\tan^{-1}\omega/\beta. \tag{16}$$

It is interesting first to investigate the resistance and reactance at the two extreme frequencies, that is at zero and infinite frequencies. Substituting $\omega=0$, we have

$$\begin{aligned} X_0&=0,\\ \phi_0&=0,\\ R_0&=(1-A)/(K+B), \end{aligned} \tag{17}$$

where the zero subscript indicates the value at zero frequency. Here we find that the reactance is zero and the resistance is finite and positive as long as A is less than unity, which is true in practice. And for $\omega=\infty$, we have

$$\begin{aligned} X_\infty&=0,\\ \phi_\infty&=0,\\ R_\infty&=Z_\infty=1/K. \end{aligned} \tag{18}$$

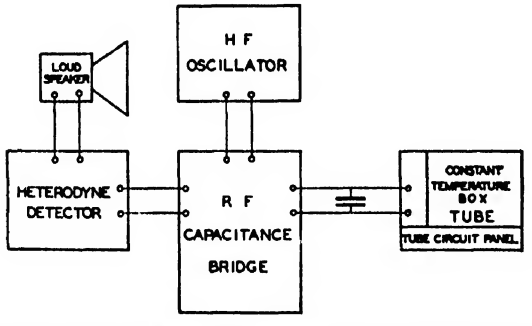

FIG. 4. Experimental set up for the measurement of high frequency impedance of a gaseous diode.

IV. THEORETICAL IMPEDANCE CURVES

Equations (11) and (12) represent the resistance and reactance components of the complex impedance of a gaseous diode. From Eqs. (14)–(16), it is seen that both the constants A and B and the transit angle δ are functions of frequency. An investigation of the frequency characteristics of this complex impedance can be made either by plotting R and X individually as a function of frequency, or by plotting the reactance against resistance. For the present discussion, the latter presentation is preferrable. As an aid in determining the shape of the impedance curve given by Eqs. (11) and (12), the intercepts on the R and X axis may first be found.

The intercepts on the X or vertical axis can be found by letting $R=0$, and solving Eqs. (11) and (12) simultaneously. The result is

$$X=\pm\left(\frac{1-A^2}{B^2-K^2}\right)^{\frac{1}{2}}, \ (R=0). \tag{19}$$

As A is always less than unity (which is required in order to have positive resistance at zero frequency), then $1-A^2$ is a positive quantity. If B^2 is greater than K^2, the term under the square root sign is real, and the positive and negative signs in front of it indicate the positive and negative intercepts on the X-axis corresponding to different frequencies. But if B^2 is less than K^2, the term under the square root sign becomes imaginary, which means that there are no intercepts.

The intercepts on the R or horizontal axis can be found by letting $X=0$ in Eqs. (11) and (12). Thus we have

$$R=(1+A)/(K-B), \quad (X=0). \tag{20}$$

It is seen that R can be either positive or negative according to whether K is greater or less than B, since both B and K are positive quantities. The above analysis leads to the discussion of two types of the impedance curves. They are very distinct in shape and are characterized by whether $B<K$ of $B>K$.

Type I, $B<K$.—In this case, the entire curve lies on the positive resistance side of the diagram, and there is no intercept on the X-axis. At low frequencies, the resistance is nearly constant while the inductive reactance increases with frequency. Above a certain frequency, both resistance and reactance change rapidly. The reactance changes from inductive to capacitive as $\sin\delta$ changes its sign. The resistance swings back and forth about the value of R at $\omega=\infty$ but remains positive. Both the resistance and reactance decrease in magnitude as ω increases and the curve spirals in a clockwise direction in towards the point corresponding to $1/K$ at $\omega=\infty$. This is indicated in Fig. 2, which is a plot of the theoretical curve of Type I for the following constants:

$\bar{I}=0.2$ ma $\quad \bar{E}_0=1$ volt, $\quad K=0.1955\cdot10^{-4}$ mhos,
$P=0.1445\cdot10^{5}$ 1/volt²-sec., $\quad \beta=0.401\cdot10^{5}$ 1/sec.,
$\tau=3.96\cdot10^{-6}$ sec.

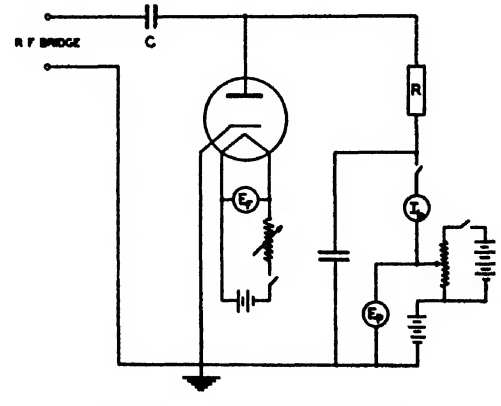

FIG. 5. Experimental tube circuit.

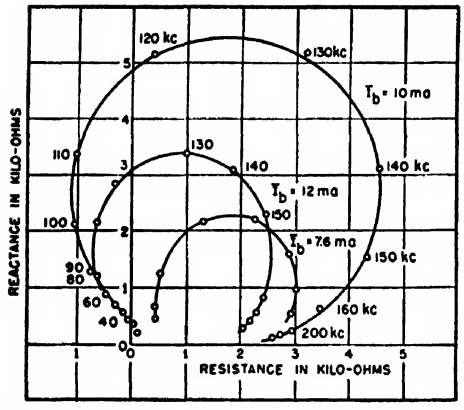

FIG. 6. Experimental impedance curve of a helium-filled diode.

Type II, for $B>K$.—For this type of curve, there are two intercepts on the X-axis which are $X=+[(1-A^2)/(B^2-K^2)]^{\frac{1}{2}}$ and $-[(1-A^2)/(B^2-K^2)]^{\frac{1}{2}}$ corresponding

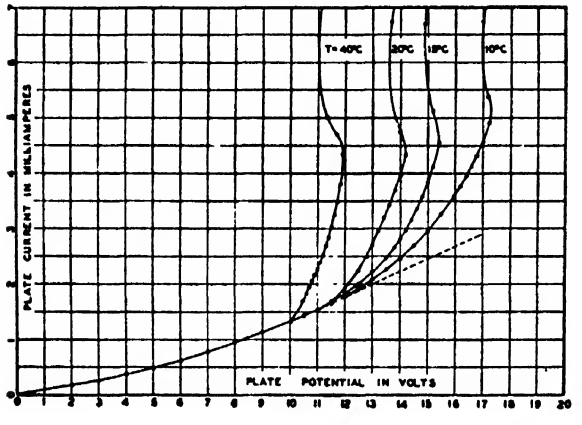

FIG. 7. Static characteristic curve of the experimental tube RK-100, containing mercury vapor.

to different frequencies. There is a negative intercept on the R-axis, which corresponds to a negative resistance. As K is a constant and a positive quantity, while B is a positive number but diminishes in magnitude as frequency increases, it is obvious that as the frequency increase further, B decreases and finally becomes less than K. Then the curve takes the form of Type I.

At very low frequencies, the resistance is positive and practically constant. As the frequency becomes greater, it decreases and becomes negative at certain frequencies and then returns to positive values progressing in a counter-clockwise direction along a spiral. For higher frequencies, an inflection point is reached and the curve spirals in a clockwise direction and the resistance varies in the manner of Type I. The entire curve of Type II is plotted in Fig. 3 for the same set of constants used for Type I curve except that $\bar{I}=1.5$ ma instead of 0.2 ma.

V. EXPERIMENT

In the theory developed so far, we made use of four unknown constants which may be determined experimentally from the intercepts of the experimental curves. These are τ, β, K, and $P(=MG/\bar{E})$. It is better to use P instead of A and B, since both A and B are derivable from P.

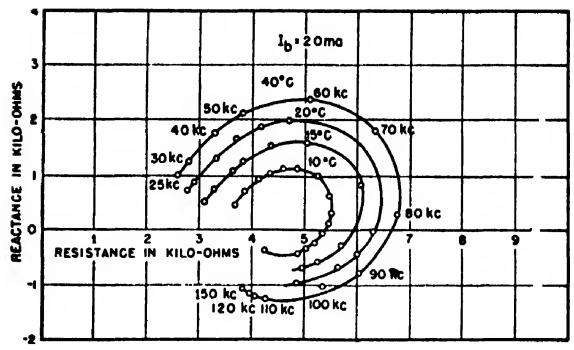

FIG. 8. Effect of gas pressure on the impedance curve at low anode current. Tube contains mercury vapor.

The general arrangement of the apparatus used for measuring the tube impedance is shown in Fig. 4. The entire set up consists of a high frequency bridge, a high frequency oscillator, a sensitive detector, and the tube circuit. The tube, whose impedance characteristic is to be measured, is mounted in a constant-temperature oil bath controlled by a thermostat. The complete tube circuit is shown in Fig. 5. In this circuit, C is a blocking condenser so as to isolate the d.c. anode potential from the bridge circuit. R is one of the several non-inductive resistances having ranges from several hundred to several hundred thousand ohms. The anode potential can be varied by battery taps and more precisely by the potential divider. The whole system is enclosed in a well-grounded aluminum box.

Before taking any measurement on the high frequency bridge, a d.c. static characteristic curve of the tube is taken. The compensation method is adopted for the measurement on the high frequency bridge. The anode potential of the tube to be measured is adjusted to a proper point on the d.c. characteristic. The output of the oscillator is kept low in order to conform to the assumption that the a.c. component is very much smaller than the d.c. values. For each frequency, the bridge is balanced by adjusting both the air condenser and the parallel resistance on the bridge. Two sets of readings are necessary; one with the anode potential of the tube on, and the other with it off. The first set of readings gives the tube admittance in parallel with that of the circuit, while the second set of readings gives the circuit admittance alone. The observed change in resistance and capacitance is that due to the tube impedance. The resistance and reactance thus measured are plotted and the intercepts on the real and imaginary axes are determined. Equations (17), (19), and (20) may then be used to evaluate the constants P, β, and K and Eq. (16) is used to calculate τ. A curve of Type II is required to provide enough intercepts to determine the four constants.

VI. RESULTS AND DISCUSSIONS

Measurements on several gaseous tubes were made. Some of the tubes were filled with helium gas, others with mercury vapor. The results obtained from the helium-filled tubes indicate that the time of flight of the positive ions is extremely small. A frequency range of from 30 to 1000 kc, is used in this experiment. The impedance curve thus obtained is plotted in Fig. 6. It is noticed that the reactance of this tube remains inductive even at extremely high frequencies. The resistance is negative during a small portion of the frequency range. But as the anode current is varied, both the resistance and reactance remain positive. The impedance curve of this tube is essentially of Type I, but has characteristics of the transition type between those of I and II where there are two positive values of X for zero values of R and where the spiraling is always clockwise. We were not able to increase the anode current $\bar{I}$ or the gas pressure sufficiently to obtain the anticlockwise spiral of Type II. The anode current saturates at a slightly higher operating point. It is therefore impossible to determine the constants of this tube.

The next group of tubes were filled with mercury vapor. Several special diodes were constructed by the Raytheon Manufacturing Company. They are cylindrical diodes with indirect-heated cathodes. The cathode radius is 0.075 cm and the anode radius is 1 cm. The d.c. characteristic curve of one of these tubes is shown in Fig. 7. The curves are taken at different temperatures of the bulb which determines the vapor pressure inside the tube. Above an anode current of 4.5 ma, a greenish glow starts and an abrupt increase of anode current results which is accompanied by a decrease in potential as is shown in the plots. All measurements were made at an anode current well below the glow discharge.

Figures 8 and 9 are taken for the purpose of illustrating the effect of varying the gas pressure on the impedance characteristics of the tube. In Fig. 8, the anode current is held constant at 2 ma, while in Fig. 9, it is held at 4 ma. It is noticed that for low anode current, the changing of gas pressure merely changes the dimension of the impedance curve without materially affecting its position or shape. These are shown as concentric curves in Fig. 8, and are essentially of Type I. For higher anode current, the variation of the gas pressure shows the evolution of the impedance curve from Type I to Type II. Figures 10 and 11 are taken for the purpose of illustrating the effect of changes of anode current on the impedance curve of the tube. Two sets of data were taken, one for low pressure and the other for high pressure. At low pressure, the shape of the impedance curve does not change very much and the increase of the anode current merely moves the curves towards lower resistance and reactance as shown in Fig. 10. For high pressures, the evolution of the impedance curves from Type I to Type II as the anode current increases is apparent as shown in Fig. 11. This time, the factor that affects B is the anode current. Hence both the anode current and the gas pressure are responsible for the change of shape of the impedance curve. For an anode current greater than 4 ma, and the bulb temperature higher than 40°C, the hiss inside the tube becomes so

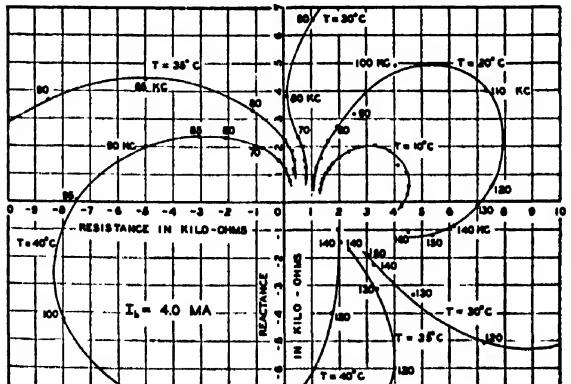

FIG. 9. Effect of gas pressure on the impedance curve at high anode current. Tube contains mercury vapor.

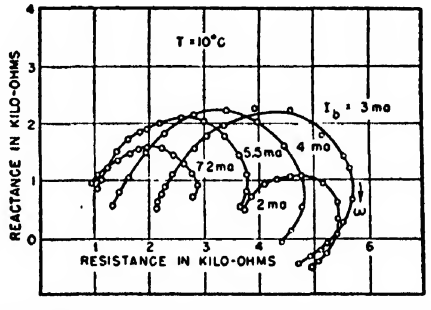

FIG. 10. Effect of anode current on the impedance curve at low gas pressure. Tube contains mercury vapor.

intense that bridge balance is difficult and inaccurate. Figure 12 is another plot of one of the curves in Fig. 11 (for $\bar{I}=4.0$ ma) together with the theoretical curve calculated from the constants preciously determined. The theoretical and experimental data are carried far into the higher frequency region in order to show the change over from an anticlockwise to clockwise rotation of the spiral as in the Type II curve.

For a typical operation corresponding to an anode current of 4.0 ma, and a mercury-vapor pressure corresponding to 40°C, the following constants were determined:

Typical operation condition	Intercepts from experimental data	Calculated constants
$\bar{E}=11.86$ volts	$R_0=350$ ohms	$K=0.239\cdot10^{-4}$ mhos
$\bar{E}_0=1.48$ volts	X (at $R=0$) $=1200$ ohms	$\beta=0.164\cdot10^{8}$ 1/sec.
$\bar{I}=4.0$ ma	R (at $X=0$) $=-7500$	$P=0.268\cdot10^{8}$ 1/V²-sec.
$T=40$°C	$\omega_1=2\pi50\cdot10^{3}$	$\tau=3.28\cdot10^{-6}$ sec.
	$\omega_2=2\pi90\cdot10^{3}$	

As an example of the application of these constants, the following computations are made. Knowing $1/\beta$, the

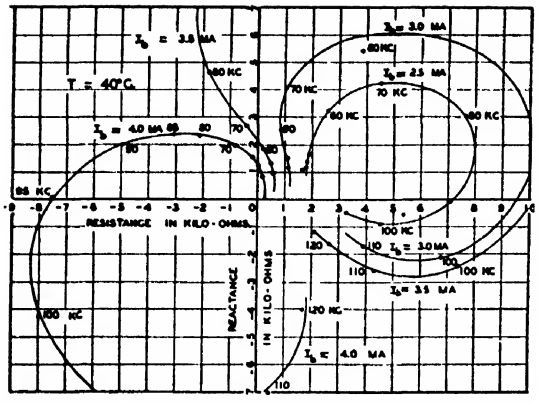

FIG. 11. Effect of anode current on the impedance curve at high gas pressure. Tube contains mercury vapor.

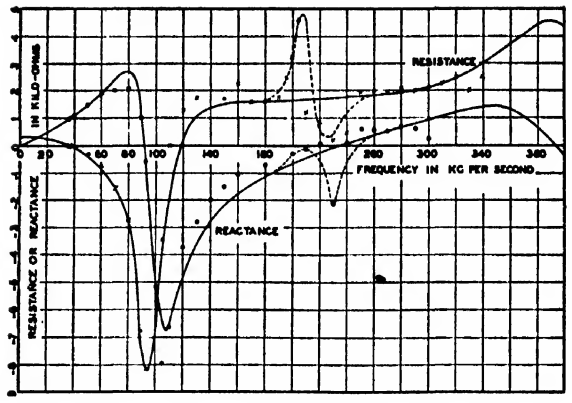

FIG. 12. Theoretical and experimental check of a typical operation: $\bar{E}=11.86$ volts, $\bar{E}_0=1.48$ volts, $\bar{I}=4.0$ ma, $T=40°$C. Theoretical curves are drawn in solid lines, the circles and crosses are the experimental values. Circles for reactance, crosses for resistance. The experiments and calculations were carried out to higher frequencies, up to 340 kc on this tube. The dotted curve indicates the region where hiss is excessive.

mean lifetime of the positive ions, we may proceed to calculate the average number of times that the positive ions circulate around the cathode provided that we know the equivalent radius of the circular path of the circulating ions. From the consideration that the centrifugal force of the moving ions are balanced by the force acting on the ions due to the electric field applied between the electrodes, and making use of γ, which is a function of r as given in Langmuir's paper,[3] the radius of the circulating path is

$$r_a=2\gamma^2/(d\gamma^2/dr_a). \tag{21}$$

This equation can best be solved by cut and try method. The solution is found for a cathode radius of 0.075 cm and is $r_a=0.080$ cm. The number of times that an ion circulates around the cathode is given by $N_a=v/2\pi r_a\beta$, where v is the velocity of the positive ions and is given by $v=(2E\epsilon/m_+)^{\frac{1}{2}}$. For a mercury ion, the average number of times that the ions circulate around the cathode for the conditions stated is 4.08 or roughly 4 times.

The constants P and β enable us to calculate approximately the average number of electrons that are neutralized by a single positive ion under the stated condition. From Eq. (7), it is seen that the rate of disappearance of positive ions is $dn/dt=-\beta N$. In order to maintain the steady state condition, the rate of supply of positive ions should be equal to βN, which is maintained by the increment in the positive ion current. If the increment in positive ions is proportional to the increment in the positive ion current, it is found that

$$\frac{\text{Number of electrons}}{\text{Number of positive ions}}=\frac{G}{\epsilon\beta}=\frac{P\bar{E}}{M\epsilon\beta}. \tag{22}$$

For an operating temperature of 313°K, which corresponds to a mercury vapor pressure of 0.004 mm of Hg, and the constant of proportionality $b=1.5$, $g=0.925$, the average number of electrons that are neutralized by a single positive ion under this operating condition is equal to 7480, or roughly 8000.

The Propagation of Plastic Deformation in Solids*

THEODORE VON KARMAN AND POL DUWEZ
Pasadena, California
(Received March 27, 1950)

The stress wave caused by a longitudinal impact at the end of a cylindrical bar has been analyzed in the case where the impact velocity is large enough to produce plastic strain. The theory gives a method for computing the stress distribution along the bar at any instant during impact. It is shown that for a given material, there is a critical impact velocity such that when subjected to a tension impact with a velocity higher than the critical, the material should break near the impacted end with negligible plastic strain.

An experimental investigation was made concurrently with the theoretical study. Some of the most significant experimental results are presented in this paper.

I. INTRODUCTION

THE testing of impact strength of materials previous to the discovery of the laws of propagation of plastic deformation used essentially two different methods: bending of notched bars, and tension or compression of short cylindrical specimens. The first method presumes a certain standardization of the shape of the specimens and tries to establish certain relative merit numbers for the impact resistance of various materials by measuring the energy absorbed by the standardized specimens. The second method is somewhat more ambitious; its aim is the determination of the energy absorption by unit volume of the material, in the case of impact, and the comparison of this amount of energy with the work absorbed in static experiments. These tests, especially the tests of the second type, have shown that for moderate impact velocities the work absorbed in impact is, in general, somewhat larger than the work absorbed in static experiments; there were some indications that this tendency is reversed as the impact velocity increases. However, the observed drop in the amount of absorbed work was not accompanied by a decrease in elongation and no explanation was offered for this phenomenon.

As the European war started, the attention of military and other engineers concerned with the construction of bomb resisting structures was focused on the impact problem. The senior author became interested in the problem of resistance of structures to impact loads beyond the elastic limit in a conference held at the National Academy of Sciences early in 1940, under the chairmanship of Dr. V. Bush. He conceived the idea of the plastic wave in order to obtain a method for theoretical calculation of the energy absorbed by various structures, as columns, beams, plates, etc. The theory of elastic wave propagation was known. It was evident from this theory that, for any especially brittle material (i.e., materials which break at their elastic limit), a critical impact velocity exists for which fracture must occur at the point of application of the impact, so that the rest of the structure has no chance to participate in the energy absorption. It appeared that if a theory of the propagation could be developed, such a theory would reveal the existence of a critical velocity for structures loaded beyond their yield strength.

The basic theory and preliminary experiments supporting the theory, at least in its fundamental conclusions, were carried out during the year 1941. The senior author presented the fundamentals of the theory in a paper sent for publication in the Proceedings of the National Academy of Sciences in December, 1941. It was found, however, that the paper might have some bearing on problems relating to National Defense. The publication was therefore delayed, but the study was described in a classified NDRC report, A-29, "On the Propagation of Plastic Deformation in Solids," February 1942. The experimental work carried out previously by the junior author was published at the same time in the classified NDRC report, A-33, "Preliminary Experiments on Propagation of Plastic Deformation." Subsequently more complete theoretical investigations on the subject were carried out by the senior author, H. F. Bohnenblust, D. H. Hyers, and J. Charyk. The main content of these investigations will probably be published in the near future.

II. LONGITUDINAL IMPACT AT THE END OF A BAR EXTENDING TO INFINITY

The propagation of elastic strains in a cylindrical bar subjected to tension impact had already been analyzed in 1807 by Thomas Young, who established the proportionality between the elastic strain and the velocity of impact. The value of the elastic strain ϵ is in this case given by the formula

$$v_1 = c_0 \epsilon,$$

in which v_1 is the velocity of impact and c_0 is the velocity of propagation of an elastic deformation. Young had pointed out in his paper that when the velocity of impact is above a certain critical value a plastic strain is initiated near the point of impact. Since Young's work, it seems that the interest of the problem has not been fully recognized, and no systematic attempt has been made to compute the stress and strain caused by an impact beyond the elastic limit of the material. In the present paper such a treatment is provided for the case of longitudinal impact.

* Presented at the Sixth International Congress for Applied Mechanics, Paris, France, September 22–29, 1946.

Consider a rod or wire extending from $x=-\infty$ to $x=0$ and assume that the endpoint at $x=0$ is suddenly put in motion with a constant velocity v_1. Let the stress-strain relation for the material be given by a function of the form $\sigma=\sigma(\epsilon)$ where σ is the stress and ϵ the strain. Stresses that depend on the time-rate of strain will be neglected; for, with the exception of the case of extremely high velocities, such stresses are small in comparison with the stresses that depend on the strain itself. To be sure, the relation $\sigma=\sigma(\epsilon)$ holds only for the first deformation of the material beyond the elastic limit; in the case of load reversal, another functional relation, which takes the hysteresis into

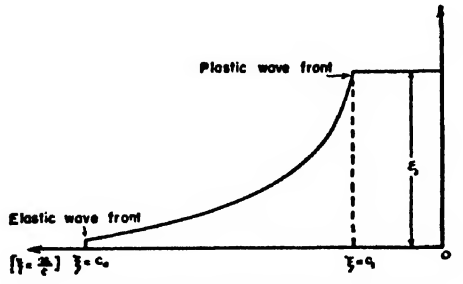

FIG. 1. Schematic representation of ϵ *versus* ξ.

account, has to be used. The lateral contraction of the material—that is, the contribution of the lateral contraction to the kinetic energy—is neglected in the following calculation.

With these simplifications, the equation of motion for an element of the rod or wire can be written in the form

$$\rho\frac{\partial^2 u}{\partial t^2}=\frac{d\sigma}{d\epsilon}\frac{\partial \epsilon}{\partial x}, \tag{1}$$

where u is the displacement of the element in the longitudinal direction, ρ is the density of the material, and t is the time.

It should be pointed out that in Eq. (1) the process of deformation is considered from the Lagrangean point of view. An arbitrary cross section of the bar is determined by a coordinate x, which gives its distance from the origin in the unloaded state. The stress is defined as the ratio of the internal reaction between two portions of the bar to the initial cross-sectional area of the bar. The strain is numerically equal to the change of length of a portion of the bar which, in the initial unloaded state, was of unit length. If u is the displacement of a cross section, the strain ϵ is equal to $\partial u/\partial x$. It is not assumed that ϵ is small in comparison with unity.

Since $\epsilon=\partial u/\partial x$, Eq. (1) can also be written in the form

$$\rho(\partial^2 u/\partial t^2)=T(\partial^2 u/\partial x^2), \tag{2}$$

where $T=d\sigma/d\epsilon$ is the modulus of deformation, elastic or plastic. The quantity T is considered to be a given function of the strain. The boundary conditions are $u=v_1 t$ for $x=0$, and $u=0$ for $x=-\infty$.

It is easily seen that a solution of the form

$$u=v_1[t+(x/c_1)] \tag{3}$$

with an arbitrary value of the velocity of propagation c_1, satisfies Eq. (2) and the boundary condition at $x=0$. For this solution the strain ϵ is constant and is equal to v_1/c_1.

A second solution is obtained by putting

$$T/\rho=x^2/t^2. \tag{4}$$

Since $T[=d\sigma/d\epsilon]$ is a given function of ϵ, Eq. (4) represents a solution for which ϵ is a function only of the variable $\xi=x/t$.

Assume $\epsilon=f(\xi)$; then the displacement u has the form

$$u=\int_{-\infty}^{x}\frac{\partial u}{\partial x}dx=\int_{-\infty}^{x}f(\xi)dx=t\int_{-\infty}^{\xi}f(\xi)d\xi \tag{5}$$

since $dx=td\xi$. By differentiation one readily obtains

$$\begin{aligned}\partial^2 u/\partial t^2&=(\xi^2/t)f'(\xi)\\ \partial^2 u/\partial x^2&=(1/t)f'(\xi)\end{aligned} \tag{6}$$

and substitution of Eqs. (6) in Eq. (2) shows that one of the two equations,

$$\rho\xi^2=T \tag{7}$$

or

$$f'(\xi)=0 \tag{8}$$

must hold. Equation (8) leads to the solution expressed by Eq. (3), whereas Eq. (7) gives the solution of Eq. (4).

The complete solution is obtained as follows:

(a) For $|x|<c_1 t$ the strain ϵ is constant and equal to ϵ_1;

(b) For $c_1 t<|x|<c_0 t$, where c_0 is the velocity of propagation of the elastic wave,

$$T(\epsilon)=\rho(x^2/t^2) \tag{9}$$

(c) For $|x|>c_0 t$, $\epsilon=0$.

The distribution of ϵ as a function of ξ is shown schematically in Fig. 1. The value of T for small values of ϵ—that is, within the elastic limit—is equal to E, Young's modulus of elasticity for the material. The elastic wave propagates with the velocity $c_0=(E/\rho)^{\frac{1}{2}}$. Between the plastic wave front, which is propagated with the velocity c_1, and the elastic wave front, the strain is variable, since every strain-increase from ϵ to $\epsilon+d\epsilon$ proceeds with a velocity equal to the specific value of $c=(T/\rho)^{\frac{1}{2}}$, corresponding to the strain ϵ.

The main problem is to determine the velocity c_1 of the plastic wave and the maximum strain ϵ_1 as a function of the velocity of impact v_1.

From Eq. (5) it follows:

$$v_1 = \frac{u(0,t)}{t} = \int_{-\infty}^{0} f(\xi)d\xi \tag{10}$$

and by changing variables

$$v_1 = -\int_0^{\epsilon_1} \xi d\epsilon$$

(See Fig. 4).

Thus, upon substituting for ξ from Eq. (7), Eq. (10) takes the form

$$v_1 = \int_0^{\epsilon_1} (T/\rho)^{\frac{1}{2}} d\epsilon. \tag{11}$$

Since T is a given function of ϵ, Eq. (11) determines ϵ_1 as a function of v_1.

If the deformation remains within the elastic limit, $T=E=$constant, and $v_1=\epsilon_1 c_0$, then $v_1=\epsilon_1(E/\rho)^{\frac{1}{2}}$. Hence, the stress σ is given by

$$\sigma_1 = E\epsilon_1 = \rho v_1 c_0. \tag{12}$$

Equation (12) is universally used for the calculation of the stress produced in an elastic body subjected to an impact velocity v_1. It appears that Eq. (11) replaces Eq. (12) in the case of a deformation beyond the elastic limit. If the stress remains within the elastic limit, there are two regions: for $|x|<c_0 t$, $\sigma=\rho v_1 c_0$ and for $|x|>c_0 t$, $\sigma=0$. In the case of plastic deformation, there are two fronts. Beyond the front of the elastic wave, $\sigma=0$; between the fronts of the elastic and plastic waves, σ increases gradually from $\sigma=0$ to a maximum value, $\sigma=\sigma_1$; and behind the front of the plastic wave, σ has the constant value σ_1, corresponding to a total strain ϵ_1 —elastic plus permanent—where ϵ_1 is given by Eq. (11).

For most materials $d\sigma/d\epsilon$ approaches zero for large values of ϵ, and at some particular value of ϵ, the material breaks. Hence the integral constituting the right-hand member of Eq. (11) has a maximum value, and one obtains a critical value of the velocity v_1. It can be expected that an impact with a velocity larger than v_1 will cause an instantaneous breakdown of the material.

III. EXTENSION OF THE THEORY; BAR OF FINITE LENGTH

The characteristic parameters that define the state of strain and motion of an element are the strain $\epsilon[=\partial u/\partial x]$, the stress σ, and the velocity of the element $v=\partial u/\partial t$. The equation of motion for the element is

$$\rho(\partial v/\partial t) = \partial\sigma/\partial x$$

or, using the definition of the velocity of propagation,

$$\partial v/\partial t = c^2(\partial\epsilon/\partial x). \tag{13}$$

On the other hand, from the relations $v=\partial u/\partial t$ and $\epsilon=\partial u/\partial x$ it follows that

$$\partial v/\partial x = \partial\epsilon/\partial t. \tag{14}$$

Equations (13) and (14) are equivalent to the differential Eq. (2).

The coordinate x of the element and the time at which the magnitude of the strain of this element is equal to ϵ and its velocity is equal to v can be considered as functions of ϵ and v. Then Eqs. (13) and (14) take the form

$$\begin{aligned} \partial x/\partial\epsilon &= c^2(\partial t/\partial v) \\ \partial t/\partial\epsilon &= \partial x/\partial v. \end{aligned} \tag{15}$$

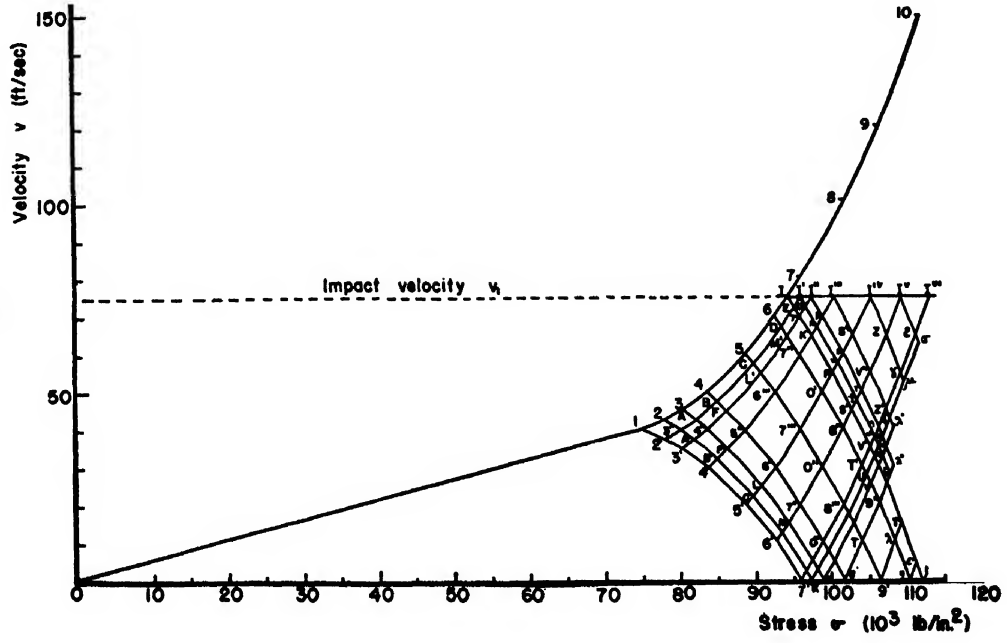

FIG. 2. Velocity *vs.* stress diagram for heat treated carbon steel.

Equations (15) become more symmetrical by the introduction of the function $\phi = \int_0^{\epsilon} c(\epsilon) d\epsilon$ and we obtain

$$\partial x/\partial \phi = c(\partial t/\partial v)$$
$$\partial x/\partial v = c(\partial t/\partial \phi). \tag{16}$$

The process of propagation can be represented in two planes. The first, with x and t as coordinates, is the Lagrangean or physical plane; the second plane is the velocity plane, in which ϕ and v are used as coordinates. The system of Eqs. (16) has fixed characteristics in the $v\phi$ plane. Hence, a relatively simple graphical method can be developed for the solution of a broad class of impact problems in the plastic range; for example, the case of a bar of finite length with one fixed end and hit at the free end. In Figs. 2 and 3 are typical (σ, v) and (x, t) diagrams for a specimen of heat treated carbon steel subjected to an impact velocity of 75 ft./sec.

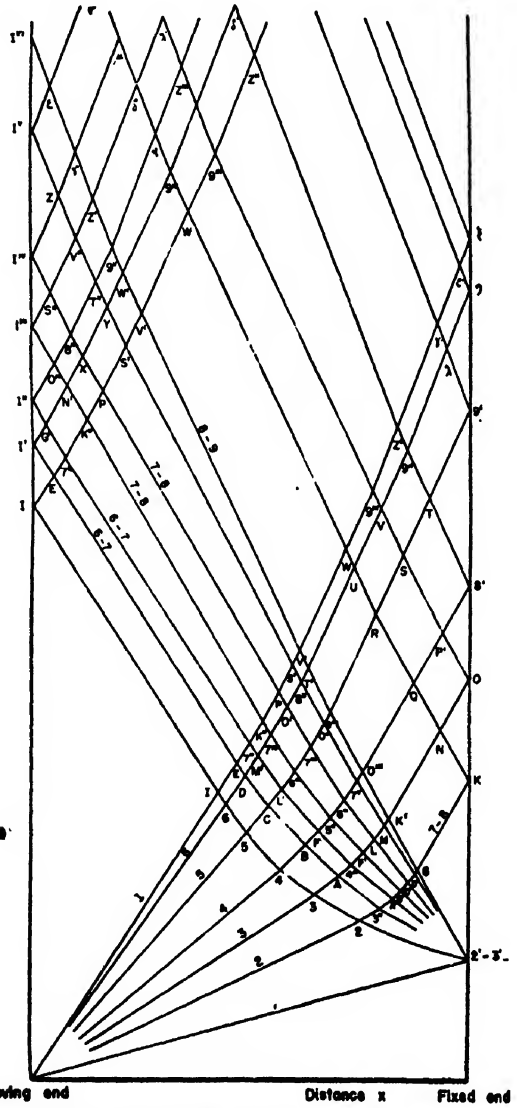

FIG. 3. Lagrange diagram for specimen of heat treated carbon steel. Impact velocity 75 ft./sec.

IV. EXPERIMENTS ON THE PROPAGATION OF PLASTIC STRAINS IN A LONG SPECIMEN SUBJECTED TO TENSION IMPACT

1. Experimental Technique

The first experiments on the propagation of plastic strain in tension were made in view of verifying the three following points resulting from the theory: (1) the existence of a plastic wave front of given amplitude; (2) the relation between the amplitude ϵ_1 of the plastic wave front and the velocity of impact v_1 (Eq. (11)); (3) the distribution of the plastic strain between the plastic and the elastic front as given by Eq. (9). The specimens used in these experiments were annealed copper wire about 100 inches long and 0.071 inch in diameter. The specimens were mounted vertically in a special testing machine built by Dr. D. S. Clark at the California Institute of Technology. The impact was produced by a hammer guided between two rails and accelerated by prestretched rubber bands. The maximum velocity attainable was approximately 200 ft./sec. The velocity was measured by a suitable electric device and a cathode-ray oscillograph. On every specimen equidistant marks were made with one inch spacings. After the test, the plastic strain was determined by measuring the displacement of each mark. Experiments were also performed in compression impact. In this case, the specimens were cylinders 12 inches long and about $\frac{3}{8}$ inch in diameter.

To control the duration of impact, the following device was employed: the bottom end of the wire is attached to a rigid piece A, as shown in Fig. 4. A vertical rod B, resting on the bottom frame of the machine, fits loosely into the tubular part of A. When a hammer H hits the piece A, the specimen elongates until A reaches the rod B. The piece A contains a circular notch N, and the rim of A breaks off at this notch after A has traveled the distance D and comes to rest on the rod B. The purpose of this arrangement is to allow the hammer to continue to move downward and also to dissipate some of its remaining energy. However, no kinetic energy is transferred to the specimen after A reaches B. The time of impact is therefore the distance D divided by the velocity of the hammer during the process of elongation.

The static stress-strain curve of one of the copper wires tested in impact was used to compute the values of $d\sigma/d\epsilon$ as a function of ϵ and the values of the velocity of propagation c, as given by the formula $c = [1/c(d\sigma/d\epsilon)]^{\frac{1}{2}}$, were then computed and a curve of c *versus* ϵ was obtained (Figs. 5 and 6). From this curve, the value of the quantity v_1 (the velocity of impact corresponding to a plastic front of amplitude ϵ_1) was calculated for each value of ϵ_1 (Fig. 7). The largest value of v_1 is obtained for the largest possible value of (16 percent in this case) and is equal to 150 ft./sec. The impact velocity of 150 ft./sec. is therefore the "critical velocity" for this material. An impact with a higher velocity

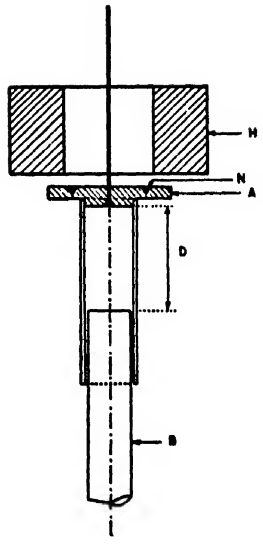

FIG. 4. Experimental device used to stop the impact after a given deformation of the specimen has been reached.

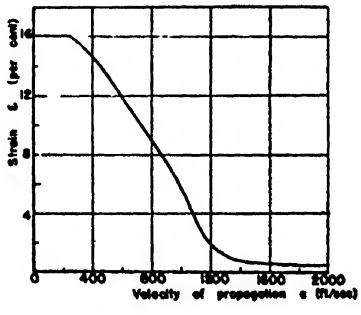

FIG. 5. Strain ϵ *versus* velocity of propagation c as calculated from the static stress-strain curve

must produce an instantaneous breakdown of the specimen.

As mentioned above, marks were made on the specimen at intervals of one inch. The distance between the origin and each mark was measured before and after the test. If x_n denotes the distance from the origin to a mark n before the test, and if x_n' is the distance between the two points after the test, the difference $x_n'-x_n$ represents the total elongation of the specimen between these two points. The values of $x_n'-x_n$ were then plotted *versus* x. The slope at any point of the curve so obtained gave the value of the permanent strain at that point. This way of measuring the strain has been found to be the most practical one. It was not necessary to make the distinction between permanent strain and actual strain, because the elastic recovery was relatively too small to be taken into consideration.

2. Results of the High Velocity Impact Tests

The results are given in three separate subsections—(i), (ii), and (iii)—in order to show to what extent they agree with the three principal theoretical results which were expressed in Section II.

(*i*) *Existence of a Plastic Wave Front*

The first series of tests was made to establish that the amplitude of the plastic front is a function of the velocity of impact alone. This amplitude remains constant while the elastic front and the plastic front travel along the specimen. In these particular experiments, the velocity of impact was always 92.50 ft./sec., but the durations of the impact varied. To control the duration of impact the two pieces A and B, shown in Fig. 4, were placed at a proper distance apart. The curves in Fig. 8 give the distribution of the strain along the specimen. They indicate clearly that a plastic front of a given amplitude ϵ_1 is revealed by the experiments, as predicted from the theory.

(*ii*) *Relation Between the Velocity of Impact and the Amplitude of the Plastic Wave Front*

In this series of tests, the velocity of impact was varied from one test to the other. The total elongation was not necessarily the same for all the tests. The stopping device was adjusted in such a manner that during the impact the plastic front traveled a distance of between 20 and 40 inches. Figure 9 gives the distribution of the strain along the specimen in each case. The experimental values of ϵ_1 corresponding to each velocity tested are listed in Table I. For comparison with the theory, the experimental values are plotted as points in Fig. 7, whereas the solid curve represents the result of the theoretical computation. The agreement between the experimental results and the predetermined curve is fairly good. The highest velocity of impact used was 171 ft./sec. For that velocity, the specimen broke within the first inch, indicating that a velocity of 171 ft./sec. is above the critical velocity, as predicted by the theory. It must be pointed out that a considerable reduction of area was observed, which indicates that the rupture was not brittle. In addition, a plastic strain of relatively small intensity (less than

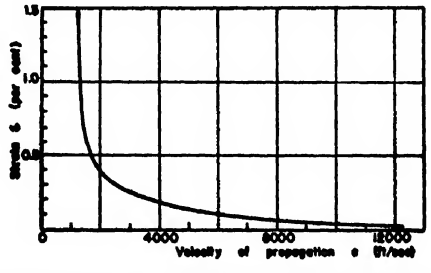

FIG. 6. Continuation of the curve of Fig. 5 up to the elastic point.

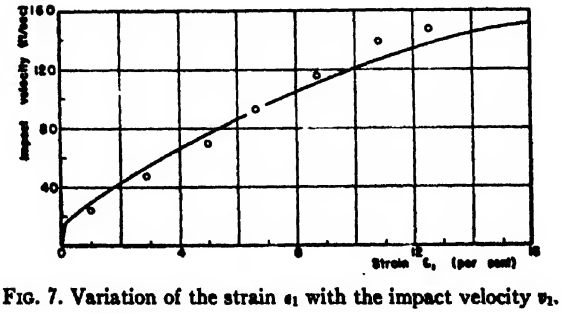

FIG. 7. Variation of the strain ϵ_1 with the impact velocity v_1.

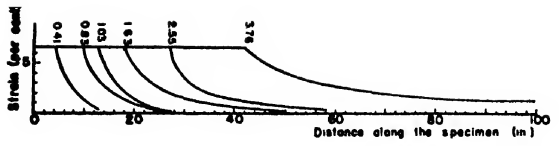

FIG. 8. Distribution of the strain ϵ along the specimen. Velocity of impact 92.5 ft./sec. The duration of impact is indicated on each curve in msec.

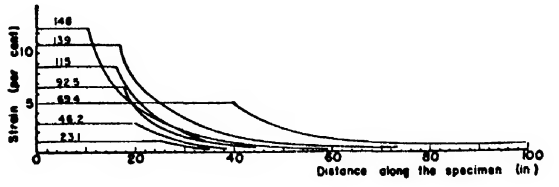

FIG. 9. Strain distribution curves for annealed copper specimens subjected to different impact velocities, indicated on each curve in ft./sec.

two or three percent) was measured along the wire over a distance of about 20 inches from the point of rupture. It is probable that a plastic wave started to propagate along the specimen during the time required to produce rupture.

(iii) *Shape of the Plastic Wave and Velocity of Propagation of the Plastic Front*

The distribution of the plastic strain along the wire between the plastic and elastic fronts may be calculated from Eq. (9), using the curves of Figs. 5 and 6. The dashed curves in Fig. 10 represent theoretically computed amplitude distributions of a plastic wave after a time interval equal to 0.83 msec.; the assumed velocity of impact, v_1, is 92.5 ft./sec. and ϵ_1 is 6.6 percent. The solid curve in Fig. 10 represents plots of the measured distribution of the strain. It is seen that the experimental and theoretical curves deviate considerably. This deviation is due to some inaccuracy in the value of the duration of impact, and especially to the perturbating effects brought by the sudden stopping of the impact. When the hammer which pulls the end of the wire with a constant velocity is stopped, the portion of the specimen that is in motion is not stopped instantaneously. During the deceleration period, the kinetic energy stored in the specimen is transformed into strain energy, and the total extension is larger than the distance D through which the hammer has been in contact with the specimen.

TABLE I. Results of impact tests on 80 inches long annealed copper specimens.

Impact velocity (ft./sec.)	Uniform strain (percent)	Duration of impact (msec.)	Velocity of propag. of uniform strain (ft./sec.)
23.1	1.0	1.70	1230
46.2	2.9	1.47	1130

139.0	10.8	1.94	730
148.0	12.5	1.40	630
171.0		Rupture	

The measured shape of the plastic wave given in Fig. 10 is greatly influenced by this "stopping effect" and cannot logically be compared with the theoretical curve that represents the shape of the wave at a certain instant during impact. The stopping effect was analyzed theoretically by the authors and especially by Drs. F. Bohnenblust and J. Charyk, who collaborated in the work reported in this paper. These investigations will be published separately. They materially reduced the variance between computed and measured values.

The reflection of plastic waves at the fixed end of a specimen was also investigated theoretically and experimentally. A typical result of this investigation is shown in Fig. 11, in which a measured strain distribution curve obtained in a compression impact test is compared with a computed curve. The two curves are not in complete agreement, but the character of the observed strain distribution curve is accounted for by the theory. It may also be pointed out that the deviation between the two curves certainly reflects some influence of the strain rate, showing that the assumption of a stress-strain curve independent of the rate of strain is not entirely justified.

A very noticeable effect of the rate of strain on the elastic limit has been observed for iron specimens subjected to both tension and compression impact. The most striking result of impact tests on iron specimens

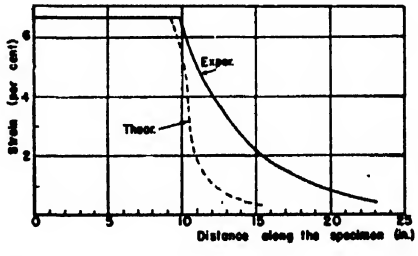

FIG. 10. Theoretical and experimental strain distribution curves for annealed copper specimen. Impact velocity 92.5 ft./sec. Duration of impact 0.83 msec.

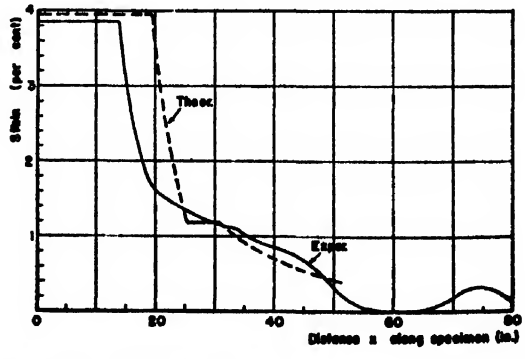

FIG. 11. Experimental and theoretical strain distribution curves for a copper wire 0.08 inch in diameter. Impact velocity 62.5 ft./sec., duration of impact 1.3 msec.

was that no plastic strain occurred near the moving end until the stress wave reached a value of the order of three times the static yield stress. The measured strain distribution curves also showed a different character, as shown in Figs. 12 and 13. It can be observed that in the case of compression the permanent set is concentrated in the neighborhood of the ends of the specimen and the center is free from plastic strain. In the tension tests there were intervals of permanent sets alternating with undisturbed regions. This is probably due to irregularities in the specimens whose influence was

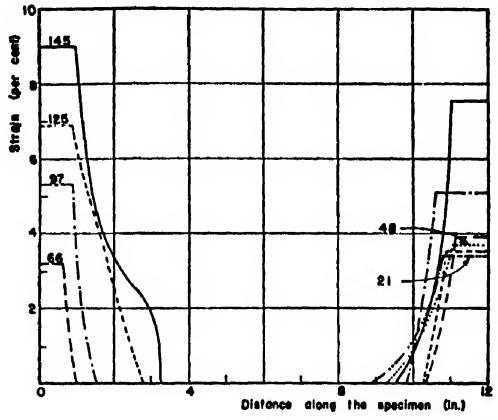

FIG. 12. Strain distribution curves for annealed mild steel specimens subjected to compression with different impact velocities, indicated on each curve in ft./sec.

enhanced by the unstable character of the tension process.

3. Force-Time Relation at the Fixed End of a Specimen Subjected to Tension Impact

An important contribution of the theory of plastic wave propagation presented in this paper is a clear explanation of the dependence on time of the force measured at the fixed end of a specimen subjected to tension impact. Force *versus* time diagrams recorded at the fixed end of the specimen have been interpreted by previous investigators in the field of high velocity impact testing as dynamic stress-strain curves. The transformation of the time axis into a strain axis infers that the strain is uniform all along the specimen at any instant during impact. The theory of strain propagation shows that for impact velocities greater than approximately 10 ft./sec., this hypothesis is not justified, and a stress-strain relation cannot be obtained in such a simple way. In order to show this, the force acting at the fixed end of a specimen subjected to tension impact was computed as a function of time by the theory outlined in Section III. This force was also measured in a series of experiments made with different types of specimens. The force was recorded by means of a resistance sensitive strain gauge in conjunction with a cathode ray oscillograph. Two records obtained for copper specimens tested with an impact velocity of 100 ft./sec. are reproduced in Fig. 14, together with a theoretical stress *versus* time diagram. The agreement between theoretical and experimental curves is very satisfactory as far as their shape is concerned. The experimental curve, however, seems to be shifted to the left. This discrepancy could be explained by assuming that any strain has a velocity of propagation slightly higher than that based on the static stress-strain curve. This gives further evidence of the influence of the rate of strain on the relation between stress and strain. In any case, the interpretation of such curves as those of Fig. 14 as dynamic stress-strain curves is completely fictitious.

4. Plastic Strain Propagation and High Velocity Impact Tests

High velocity tensile impact tests have been reported by several investigators.[1–6] Some of the results[1] have shown that the energy absorbed before rupture decreased when a certain impact velocity was reached.

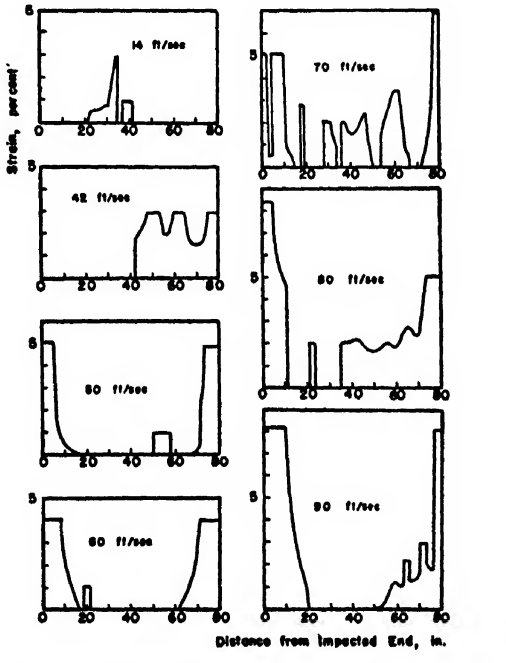

FIG. 13. Strain distribution for annealed iron wire in tension for different impact velocities.

However, the observed drop in the amount of absorbed word was not accompanied by a decrease in elongation

and no explanation was offered for this phenomenon. Other investigators did not observe any drop in energy absorption, even with impact velocities as high as 200 ft./sec.

After the discovery of the laws of propagation of plastic deformation, it became evident to the authors that both the elongation and the energy should decrease more or less suddenly when the critical velocity is reached. The first tests made with long copper wires and described in Section III clearly established the existence of a critical velocity, as predicted by the theory. The rupture of the specimen, however, at velocities above the critical, was still of the ductile type, and some appreciable strain due to necking could still be measured near the end of the specimen subjected to impact. The elongation due to necking and the energy absorbed by the necking process are relatively important when the test specimen is short, or rather when the ratio between the length and the diameter of the specimen is small. Systematic experiments indicated that, in order to observe a definite drop in both energy and total elongation beyond the critical velocity, specimens should have a ratio of length to diameter at least equal to 20. These results furnished a clear explanation why a critical velocity was not observed by previous investigators, who made high velocity impact tests on short specimens.

One of the fundamental questions in high velocity impact tests is the influence of the rate of strain. The investigations of the authors clearly showed that such an influence exists. In fact, whereas the general character of the impact process was fairly well described by a theory neglecting the influence of the rate of strain, there was always a certain systematic discrepancy pointing to such an influence. However, it should be emphasized that in high speed impact tests the rate of strain varies from one point to the other and is a function of time. Computations resulting from the theory of wave propagation have shown that the average rate of strain calculated on the basis of uniform strain is far from the actual rate of strain, even when the velocity of impact is as low as 10 ft./sec. It is therefore not logical to utilize tension impact tests to study the influence of the rate of strain on the properties of metals.

Finally, it appears that for materials having a yield point like soft iron, the interpretation of high velocity impact tests is made rather difficult because of the phenomena reported in Section IV-2. The authors believe that the understanding of these phenomena requires a deeper insight into the whole question of plastic deformation and the physics of solids.

V. PRACTICAL APPLICATIONS

As previously stated, the theory of propagation of plastic deformation was developed for the understanding of the resistance of structures against impact. Hence the first application which appears to be important is the development of rules which enable the designer to compute the amount of energy which can be absorbed by a given structure. It has been shown quite clearly for the first time that the amount of energy is a function of the impact velocity, with a rather sudden decrease of the energy absorption beyond a critical velocity. The theory has already been extended to beams subjected to transverse impact. A class of ballistic problems which have not been sufficiently discussed from the point of view of plastic strain should be mentioned. Certain aspects of the problem of penetration of projectiles through metal plates are connected with plastic wave propagation. It seems, for example, that the notion of critical velocity could lead to the discrimination of the cases in which the penetrating projectile merely pushes aside the material from those in which a plug is separated from the back of the plate. Finally, the notion of plastic strain propagation might bring about a better understanding of some anomalies encountered in high speed machining.

A Kerr Cell Camera and Flash Illumination Unit for Ballistic Photography

H. F. Quinn, W. B. McKay, and O. J. Bourque
Canadian Armament Research and Development Establishment, Valcartier, Quebec, Canada
(Received March 30, 1950)

This paper describes an experimental model of a combination Kerr cell camera and flash illumination unit designed specifically for the photography of projectiles under conditions of strong ambient illumination. Specific cases wherein such conditions are found are considered and the applicability of the Kerr cell as a secondary protecting shutter is described. A description is given of a pulse forming network—pulse transformer circuit designed to apply an operating voltage pulse to a Kerr cell of thirty-six (36) kilovolts amplitude and one point nine (1.9) microseconds duration. Limitations inherent in the present equipment are considered together with proposals for overcoming these defects in future models. Typical results are presented, including (a) a picture taken with the unit showing a twenty-millimeter shot at the time of emergence from the muzzle of a gun, and (b) a picture of a thirty-seven millimeter shot taken shortly after penetration of a metal target plate.

THE "single shot" photography of projectiles in flight by means of a high intensity flash lamp of the Egerton type is now a well-established technique in most ballistic research laboratories. In this technique, the exposure time of each picture is determined by the effective photographic duration of the particular flash lamp employed and is normally of the order of a microsecond. Such an effective exposure is entirely adequate to "stop" all but the highest speed projectiles in flight. It is a conventional procedure to use a good camera of the Eastman "Speed Graphic" type with a shutter setting of 1/100 second, the shutter opening being suitably controlled by electrical circuits of various degrees of complexity to ensure that the shutter is open for some short interval before, while, and for a short interval after the projectile is in the field of view of the camera. Auxiliary electrical circuits are provided whereby the projectile, in passing some predetermined position in the field of view, triggers the flash lamp and the required picture is taken. As it is a common procedure to employ very fast film in these applications, some means must be provided to protect the film from fogging caused by ambient daylight even with the short exposure of 1/100 second and, in many cases, both the camera and the light source are positioned in a darkened hut through which the projectile passes via suitably placed apertures in the walls. A typical photograph of a conventional shell taken under such conditions is shown in Fig. 1.

Frequently, however, it is required to obtain pictures of projectiles under conditions where the subject is either completely or partially surrounded by a glowing medium of considerable luminosity. Examples of such cases are:

(a) A projectile emerging from the muzzle of a gun and surrounded by high intensity luminous gases (muzzle flash).

(b) A projectile striking an armor plate and surrounded by an atmosphere of glowing, incandescent particles of metal which have been stripped from the plate by the projectile impact.

A particularly good example of the ambient flash illumination produced in (b) is illustrated in Fig. 2, a photograph taken at this laboratory of an aluminum-capped projectile attacking an armor plate. It should be observed that the extraneous illumination present in such cases would not only tend to screen the projectile from the external photographic flash but also, by its own inherently high luminosity and relatively long duration (of the order of 1/100 second) would very completely fog the film during the 1/100 second opening of the mechanical shutter. Such total fogging will be observed in Fig. 2 in the regions of maximum interest to the terminal ballistician namely at the point of impact (A) on the front surface of the plate and at the point of emergence (B) at the rear. An attempt to employ a faster mechanical shutter would be entirely ineffective: the fastest mechanical shutter is one of the focal plane type, models of which have been built with quoted shutter speeds of 1/5000 second. Not only would such a shutter prove almost impossible to synchronize with the external flash source but would also fail to protect the film from fogging due to the ambient illumination from regions A and B even with the above short exposure. It is, then, necessary to resort to a relatively inertia-less, non-mechanical shutter. Some wartime investigations

Fig. 1. Conventional "Microflash" photograph of a shell in flight.

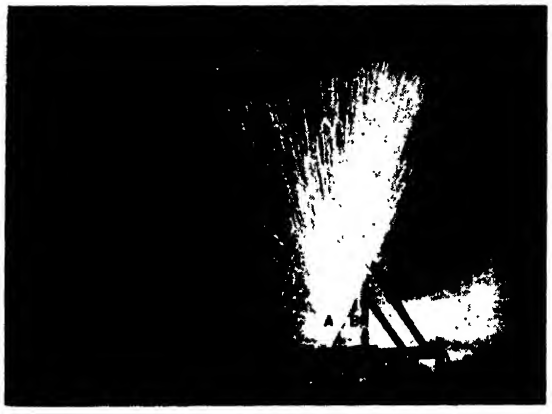

FIG. 2. Ambient flash illumination produced by an aluminum-capped projectile striking an armor plate.

performed in Germany and also in Great Britain suggested the possibility of utilizing the practically inertialess Kerr Cell electro-optical shutter in series with a conventional mechanical shutter to exclude the effect of the ambient flash. Security limitations do not, unfortunately, permit reference either to these investigations or to the results obtained therein. It would, of course, be imperative to effect a precise synchronization between the opening of the Kerr shutter and the initiation of the external flash lamp to insure that the illumination caused by the latter was fully utilized. At the end of the external flash, the Kerr shutter would close to exclude the ambient flash and, finally, the mechanical shutter would close to eliminate daylight fogging of the film noting particularly that the crossed polaroid sheets commonly used in most present day Kerr cells are reasonably transparent in the red portion of the spectrum. We desire to report on a preliminary, experimental model of a simple, self-contained unit incorporating both a Kerr cell camera and its associated flash illumination source for use in such applications as have been described above. The use of an artificial transmission line type of pulse-forming network together with a pulse transformer to obtain a substantially rectangular voltage pulse of two microsecond duration and 36 kilovolt peak amplitude for operating the Kerr cell is believed to be a new feature. It is further desired to point out some major disadvantages in the present equipment and to indicate how these may be overcome in a future model.

THEORY OF THE KERR CELL SHUTTER AND PREVIOUS APPLICATIONS

The theory and method of operation of the Kerr cell electro-optical shutter has been extensively discussed in the physics literature of the past fifty years; probably the most modern and satisfactory treatment being that due to Zarem.[1] It is not, therefore, proposed to include this information in the present report. It is, however, of interest to mention some of the uses to which the Kerr shutter has been applied by previous investigators and to consider the various aspects in which the present usage of the cell differs from them. Accordingly, Table I has been constructed in which several of the former applications have been listed together with the duration of the effective photographic exposure obtained in each case.

It is to be noted that, in all but the present application, the subjects to be photographed themselves provided all the necessary illumination to enable reasonably good pictures to be obtained notwithstanding the high light absorption losses in the active fluid (usually nitrobenzene) of the cell. The present usage of the Kerr shutter differs markedly from the others in that the useful light must be provided from an external, high intensity flash source, the light flash being accurately

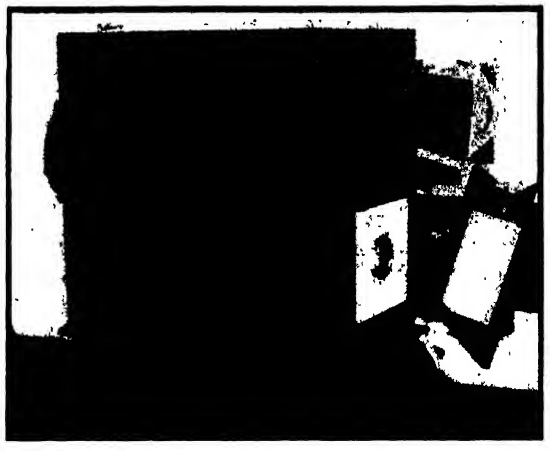

FIG. 3. Kerr cell camera and flash illumination unit.

synchronized with the opening of the shutter. Further, in the present application, the effective opening of the shutter need not be set precisely equal to the desired exposure time, provided it is at least sufficient to admit the external flash illumination and it is the effective photographic duration of the light flash that determines the exposure and not the opening of the Kerr shutter. Finally, the present application necessitates the use of a Kerr cell of much greater aperture and angular field of view than those employed by the above investigators; this, in turn, requires the use of much higher driving voltages in order to obtain a satisfactory opening of the shutter.

DESCRIPTION OF THE APPARATUS

A. Optical Arrangements

A photograph of the complete unit is shown in Fig. 3. The mirrors mounted on the front of the unit enable the latter to be suitably protected from flying fragments in the case of armor plate investigations and from the effect of muzzle blast in applications where it is desired to photograph projectiles emerging from a gun muzzle.

[1] Zarem, Marshall, and Poole, Elect. Eng. 68, No. 4, 282 (1949).

The general arrangement of equipment as used in the latter application is shown in Fig. 4 wherein the unit is seen in position beside the gun: the lower mirror enables the substantially parallel beam of light from the flash lamp to be trained on the muzzle while the upper mirror allows the camera to view the projectile on emergence. Initiation of both the Kerr camera and the flash lamp is provided by electrical contact between the emerging projectile and a stout wire tightly strung some one-half inch clear of the muzzle.

The camera proper consists of a "Baco" mounting and bellows together with a suitable adapter which permits the mounting of a $f/2.5$ "Aero Ektar" lens having a focal length of 8 inches. In this preliminary, experimental model the mechanical shutter was dispensed with and all tests were carried out at night inside a darkened gun shed. Suitable synchronization of a conventional, mechanical shutter from the gun itself would, however, present no great problem such an arrangement having been frequently employed by this laboratory in the past.

FIG. 4. Experimental arrangement for photography of a projectile at point of emergence from a gun muzzle.

Insofar as the dimensions of the electrodes are concerned, the Kerr cell follows exactly a German wartime model specified to operate at a peak voltage pulse of 36 kilovolts. As it was anticipated that considerable investigation might have to be carried out before the optimum design of the cell was finalized, the use of the more convenient (and much more expensive) all-glass cell was avoided and, to date, all the experimental cells have been constructed from one-inch Bakelite sheet and ordinary quarter-inch plate glass. All joints have been carefully sealed with ceresin wax and care has been taken to remove the nitrobenzene from the cell after each trial to eliminate the small but noticeable solution of this wax in the fluid. Type J Polaroid film pressed between the cell windows and external glass plates has been used to date for the linear polarizers but it is intended shortly to replace this by Type H film laminated in glass. The particular Kerr cell used in the first successful trial of the unit is shown in Fig. 5. The cell is placed immediately in front of the camera lens in the unit. It is not possible at the present time to calculate

accurately the theoretical maximum transmission of the Kerr cell when used with the present light source, the spectral distribution of energy in the flash being unknown. It is, however, planned to photograph the spectrum of the discharge lamp using Super XX film (the film actually used in applications of the equipment) and to substitute in the transmission formula the appropriate value of the Kerr constant corresponding to the spectral region of maximum light intensity. Some idea of the performance of this particular cell can, however, be obtained by substitution in the transmission equation of values for both the Kerr constant and the

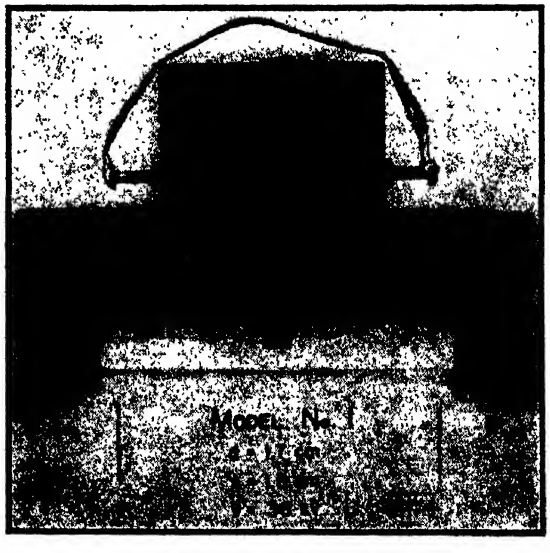

FIG. 5. First experimental Kerr cell.

absorption coefficient for a wave-length reasonably well in the center of the optical spectrum: let the following numerical values be used:

Kerr constant for nitrobenzene at λ
$= 5460$ angstroms $= 410 \times 10^{-7}$.

Absorption coefficient at $\lambda = 5460$ angstroms $= 1/15$.

The transmission equation, corrected for absorption in the cell, can be given in the form:

$$\text{Percent transmission, } T = 50 \exp -\rho \times \sin^2\left(\frac{\pi \times BV^2}{d^2}\right), \quad (1)$$

where x (cm) is the axial length of the cell plates, B the Kerr constant, d (cm) the plate separation, ρ the absorption coefficient and V (statvolts) the applied voltage. Substituting the above numerical values and the cell dimensions we obtain the result, $T = 37.1$ percent, the losses inherent in the linear polarizers being neglected.

In the present apparatus, the components available permitted operation of the cell only up to the originally specified limit of 36 kilovolts. Provided the dimensions x and d be fixed, it is apparent from Eq. (1) that a maximum possible percent transmission of 44.3 percent would be obtained for $V = 41.9$ kilovolts.

B. Electrical Circuits

The complete electrical circuit for the Kerr camera and its associated flash lamp is given in Fig. 6. Referring to Fig. 6, it will be seen that, when the high voltage supply is energized, one side of the main spark gap S charges to $+9$ and the other to -9 kilovolts. These potentials also appear across the flash energy storage capacitors C-4, C-5 and the pulse-forming network, PFN. On shorting the grid of the mercury thyratron V-3 to ground, a negative pulse of 4.5 kilovolts amplitude appears at the center electrode this being sufficient to trigger the main gap. Proper initiation of the main spark was found to be ensured by adding the capacitor C-3 across the gap. As soon as the gap fires, a total potential of 18 kilovolts appears across the flash lamp, a General Electric type FT-125, and this breaks down immediately, simultaneously discharging the pulse-forming network through the primary of the pulse-transformer T-5 and also the storage capacitors through the lamp itself. This arrangement of the circuit ensures a consistent synchronization between the camera and the flash lamp. A suitable purely resistive load of 640 ohms is connected in parallel with the Kerr cell across the

secondary of the pulse transformer to match the transformer primary to the characteristic impedance of the pulse-forming network (40 ohms, in this particular case). While it will be noted that the voltage pulse at the transformer secondary cannot begin to rise until the initiation of the flash lamp, and that, by this means an approximate synchronism of the cell opening and the light flash is achieved, it is immediately apparent that the "rise time" to peak of the secondary voltage of a pulse transformer is quite considerable particularly when the latter works into an essentially capacitive load such as the Kerr cell (capacity of the order of 55 micro-microfarads). Lack of a suitable high speed single transient type oscilloscope has prevented the determination of the "rise time" in the present transformer. The photographic evidence is, however, that the "rise time" is, unfortunately, long enough to limit the useful light to that from the tail-end of the flash. There is no apparent simple means of eliminating this objectionable feature in the present equipment but, in future models, it is proposed to provide separate triggering of the cell and the lamp together with a precision time delay in between the two trigger pulses whereby the secondary voltage of the pulse-transformer will be given adequate time to rise to peak before the initiation of the flash. The fact that the photographic results obtained to date with this relatively crude apparatus have been so promising would seem to augur well for the success of the new equipment which is presently under construction.

It is important to note that the pulse transformer application is particularly appropriate to the present problem wherein a cell opening of one or two microseconds duration is the shortest required. The production of a pulse transformer with a four or five to one step-up ratio capable of providing a shorter voltage pulse of, for example, 0.1 microsecond to a capacitive load of some 60 micro-microfarads in parallel with the normal stray winding capacity (itself normally of the order of 40 mmf) would be a practical impossibility. Since, however, recent pulse transformers (with step-up ratios as great as one to seventeen) have been designed to handle two or three microsecond pulses, the use of a suitable pulse transformer should enable the operation of Kerr cells of much larger aperture with a consequent improvement in the photographic properties of the system as a whole. Furthermore, by the use of larger aperture Kerr cells, it should be possible to effect a substantial reduction in the capacity of the cells with a consequent reduction in the required power rating of the pulse transformer.

Concerning the several components used in the circuit, the pulse-forming network is of conventional design having been salvaged from a wartime radar set: it is rated at 25 kilovolts, has a specified pulse-width of 1.9 microseconds and a characteristic impedance of 40 ohms. The energy storage capacitors C-4 and C-5 were chosen from the standpoint of availability and insulation rating rather than for their particular suitability for flash duty; in fact they are high voltage filter capacitors. These capacitors will, of course, be replaced in future models.

Considerable difficulty was encountered throughout our investigations in the search for a suitable flash tube which would absorb the necessary power without disintegrating and which would also trigger from a suddenly applied surge voltage. While the FT-125 lamps

FIG. 7. Kerr cell photograph of a 20-mm shell emerging from gun muzzle.

finally selected are required to operate at a power level greatly in excess of their normal commercial rating, these lamps have given excellent results to date and, after some hundred flashes, still show no apparent signs of deterioration.

The pulse transformer was constructed in this laboratory: as it was initially desired merely to examine the applicability of the electrical circuit, no great effort was made in the construction of the device to minimize either the leakage inductance or the winding capacitance. A silicon steel core obtained from a surplus radar pulse transformer was utilized. The primary winding consists simply of two 40 turn windings each wound on one leg of the core and connected in parallel, the secondary consisting of two 80 turn windings each wound over one primary section and connected in series to give a voltage transformation ratio of 1 to 4. The transformer is immersed in oil in an old automotive battery case. Since the first promising results were obtained with the present equipment, orders have been placed with a manufacturer for a suitable pulse-forming

network having a characteristic impedance of 200 ohms and a pulse-width of 2 microseconds together with an associated pulse transformer having a 1 to 5 step-up ratio. This combination should enable a cell to be pulsed with a peak voltage up to the limit of 50 kilovolts.

EXPERIMENTAL PROCEDURE AND INITIAL RESULTS

The first significant and promising results were obtained in an application of the equipment wherein it was desired to obtain pictures of a twenty (20)-millimeter cannon shot just emerging from the muzzle of the gun for the purpose of determining the amount of propellant gas leakage past the driving band of the projectile. The experimental arrangement has already been illustrated in Fig. 4. The filament and high voltage power supplies were switched on and the thyratron grid connected to the contact wire at the muzzle; since the gun itself was grounded, the emerging projectile connected the grid to ground on contact with the wire. When these preliminary arrangements had been completed, the gunshed was darkened and the protecting slide removed from the film holder. Immediately after firing the gun, the slide was replaced in order to protect the film from stray illumination. A typical photograph of the emerging projectile (one of a series of twenty pictures obtained) is shown in Fig. (7) while Fig. (8) shows the opaque gas cloud surrounding the projectile when the latter had just cleared the muzzle. It should be remarked that these and all the pictures obtained with the Kerr camera have been recorded on Super-Pan Press, Type B film; the film records have in all cases been processed for nine (9) minutes in Eastman DK-60 developer at sixty-eight (68) degrees Fahrenheit.

While the operation of the equipment either in the laboratory or in an enclosed gun shed proved entirely satisfactory, it was found impossible to achieve successful synchronization of the unit when used under outdoor conditions on the open ranges. This failure has just recently been traced to the considerable ambient temperature sensitivity of the mercury control thyratron. Excellent synchronization in all cases has since been achieved by the simple expedient of replacing this thyratron by a hydrogen thyratron (type 5C22). A series of tests were recently carried out to determine the accuracy of synchronization of the unit and also its applicability to armor plate investigations. For this purpose, a target consisting of a one-eighth (1/8)-inch sheet of Dural metal was located down range from the gun with its plane at an angle of forty-five (45) degrees to the line of fire. A contact screen consisting of a cardboard sheet on which horizontal conducting bands of aluminum had been sprayed was located approximately eighteen inches behind the target with its plane perpendicular to the line of fire. Connections are made to alternate bands on such a screen so that triggering of the light and camera is effected as soon as the nose of the projectile connects any two bands. Figure 9 shows a picture of a thirty-seven millimeter armor piercing shot which was equipped with a standard, light alloy ballistic cap taken shortly after passage of the projectile through the target plate. It will be noted that the detail (particularly that of the destruction of the ballistic cap) is uniformly good. It will also be observed that triggering has been effected in this instance by the penetration of the inner, armor-piercing cote of the shot through the contact screen. It should be noted here that an Ilex

FIG. 8. Kerr cell photograph of gas cloud surrounding 20-mm shell shortly after complete emergence from the muzzle.

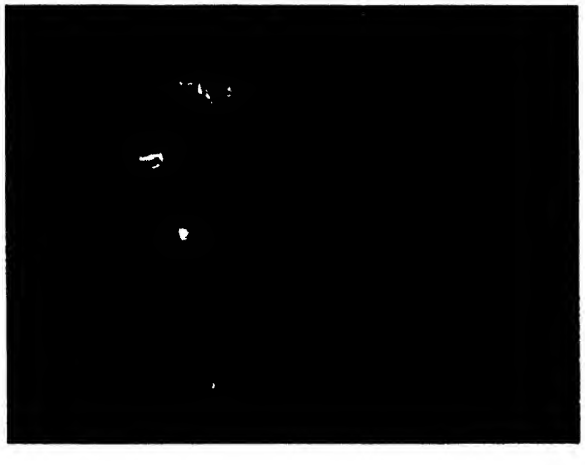

FIG. 9. Kerr cell camera photograph of a thirty-seven millimeter shot taken shortly after penetration of a metal target plate.

"Paragon" lens of aperture $F/4.5$ and focal length six point four (6.4) inches equipped with an electromagnetically operated Acme "Synchro" shutter was employed in this last series of tests; the shutter setting was one twenty-fifth (1/25) second and it was operated via an amplifier by an inertia switch mounted on the barrel of the gun.

ACKNOWLEDGMENTS

The authors wish to record their indebtedness to Mr. E. W. Greenwood of this laboratory for his continued assistance in connection with the purely photographic aspects of the problem and for many invaluable suggestions. Effect of a Circular Groundplane on Antenna Radiation*

(Received May 15, 1950)

The field of a quarter-wave-length antenna above a circular conducting disk of zero thickness—the groundplane—is calculated theoretically by use of the wave functions of the oblate spheroid. Assuming a sinusoidal distribution of current on the antenna, we compute the currents on the groundplane, the radiation resistance and the radiation pattern of the system for various values of the radius a. With these results the distortion of antenna radiation by finite groundplanes can be studied. We find good agreement with recent experimental data.

INTRODUCTION

IT is well known that the behavior of an antenna placed above a conducting plane of either finite or infinite extent differs from that of an identical antenna in free space. While the effect of an infinite plane can easily be predicted in terms of images, the effect of a plane of finite extent poses a much more difficult problem. The latter problem is of some practical importance since in certain situations it may be desirable to place an actual antenna over a conducting surface of finite extent and since in laboratory tests on scale models of antennas it is often assumed that the effect of the earth may be simulated by a finite conducting plate.

Recently Meier and Summers[1] have shown experimentally that the input impedance of a vertical antenna placed above a finite groundplane depends rather markedly on the size of the plane. The only theoretical attack on this problem which has come to the attention of the present authors is the work of Bardeen[2] on the effect of a circular groundplane on a vertical antenna. In the present paper we reconsider essentially the same problem using a method quite different from that of Bardeen. Our method has the advantage that it is less restricted to planes of small radius although even in our case the computation becomes tedious for planes whose radius is very large compared to the length of the antenna.

In the actual problem considered here the groundplane is assumed to be a perfectly conducting disk of radius a and zero thickness. The antenna is assumed to be one quarter of a wave-length long, infinitely thin, and lies along the axis perpendicular to the disk with its lower end in contact with the disk. The antenna is driven in such a way that the current distribution is sinusoidal. While it is fully realized that the last statement postulates a rather idealized situation it hardly seems worth while to take a more elaborate model for a calculation in which the choice of the antenna is not of primary concern.

THE GREEN'S FUNCTION

The central problem of the present calculation consists of constructing a Green's function from which it is possible to calculate the *total* magnetic field **H** at any point in space in terms of the current distribution on the antenna. This means that the Green's function must be so constructed that all the boundary conditions on the electric and magnetic fields **E** and **H** are automatically satisfied on the groundplane. The Green's function will be proper not only in the present problem, but in any circularly symmetric problem involving the perfectly conducting circular disk. Because of the rather peculiar symmetry of the problem, the magnetic field consists of the single azimuthal component H_φ and therefore the Green's function for the magnetic field has a simple scalar form and not the more complicated dyadic form generally found in electromagnetic problems. A further consequence of this symmetry is the fact that H_φ is

[1] A. S. Meier and W. P. Summers, Proc. I. R. E. 37, 609 (1949).
[2] J. Bardeen, Phys. Rev. 36, 1482 (1930).

independent of the azimuthal angle φ. These conditions automatically insure the solenoidal character of **H**. The vector wave equation for **H** reduces to the simple scalar form[3]

$$L[H_\varphi(\rho, z)]=\left(\frac{\partial}{\partial\rho}\frac{1}{\rho}\frac{\partial}{\partial\rho}\rho+\frac{\partial^2}{\partial z^2}+k^2\right)H_\varphi(\rho, z)=0, \quad (1)$$

where ρ and z are the usual cylinder coordinates. These coordinates are not particularly well suited for handling the boundary conditions on the disk and so we introduce a set of oblate spheroidal coordinates η, ξ, φ, which are given by the transformations

$$\rho=a((1-\eta^2)(1+\xi^2))^{\frac{1}{2}}, \quad (2a)$$

$$\varphi=\varphi, \quad (2b)$$

$$z=a\eta\xi, \quad (2c)$$

and for which the surface $\xi=0$ is a disk of zero thickness and radius a. The boundary condition upon the magnetic field on the disk may now be written

$$\partial H_\varphi/\partial\xi=0 \quad \text{when} \quad \xi=0. \quad (3)$$

In the new coordinates Eq. (1) becomes

$$L[H_\varphi(\eta, \xi)]=\left[\frac{\partial}{\partial\eta}(1-\eta^2)\frac{\partial}{\partial\eta}+\frac{\partial}{\partial\xi}(1+\xi^2)\frac{\partial}{\partial\xi}-\left(\frac{1}{1-\eta^2}-\frac{1}{1+\xi^2}\right)+k^2a^2(\eta^2+\xi^2)\right]H_\varphi(\eta, \xi)=0. \quad (4)$$

The solutions of (4) constitute a set of orthogonal functions $\psi_{l1}(\eta, \xi)$ which may be written

$$\psi_{l1}(\eta, \xi)=u_{l1}(\eta)v_{l1}(\xi), \quad l=1, 2, 3\cdots. \quad (5)$$

The functions $u_{l1}(\eta)$ and $v_{l1}(\xi)$ are respectively the "angular" and "radial" oblate spheroidal wave functions[4] of the first order.

The Green's function $G(\eta, \xi; \eta', \xi')$ satisfies

$$L[G(\eta, \xi; \eta', \xi')]=-\frac{\delta(\eta-\eta')\delta(\xi-\xi')\delta(\varphi-\varphi')}{h_\eta h_\xi h_\varphi}, \quad (6)$$

where

$$h_\eta=a((\eta^2+\xi^2)/(1-\eta^2))^{\frac{1}{2}}, \quad h_\xi=a((\eta^2+\xi^2)/(1+\xi^2))^{\frac{1}{2}}, \quad h_\varphi=a((1-\eta^2)(1+\xi^2))^{\frac{1}{2}}, \quad (7)$$

are the metric coefficients of the oblate spheroidal system. Once the Green's function is determined, $H_\varphi(\eta, \xi)$ may be found from

$$H_\varphi(\eta, \xi)=-\int_{\sigma'}[H_\varphi(\eta', \xi')\partial G/\partial n'-G\partial H_\varphi(\eta', \xi')/\partial n']d\sigma' \quad (8)$$

in terms of the values of the integrand on the boundary σ'. The sense of $\partial/\partial n'$ is out of the volume enclosed by σ'. The integral is over the surface of the antenna and the groundplane, provided both H_φ and G satisfy the radiation condition at infinity. If we also require that G satisfy the same boundary condition as H_φ,

$$\partial G/\partial\xi=0 \quad \text{when} \quad \xi=0, \quad (9)$$

then the integrand vanishes on the groundplane.

The conditions imposed upon G suffice to determine it uniquely as a solution of (6), and it will be represented in the wave functions (5).

$$G=\frac{1}{2\pi}\sum_{l=1}^{\infty}\frac{u_{l1}(\eta)u_{l1}(\eta')}{N_{l1}}\begin{cases}{}_1v_{l1}(\xi)^{(3)}v_{l1}(\xi'), & \xi\leq\xi',\\ {}_1v_{l1}(\xi')^{(3)}v_{l1}(\xi), & \xi\geq\xi'.\end{cases} \quad (10)$$

This function is symmetric in η, ξ and η', ξ'. The radial functions $v_{l1}(\xi)$ are solutions of the ordinary differential equation

$$\left[\frac{d}{d\xi}(1+\xi^2)\frac{d}{d\xi}+\frac{1}{1+\xi^2}-\alpha_{l1}+k^2a^2(1+\xi^2)\right]v_{l1}(\xi)=0, \quad (11)$$

which one obtains upon separation of variables in (4). The separation constant is constrained to eigenvalues α_{l1}, $l=1, 2, 3, \cdots$, because of conditions of analyticity in the η dimension. Equation (11) has a fundamental set of solutions, ${}^{(1)}v_{l1}$, ${}^{(2)}v_{l1}$. The linear combination

$${}^{(1)}v_{l1}+i^{(2)}v_{l1}=\underset{\xi\to\infty}{{}^{(3)}v_{l1}\longrightarrow}-(2q_{l1}/ka)e^{ikr}/kr, \quad (12)$$

called *function of the third kind*, has the property that it behaves like an out-going wave at large ξ, as shown in (12).[5] Thus G obeys the radiation condition as ξ or $\xi'\to\infty$, cf. (10). The factor $(1/2\pi)$ normalizes G in the φ dimension and the norm N_{l1} of u_{l1} does the same for η; the quantity q_{l1} is a factor arising from the normalization of the radial functions, discussed in reference 4. Finally, ${}_1v_{l1}$ is the combination

$${}_1v_{l1}=a_l{}^{(1)}v_{l1}+b_l{}^{(2)}v_{l1} \quad (13)$$

chosen such that the condition (9) be satisfied as ξ or $\xi'\to0$, i.e.

$$a_l{}^{(1)}v_{l1}'(0)+b_l{}^{(2)}v_{l1}'(0)=0. \quad (14)$$

A second equation linear in the a_l, b_l is found when (10) is substituted into (6), the result multiplied by any one of the orthogonal set (u_{l1}) and integrated over the range of η, $-1\leq\eta\leq1$. We obtain the differential equation

$$\left[\frac{d}{d\xi}(1+\xi^2)\frac{d}{d\xi}+\frac{1}{1+\xi^2}-\alpha_{l1}+k^2a^2(1+\xi^2)\right]\times\begin{Bmatrix}{}_1v_{l1}(\xi)^{(3)}v_{l1}(\xi')\\ {}_1v_{l1}(\xi')^{(3)}v_{l1}(\xi)\end{Bmatrix}=-\delta(\xi-\xi')/a, \quad \begin{Bmatrix}\xi\leq\xi'\\ \xi\geq\xi'\end{Bmatrix}. \quad (15)$$

[3] Note that neither Eqs. (1) nor (4) represent scalar wave equations.

[4] A comprehensive discussion of these functions in the notation of the present paper may be found in a paper by the present authors. See J. Frank. Inst. 249, 299 (1950).

[5] We assume a dependence $e^{-i\omega t}$ on time.

Integrate this equation with respect to ξ over an interval surrounding the point ξ' and let the interval shrink into this point. The function between braces is continuous but its derivative is by this procedure seen to possess a discontinuity at ξ' of the amount

$$-1/a(1+\xi'^2)={}_1v_{l1}(\xi')^{(3)}v_{l1}'(\xi')-{}_1v_{l1}'(\xi')^{(3)}v_{l1}(\xi'),$$
$$=(ia_l-b_l)W_{l1}({}^{(1)}v_{l1}(\xi'),\ {}^{(2)}v_{l1}(\xi')),$$
$$=(ia_l-b_l)\frac{(-)^{l-1}(2q_{l1}/ka)^2/ka}{1+\xi'^2}, \qquad (16)$$

wherein $W_{l1}({}^{(1)}v_{l1},\ {}^{(2)}v_{l1})$ is the Wronskian of the fundamental set of radial functions whose analytical value is taken from reference 4 and finally substituted above. This leads to a second equation for the constants a_l, b_l and to the result

$${}_1v_{l1}=-\frac{(-)^{l-1}k}{(2q_{l1}/ka)^2}[{}^{(2)}v_{l1}'(0)^{(1)}v_{l1}-{}^{(1)}v_{l1}'(0)^{(2)}v_{l1}]. \qquad (17)$$

Let us call the function inside brackets v_{l1}. Then

$$G=-\frac{k}{2\pi}\sum_{l=1}^{\infty}\frac{(-)^l u_{l1}(\eta)u_{l1}(\eta')}{N_{l1}(2q_{l1}/ka)^2{}^{(3)}v_{l1}'(0)}$$
$$\times\begin{cases}{}_2v_{l1}(\xi)^{(3)}v_{l1}(\xi'), & \xi\leq\xi',\\ {}_2v_{l1}(\xi')^{(3)}v_{l1}(\xi), & \xi\geq\xi'.\end{cases} \qquad (18)$$

On the groundplane $\xi=0$. It can be shown that

$$(-)^{l-1}{}_2v_{l1}(0)/(2q_{l1}/ka)^2=1/ka. \qquad (19)$$

Therefore

$$G(\eta, 0; \eta', \xi')$$
$$=-\frac{1}{2\pi a}\sum_{l=1}^{\infty}u_{l1}(\eta)u_{l1}(\eta')^{(3)}v_{l1}(\xi')/N_{l1}{}^{(3)}v_{l1}'(0). \qquad (20)$$

At large distances $\xi\to\infty$, and

$$G(\eta, \infty; \eta', \xi')$$
$$=\frac{ka}{4\pi}\frac{e^{ikr}}{r}\sum_{l=1}^{\infty}\frac{(-)^{l-1}u_{l1}(\eta)u_{l1}(\eta')_2v_{l1}(\xi')}{N_{l1}q_{l1}{}^{(3)}v_{l1}'(0)}. \qquad (21)$$

DERIVATION OF THE MAGNETIC FIELD

The integral (8) for H_φ is taken over the antenna, a section of the z-axis where $\eta'=1$ and $0\leq\xi'\leq\pi/2ka$, $\partial/\partial n'=\partial/h_{\eta'}\partial\eta'$ and $d\sigma'=(h_{\xi'}h_{\varphi'})_{\eta'=1}d\xi'd\varphi'$. We get

$$H_\varphi=-2\pi a\int_0^{\pi/2ka}[(H_{\varphi'}\partial G/\partial\eta'$$
$$-G\partial H_{\varphi'}/\partial\eta')(1-\eta'^2)]_{\eta'=1}d\xi'. \qquad (22)$$

On the surface of the antenna $H_{\varphi'}$ approaches

$$I_0\cos kz'/2\pi\rho'=I_0\cos ka\xi'/2\pi a(1-\eta'^2)^{\frac{1}{2}}(1+\xi'^2)^{\frac{1}{2}},$$

where $I_0\cos kz'$ is the current on the antenna, and $\partial H_{\varphi'}/\partial\eta'$ approaches

$$I_0\cos ka\xi'/2\pi a(1-\eta'^2)^{\frac{1}{2}}(1+\xi'^2)^{\frac{1}{2}}.$$

When these values and Eqs. (20) and (21) are substituted into the integral one finds

$$H_\varphi(\eta, 0)=-\frac{I_0}{\pi a}\sum_{l=1}^{\infty}{}^{(3)}g_l u_{l1}(\eta)/N_{l1}{}^{(3)}v_{l1}'(0), \qquad (23)$$

$$H_\varphi(\eta, \infty)=\frac{kaI_0}{2\pi}\frac{e^{ikr}}{r}$$
$$\times\sum_{l=1}^{\infty}(-)^{l-1}{}_2g_l u_{l1}(\eta)/N_{l1}q_{l1}{}^{(3)}v_{l1}'(0). \qquad (24)$$

In both expressions

$${}^{(3)}g_l=\int_0^{\pi/2ka}[v_{l1}(\xi')\cos(ka\xi')/(1+\xi'^2)^{\frac{1}{2}}]d\xi'. \qquad (25)$$

The different sub- and superscripts on g_l in (23) and (24) refer to the type of radial function implied in the integrals. These can be evaluated explicitly. We define

$$w_{l1}=(1+\xi^2)^{\frac{1}{2}}v_{l1}, \qquad (26)$$

and find on substitution into (11) that these functions satisfy

$$w_{l1}''+k^2a^2w_{l1}=\alpha_{l1}w_{l1}/(1+\xi^2). \qquad (27)$$

Let

$$y=\cos ka\xi. \qquad (28)$$

Then

$$\left|yw_{l1}'-y'w_{l1}\right|_{\xi_1}^{\xi_2}=\alpha_{l1}\int_{\xi_1}^{\xi_2}[yw_{l1}/(1+\xi^2)]d\xi, \qquad (29)$$

and

$${}^{(3)}g=-{}^{(3)}v_{l1}'(0)[1-ka{}^{(3)}w_{l1}(\pi/2ka)/$$
$${}^{(3)}w_{l1}'(0)]/\alpha_{l1}, \qquad (30)$$

$${}_2g=ka_2w_{l1}(\pi/2ka)/\alpha_{l1}. \qquad (31)$$

Finally

$$H_\varphi(\eta, 0)=\frac{I_0}{\pi a}\sum_{l=1}^{\infty}A_l u_{l1}(\eta), \qquad (32)$$

$$H_\varphi(\eta, \infty)=\frac{I_0k^2a^2}{2\pi}\frac{e^{ikr}}{r}\sum_{l=1}^{\infty}B_l u_{l1}(\eta), \qquad (33)$$

where

$$A_l=\frac{1-ka{}^{(3)}w_{l1}(\pi/2ka)/{}^{(3)}w_{l1}'(0)}{\alpha_{l1}N_{l1}}, \qquad (34)$$

$$B_l=(-1)^{l-1}{}_2w_{l1}(\pi/2ka)/\alpha_{l1}N_{l1}q_{l1}{}^{(3)}v_{l1}'(0). \qquad (35)$$

DISTRIBUTIONS OF CURRENT ON THE GROUNDPLANE

The eigenfunction expansion (32) for the magnetic field on the groundplane is analytic term by term but

the coefficients A_l diverge at least as slowly as the sequence of integers l. We will omit the proof of this assertion here.

The divergence is due to singularities in H_φ which occur when $|\eta| = 1$, that is, when $\rho = a(1-\eta^2)^{\frac{1}{2}} = 0$. These are the points at the centers of both sides of the disk. Now the part of H_φ which is due to the antenna alone has the singularity

$$I_0/4\pi\rho = I_0/4\pi a(1-\eta^2)^{\frac{1}{2}} \text{ as } \rho \to 0.^6 \quad (36)$$

The remaining part of H_φ represents the field scattered by the disk. We will show that it must have a singularity of the form

$$I_0\eta/4\pi a(1-\eta^2)^{\frac{1}{2}} \text{ as } \rho \to 0 \quad (37)$$

on the surface of the disk. The behavior of H_φ would now be

$$H_\varphi(\eta, 0) \to I_0(1+\eta)/4\pi a(1-\eta^2)^{\frac{1}{2}}, \text{ as } \rho \to 0. \quad (38)$$

This will insure continuity between the radial current flowing into the center on the disk and the current flowing upward along the antenna. The latter is $I_0 \cos kz$ and has the value I_0 at the base. The current on the disk (flowing into the center $\eta = +1$ on the top-, and out of the center $\eta = -1$ on the underside) is simply $2\pi\rho H_\varphi(\eta, 0)$. It is clear from Eq. (38) that at $\eta = +1$ the groundplane current will be I_0 and will vanish at $\eta = -1$.

Note also that the scattered part of H_φ is now odd in η, i.e., odd about the plane of the disk. This is a general property in problems involving plane scatterers subject to the boundary condition (3) and can be proven independently.[7]

The even part of the expansion (32) for $H_\varphi(\eta, 0)$ are the terms for which the $(l-1)$ are even. This part corresponds to the value of the magnetic field of the antenna alone on the surface of the disk. There exist explicit expressions for this quantity as already mentioned.[6] The divergence in the even terms is therefore removed when they are replaced by these expressions.

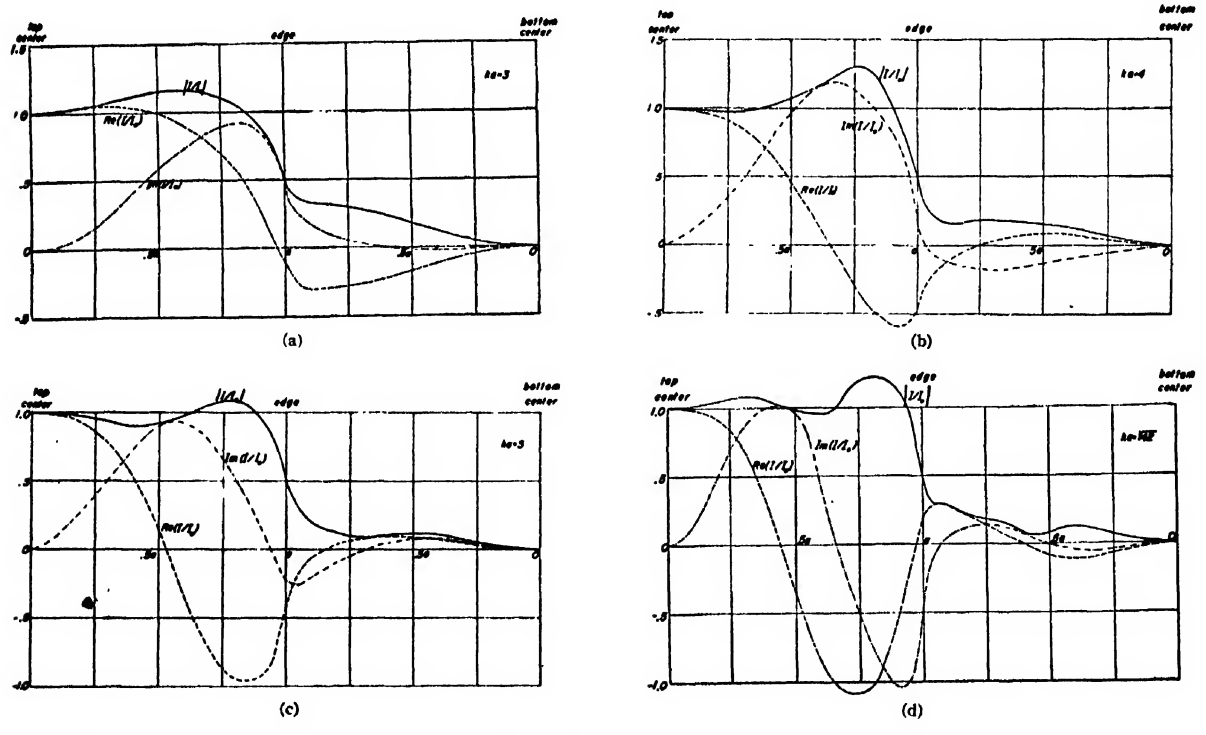
The divergence in the odd part is removed by expanding the singularity in (37) in the odd angular functions,

$$\eta/(1-\eta^2)^{\frac{1}{2}} = \sum_{l=2}{}' C_l u_{l1}(\eta). \quad (39)$$

The series is over alternate integers l (indicated by a prime on the summation sign), and the sequence of coefficients

$$C_l = (1/N_{l1}) \int_{-1}^{1} [\eta u_{l1}(\eta)/(1-\eta^2)^{\frac{1}{2}}] d\eta, \ (l-1) \text{ odd}, \quad (40)$$

must necessarily diverge.



FIGS. 1(a) to (d). Ratio of radial current I (on both sides of the groundplane) to the amplitude I_0 of the current on the antenna. Plotted against distance from the center for the cases when $ka = 3, 4, 5, (42)^{\frac{1}{2}}$.

[6] One may obtain this result upon substitution into the expressions for the field of our antenna which are given in the literature. See for instance J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill Book Company, Inc., New York, 1941), p. 457, Eq. (75). (Practical units are used in the present paper.)

[7] See, for example, A. Leitner, J. Acous. Soc. Am. 21, 331 (1949).

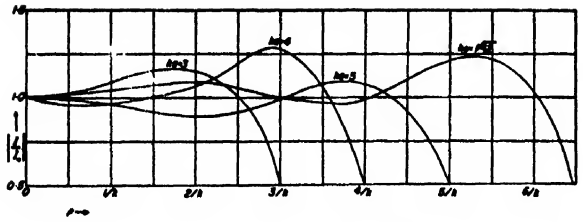


FIG. 2. Absolute values of the ratio of radial current I (on the *antenna* side of the groundplane) to the amplitude I_0 of the current on the antenna. Plotted to common scale against distance from the center for the cases when $ka=3, 4, 5, (42)^{\frac{1}{2}}$.

Finally, the current $I(\eta)$ on the groundplane has the value

$$I(\eta)=2\pi\rho H_\varphi(\eta,0)$$
$$=(I_0/2)[-i\exp[ik(\rho^2+(\lambda/4)^2)^{\frac{1}{2}}]$$
$$+\eta+(1-\eta^2)^{\frac{1}{2}}\cdot\sum_{l=2}^{\infty}{}'(4A_l-C_l)u_{l1}(\eta)]. \quad (41)$$

Numerical computations show that the remaining series in this expression converges.

The ratios of $I(\eta)$ to I_0 are plotted against distance from the base of the antenna in Fig. 1. Since $I(\eta)$ is continuous at the edge $\rho=a$, it was possible to plot the values on both sides continuously on one graph.

As ka increases, the currents on the underside become smaller, while on the antenna side the average of the absolute value becomes more nearly unity for each ka. Figure 2 illustrates this latter point more clearly. Theer we have plotted the currents on the *antenna* side on one graph for the various values of the parameter ka, with a common scale for the distance from the center. The larger ka correspond to larger groundplanes.

The trends revealed in the figures are consistent with the case of an infinite groundplane. In that case no current would flow on the underside, while the absolute value would be I_0 at all points on the upper side.

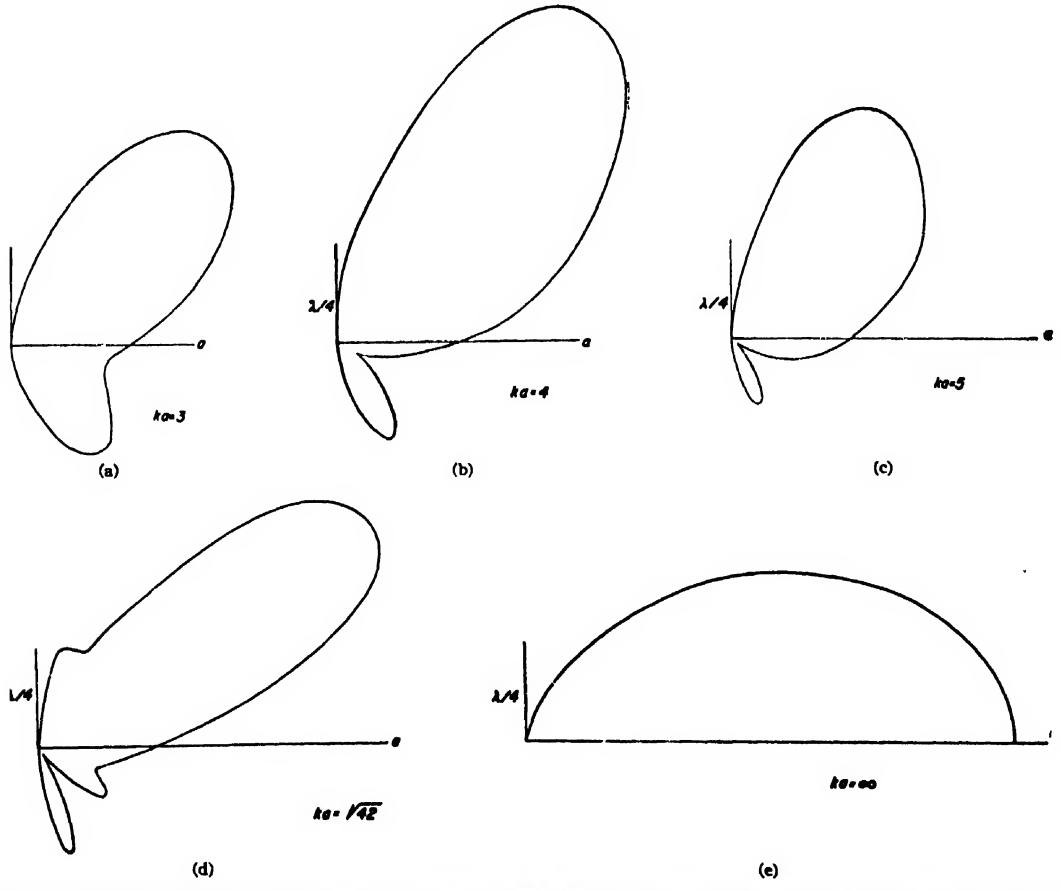
RADIATION PATTERNS

We next study the field at large distances from the radiating system.

As $r\to\infty$ the electric vector is entirely transverse to the radial direction,

$$E\to E_\eta\to(\mu_0/\epsilon_0)^{\frac{1}{2}}H_\varphi, \quad (42)$$

where μ_0 and ϵ_0 are the free space permeability and dielectric constant, respectively. So the Poynting flux



FIGS. 3(a) to (e). Radiation patterns (polar graphs in any azimuthal plane) of a quarter wave-length antenna situated above circular groundplanes for the cases when $ka=3, 4, 5, (42)^{\frac{1}{2}}, \infty$.

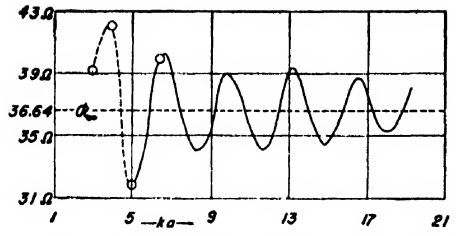


FIG. 4. Radiation resistance of the system of antenna and groundplane plotted against ka. *Solid curve:* experimental data of Meier and Summers. *Dotted curve:* extrapolation of data. *Circles:* calculated values. *Dotted horizontal line:* corresponds to $ka=\infty$.

becomes

$$S=\tfrac{1}{2}E_\eta\tilde{H}_\varphi$$

$$=(I_0^2/8\pi r^2)(\mu_0/\epsilon_0)^{\frac{1}{2}}(ka)^4\Big|\sum_{l=1}^{\infty}B_l u_{l1}(\eta)\Big|^2. \quad (43)$$

This quantity is to be compared to the case of the infinite groundplane, when the Poynting flux is the same as for the half-wave-length antenna in the region $\theta\leq\pi/2$, and vanishes below. In this familiar case[8]

$$S_\infty=(I_0^2/8\pi r^2)(\mu_0/\epsilon_0)^{\frac{1}{2}}\cos^2[\pi(\cos\theta)/2]/\sin^2\theta.^9 \quad (44)$$

(The subscript ∞ refers to the infinite groundplane.)

A polar graph of the dependence of S on the angle θ is the radiation pattern. It is drawn, to common scale, for each of the parameter values $ka=3, 4, 5, (42)^{\frac{1}{2}}$ and ∞, in Fig. 3.

We see that the patterns 3(a) to (d) differ greatly from the pattern 3(e). The radiation field shows no sign of approaching the case corresponding to the isolated half-wave-length antenna. Technical applications may possibly be found for the peculiar directivity of the finite groundplane system illustrated by the figure: while the isolated antenna radiates its energy most strongly in a direction perpendicular to the antenna, the finite groundplane system radiates preponderantly in an oblique direction.

RADIATION RESISTANCE

The radiation resistance of the finite groundplane system is calculated from the Poynting flux, and becomes

$$\mathfrak{R}=(1/2\pi)(\mu_0/\epsilon_0)^{\frac{1}{2}}(ka)^4\sum_{l=1}^{\infty}N_{l1}|B_l|^2\ \text{ohms}, \quad (45)$$

while in the infinite case

$$\mathfrak{R}_\infty=36.64\ \text{ohms}, \quad (46)$$

exactly one-half the resistance of the half-wave antenna.

These values are plotted in Fig. 4. The solid line represents the experimental data of Meier and Summers, taken on thin wire antennas approximately one quarter of a wave-length long with thin circular conducting plates as groundplanes. The results of our calculation are entered as circles and lie on the experimental curve or an extrapolation of this curve, drawn as a dotted line.

The value of $\mathfrak{R}$ never differs greatly from $\mathfrak{R}_\infty$ and, as a function of ka, oscillates about $\mathfrak{R}_\infty$, approaching this value asymptotically, as is to be expected when $ka\to\infty$.

When one wishes to measure the resistance of an isolated antenna, the rule has been to mount the test model over a groundplane, and consider the resistance of the system as the resistance of the isolated antenna. The error in this measurement depends on the relative size of the groundplane, as follows clearly from the curve in Fig. 4. An improvement over this procedure suggests itself from the nature of the curve. Rather than a single groundplane, one might use a whole series of them, similar in shape but differing in size, for each single antenna to be tested. A graph of resistance against the size of the groundplane will resemble the curve in Fig. 4. From such a curve it should be possible to estimate the position of the asymptote $\mathfrak{R}=\mathfrak{R}_\infty$ with greater accuracy.

We wish to thank Professor C. Kirkuchi for reading the manuscript and are particularly grateful to Miss J. Bruno for performing the computations.

[9] Note that $\eta\to\cos\theta$ as $r\to\infty$.

Turbulence in Apparatus for Measurement of Streaming Double Refraction

H. G. JERRARD
Physics Department, University College, Southampton, England
(Received March 16, 1950)

The different apparatus used by some thirty investigators, who have induced double refraction in a liquid contained in the annular gap between two concentric cylinders, are examined with particular reference to the onset of turbulence. In the case where the outer cylinder alone rotates, curves are given which easily enable the critical gradients corresponding to the dimensions of the apparatus used to be found. The results of the examination are so tabulated that present and future workers in this field can quickly decide on the significance of the measurements obtained by any of the investigators. An explanation is put forward of the surprising fact that with either the inner or outer cylinder rotating measurements of double refraction apparently show no very sharp break between regions of laminar and turbulent flow. The value of making simultaneous measurements of streaming double refraction and viscosity is pointed out and the advantages of using an apparatus with rotating outer and stationary inner cylinder are briefly summarized. Mention is made of optical design.

I. INTRODUCTION

IT was observed by Maxwell[1] that Canada balsam, although normally isotropic, becomes birefringent when subjected to a shearing stress. The name streaming double refraction is usually applied to this effect in analogy to the terms magnetic and electrical double refraction. Since the original work of Maxwell, streaming double refraction in liquids has been extensively studied and is now recognized as a powerful method for the determination of molecular size and shape.[2]

The essential condition for the appearance of streaming double refraction is the production of a velocity gradient in the moving liquid, which is then examined by a suitable optical method. As a prelude to the construction of apparatus for streaming double refraction experiments, the descriptions of the apparatus used by previous workers in this field have been examined. It appears that only two methods are in use to produce the required velocity gradient. One method is to produce a gradient by flow of a liquid in a narrow tube of rectangular cross section and the other by motion of a liquid confined in the annular gap between two concentric cylinders, one of which is stationary, the other rotating.

The first method is suitable for the production of gradients of the order of 2000–3000 sec.$^{-1}$ but which, however, are not constant across the tube. For pure liquids the gradient varies linearly from zero at the center to a high value near the walls; this corresponds to a parabolic distribution of velocity across the tube. Colloidal solutions on the other hand show a non-linear variation of gradient from zero at the center to a maximum at the walls and give a non-parabolic distribution of velocity.[3]

In both cases, therefore, there is no uniquely defined value of the velocity gradient which can be correlated with a given double refraction measurement. The second method is capable not only of producing an almost constant velocity gradient across the gap for both homogeneous and colloidal solutions but enables very high gradients (of the order of 30,000 sec.$^{-1}$) to be obtained.

The majority of observers have used this second method but unfortunately many workers have paid insufficient attention to the possibility of turbulence. The latter is, however, of prime importance since streaming double refraction is not amenable to theoretical treatment in the turbulent region and the results obtained for the double refraction, although of the right order of magnitude, can have no quantitative significance. It is a surprising fact, however, that except in a few isolated cases of colloidal solutions the onset of turbulence does not seem to produce any sharp break in curves showing the variation of double refraction with velocity gradient.[4]

In this paper the results of the examination, from the point of view of turbulence, of the concentric cylinder apparatus described by various authors are presented and reasons why the onset of turbulence may escape notice are given. It is hoped that the results may be of use to other workers in the fields of streaming double refraction and viscometry.

II. THEORY

In the concentric cylinder method, either the inner cylinder can rotate with the outer stationary or vice versa. The equations of motion for steady flow are the same in both cases but there is considerable difference in the velocity at which turbulence first occurs, because the distribution of centrifugal forces for the case of the rotating outer cylinder is such as to stabilize the motion of the fluid, whereas with the rotating inner cylinder this is not so.

1. Steady Motion

Suppose V be the velocity at any point P of an incompressible viscous fluid in steady motion between

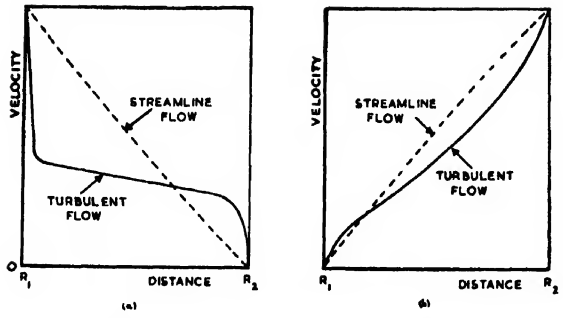

FIG. 1. Velocity distribution across the annular gap. (a) Inner cylinder rotating (after Wattendorf). (b) Outer cylinder rotating (after G. I. Taylor).

two infinitely long concentric rotating cylinders of radii R_1 and R_2, $(R_2>R_1)$. If r is the distance of P from the axis and if Ω_1 and Ω_2 are the angular velocities of the cylinders, then from the Navier-Stokes equations,[5] it may be shown that:

$$V=Ar+(B/r),$$

where

$$A=\frac{R_2^2\Omega_2-R_1^2\Omega_1}{R_2^2-R_1^2} \quad \text{and} \quad B=\frac{R_1^2R_2^2(\Omega_1-\Omega_2)}{R_2^2-R_1^2}.$$

The linear velocity gradient G is given by

$$G=dV/dr=A-(B/r^2)$$

and the change of gradient with distance is

$$dG/dr=2B/r^3.$$

If either cylinder is stationary and the other has an angular velocity Ω, then for small gap widths, the change in gradient across the gap is given by $dG=\Omega$, and the average gradient by $G=\Omega R/s$. In the latter $R=R_2\doteq R_1$, $s=R_2-R_1$ and $s\ll R$. Hence, $dG/G=s/R$. This ratio may be taken as representative of the constancy of the velocity gradient: it will be called the constancy factor.[6] Clearly if s/R is small, then so also is the error in assuming the gradient to have the constant value $(R\Omega)/s$ across the gap. The importance of this will be seen later.

2. Turbulent Motion

The stability for symmetrical disturbances of a viscous liquid in steady motion between concentric cylinders has been the subject of a very thorough theoretical and experimental treatment by Taylor.[7]

(a) *Inner cylinder rotating.* The motion of the liquid in this case is two-dimensional and according to Taylor is stable for angular velocities of the cylinder not exceeding a critical value Ω_c, given by the equation

$$\Omega_c^2=\frac{\pi^4\nu^2(R_1+R_2)}{2Ps^3R_1^2}, \tag{1}$$

which corresponds to a critical Reynolds number Re such that

$$\mathrm{Re}=\frac{(R_1\Omega_c)s}{\nu}=\pi^2\left(\frac{R_1+R_2}{2Ps}\right)^{\frac{1}{2}}. \tag{2}$$

In Eqs. (1) and (2), ν is the kinematic viscosity, s, R_1 and R_2 have the same meaning as before and P is a constant which Taylor gives as

$$P=0.0571[1-0.652(s/R_1)]+0.00056[1-0.652(s/R_1)]^{-1}.$$

When s/R_1 is small, P may be taken as 0.057. If s/R_1 is not small the value of P above, which neglects second-order terms of s/R_1 and Taylor states is to an order of approximation of about 1 percent, holds when $s/R_1\geqslant 0.33$. Some other limitations of Taylor's criteria are mentioned later. The validity of Eq. (1) was investigated experimentally by Lewis,[8] who states that it holds for values of s/R_1 as high as 0.71 and for liquids whose coefficients of kinematic viscosity vary from 0.006 to 0.018 stokes. A less detailed theoretical study, which has the merit that it involves no approximations based on the thinness of the liquid layer, has been given by Synge.[9]

As soon as the velocity given by Eq. (1) is exceeded the laminar motion is succeeded by a three-dimensional motion such that the liquid breaks up into symmetrical ring-shaped vortices spread at regular intervals along the length of the cylinder: these vortices rotate alternately in opposite directions. It is true that this is not exactly turbulence, as we generally understand it, since the pattern is regular and stationary, but it is an intermediate stage between laminar and turbulent motion.

In an experimental investigation of the velocity

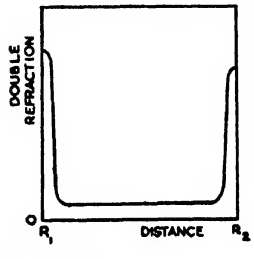

FIG. 2. Distribution of double refraction across annular gap for case of rotating inner cylinder.

[5] See for example H. Lamb, *Hydrodynamics* (Cambridge University Press, London, 1930), 5th Ed. Chapter 11.

[6] For the dimensions of the apparatus given in Tables I and II, the radii of the outer and inner cylinders are not always approximately equal. In order that the values of the constancy factor shall be comparable, the inner cylinder radius, R_1, has been used instead of R.

distribution in the gap, Taylor[10] showed that there was a large change in velocity near the walls but throughout some 83 percent of the gap the product of linear velocity and radius was constant. This confirmed the work of Wattendorf[11] who obtained a velocity distribution curve of the type shown in Fig. 1a. These facts can be explained on the theory that the dynamics of turbulent motion should be regarded as a transport of vorticity[12] and is important because it explains the phenomenon mentioned by Snellman[13] and Buchheim, Stuart, and Menz[14] that in some cases, near the surfaces of the cylinders doubly refracting layers have been seen and between them a domain without any double refraction.[15] Thus if V_1 and V_2 be the velocities at points of the liquid

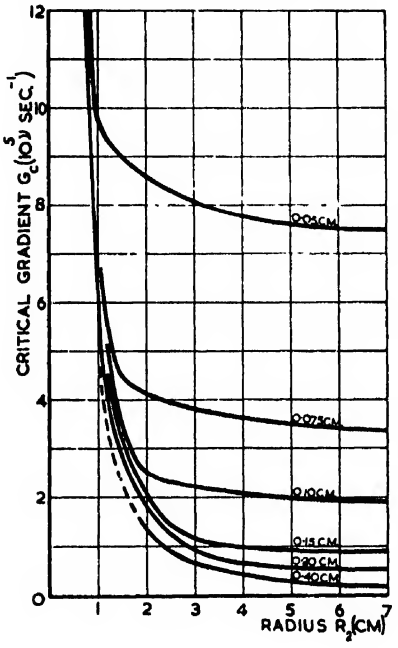

FIG. 3. Variation of critical velocity gradient with radius of outer cylinder. Gap widths 0.05, 0.075, 0.10, 0.15, 0.20, 0.40 cm. Outer cylinder rotating.

distance r and $r+x$, respectively from the axis, then

$$V_1 r = V_2(r+x) = K \text{ (a constant)},$$

so that

$$V_2 - V_1 = Kx/r(r+x) \qquad (3)$$

or the linear velocity gradient, $(V_2-V_1)/x = K/(r(r+x))$. The gradient, therefore, is approximately inversely proportional to r^2 and will be small at the center of the gap where Eq. (3) holds and large near the surfaces of

the cylinders where the velocity change is considerable (see Fig. 1a). Doubly refracting layers will, therefore, be more easily seen at the cylinder surfaces, the distribution of double refraction across the gap being as in Fig. 2. If a well-aligned optical system is used for observation such a distribution may be detected,[16] but with a less efficient system the double refraction may appear as a mean value, uniform across the gap. The mean value may be greater than that which would exist for laminar flow if the layers near the cylinder surfaces are traversed by the light and smaller (even zero) if the middle region is traversed. Thus as previously mentioned the onset of turbulence may cause no sharp break in the curve showing variation of double refraction with gradient but perhaps a slight departure from the curve for laminar flow to give either too high or too low values of the double refraction. This has been detected by Sadron.[17]

(b) *Outer cylinder rotating.* In this case the critical velocity is very much higher than that when the inner cylinder is the rotor. Taylor[18] gives the value of Ω_c in the form of a curve which shows $\log_{10}(\Omega R_2 s/\nu)$ plotted against $\log_{10}(s/R_2)$. This curve is good for Taylor's purpose, but is somewhat tedious to use if one wishes to find quickly the critical speeds and gradients for a specific piece of apparatus. For this reason curves shown in Fig. 3 have been drawn from data derived from Fig. 11 of Taylor's article: they show the values of the critical gradients plotted against the radii of the outer cylinder for various gap widths. Figure 3 must be understood as giving a limit to the critical gradient below which no turbulence occurs. Because of the inevitable inaccuracy in obtaining data from Taylor's published diagram, Fig. 3 does not give with equal certainty the upper limits. These curves should prove of value in the design and use of high speed concentric cylinder viscometers.

From these curves it is easy to calculate the critical number of revolutions per sec. N_c for any system (i.e. the number of revolutions per sec. above which turbulence occurs) and a graph of s against N_c for a fixed value of the radius takes the form shown in Fig. 4. This

[16] In the experiments of Sadron on pure liquids and colloidal solutions (Schweiz. Arch. angew. Wiss. Tech. (3–4) 158, 8 (1937–(38)) this appears as a non-uniform illumination of the half-shadow.

The published details of the apparatus give only the gap widths and so it is impossible to calculate Ω_c and G_c. However, the formula used by these workers for calculating these values is identical with that used by Buchheim, Stuart and Menz and is incorrect. The anomalies mentioned may therefore be partly due to turbulence.

curve clearly shows that as s increases from zero to infinity so N_c changes from infinity, through a minimum value to a large value again, so that for a given radius of the outer cylinder a decrease in gap width may or may not allow an increase in the speed of revolution. Beyond a certain value of s, as s increases, so N_c increases but the advantage derived by having a large gap is counteracted by the fact that the gradient constancy factor increases, which means that the error in assuming the gradient to be constant across the gap is now larger.

Taylor[19] investigated the velocity variation across the gap and found (see Fig. 1b) that (a) the velocity distribution is similar to that obtained with stream line flow, (b) turbulence is not very effective at the outer layers and (c) due to the stabilizing effect of rotation there is a large velocity gradient across the gap. Consideration of Fig. 1b indicates that even when turbulence sets in a sharp break may not occur in the double refraction velocity gradient curves as the gradient does not differ greatly from that occurring with stream-line flow.

[19] G. I. Taylor, Proc. Roy. Soc. A157, 565 (1936).

III. APPLICATION TO EXISTING APPARATUS

(a) Inner Cylinder Rotating

The criterion for turbulence given by Eq. (1) has been applied to the apparatus of the majority of observers who have published the dimensions used. The results are summarized in Table I. Only in the apparatus of de Metz does the ratio s/R_1 exceed 0.33 and even then it is less than 0.71. The values of Ω_c, G_c, and N_c given,

can in all cases therefore, be taken as accurate to 1 percent. To find which of the results of the various authors are taken for conditions of laminar flow it is only necessary to calculate the value of ν for the liquid used. If then the number of revolutions per second of the cylinder exceeds that given in the seventh column, the results cannot be regarded as being of any quantitative significance.

(b) Outer Cylinder Rotating

The results in this case are given in Table II in which the values quoted for the critical constants are lower limits; in fact values given for $s/R_2 > 0.22$ are probably very much below the truth. It is immediately obvious that the values of G_c are very much greater than in the case of rotation of the inner cylinder although the constancy factor is greater. In only one case were the measurements made in the turbulent region and that is in the work of Winkler who studied benzene at gradients of 7710, 11,600 and 14,000 sec.$^{-1}$. If ν is assumed to be 0.0074 stokes[20] at 20°C the critical gradient is about 420 sec.$^{-1}$. Winkler was led to believe he was working in the laminar region for he refers only to Taylor's conclusion published in 1923[21] that flow should be laminar at all speeds of rotation. This conclusion was superseded by Taylor's 1936 paper,[22] to which Winkler made no reference.

IV. OPTICAL DESIGN

The concentric cylinders form only one component of the apparatus for investigating streaming double refraction. In designing an apparatus attention must also be paid to the optical components, for there are numerous optical sources of error, which, if ignored, are liable to introduce double refraction of the same order as that being measured. The main errors are (a) polarization at lenses, (b) polarization by reflection from metal surfaces (c) strain in the cover glasses through which the light leaves the liquid (d) the effect of heat developed in the liquid annulus.

An excellent survey of these effects has been given by Snellman[23] and they will, therefore, not be discussed in detail here. It is sufficient to say that no trouble occurs from (a) if no lenses are situated between the polarizing prisms; the effects of (b) are avoided if the optical system as developed by Bjornstahl[24,25] be used; the effects of (c) are avoided if the method of Frey-Wyssling and Weber[26] be used while the effect of the heat developed can be calculated by a theory developed by Bjornstahl.[27]

V. GENERAL REMARKS

From the results obtained in streaming double refraction experiments it is possible to get information on the properties of the particles or molecules in the liquid. One of the important parameters required to interpret the results is the viscosity under the prevailing conditions. The fact that the viscosity coefficient must be that measured under the prevailing conditions is especially important for non-Newtonian liquids or those exhibiting anomalous viscosity. Results derived from a combination

of double refraction measurements made in a concentric cylinder apparatus and viscosity measurements made in a flow-tube viscometer are subject therefore to errors, which may be large for anomalous liquids. This point seems to have been overlooked by the majority of observers and suggests the use of a streaming double refraction apparatus with rotating outer cylinder and the inner cylinder freely suspended so that the whole forms a Couette viscometer.

It might well be mentioned here that the usual equation employed for obtaining the viscosity coefficient in a Couette viscometer is one deduced on the assumption that the liquid in the annular gap is Newtonian. If this equation is used for a non-Newtonian liquid the viscosity coefficient so obtained is an "apparent" coefficient equal to that of a Newtonian liquid producing the same deflection under identical conditions in the particular apparatus used.[28]

From the point of view of obtaining high values of the velocity gradient without turbulence there is theoretically an advantage in employing the outer cylinder as rotor although this advantage becomes less marked as the gap width is narrowed. However, from the practical point of view the difficulty experienced in the optical system with a narrow gap is greater than with a large gap.

Finally it must be remembered that the criteria for turbulence as given by Taylor hold only for Newtonian liquids and only when turbulence is due solely to centrifugal forces. Also it would appear that the ratio of cylinder length to gap width should be large. Any external disturbance, such as vibration, will tend to change the conditions and turbulence may therefore occur before the critical values given by Eq. (1) or the curves of Fig. 3. This was mentioned to the author in a private communication by Sir Geoffrey Taylor. Some such disturbance has in fact been detected by Buchheim, Stuart, and Menz[29] for even when allowance has been made for their mistake in applying Taylor's criterion incorrectly, turbulence sets in prematurely. Furthermore solutions which have long rod-shaped particles (i.e. which exhibit rod double refraction) may show turbulence earlier than Taylor's criteria would indicate. This is in accordance with the fact that the anomalous viscosity of such solutions will tend to change the value of the critical velocity (or the critical value of Reynolds number) for which turbulence occurs. Such a case has been observed by Andrade and Lewis[30] with ammonium oleate, the critical value of the velocity gradient being found to be about 30 percent lower than that given by Taylor's criterion for homogeneous liquids. This is probably the explanation of the anomalies observed by Hatschek and Jane.[31–33]

These facts indicate that it would be advantageous to have some physical indication of the onset of turbulence rather than having to rely upon calculations. This is possible if one adopts as a test for the onset of turbulence the fact that the relationship between viscous torque on the stationary cylinder and the speed of rotation of the moving cylinder instead of being linear becomes irregular. A brief discussion of this criterion as applied by Couette[34] and Mallock[35] is given by Taylor.[36]

A gradual departure from the linear law must, however, be carefully considered before it is taken as being due to turbulence for if the liquid under investigation is anomalous the torque may increase less quickly than the speed of rotation.[37]

VI. CONCLUSIONS

Tables I and II provide means by which an estimation may be made of the significance of the results of published work.

Theoretical and practical advantages in using the outer cylinder as rotor instead of the inner one are the following: (a) A larger gap can be used without the risk of turbulence and consequently greater ease is experienced in the optical measurements. (b) With a larger gap the temperature rise in the liquid is less. As the viscosity varies appreciably with temperature, the temperature of the liquid should be measured and not assumed to be that of the cooling bath. For this purpose it is advisable to incorporate a thermocouple in the concentric cylinder apparatus which may conveniently be built in the surface of the stationary cylinder. (c) The instrument can be used as a Couette viscometer so that double refraction and viscosity measurements can be made simultaneously.[38] (d) The onset of turbulence may be directly detected by irregularities in the torque-speed curve.

The onset of turbulence in pure liquids may not be accompanied by an abrupt change in the double refraction across the gap, although some change should occur consistent with the observed velocity distribution existing across the gap. A similar result holds for anomalous liquids, although it is probable that the velocity distribution across the gap under turbulent conditions differs slightly from that for a pure liquid.

Effective Stress and Effective Strain in Relation to Stress Theories of Plasticity*

G. N. White, Jr.** and D. C. Drucker†
Brown University, Providence, Rhode Island

(Received April 3, 1950)

The correlation of experimental data and the proper description of the state and history of deformation of work-hardening materials has received much attention. An often desired objective is the plotting of a variable involving stress alone, a so-called *effective stress*, against a variable depending on the instantaneous strain or the history of strain, *effective strain*. Quantities such as maximum or octahedral shearing stress and strain or better an integrated effective strain increment have been employed. Also, simple effective stress definitions have been given for anisotropic as well as isotropic metals by Dorn, by Jackson, Smith, Lankford, and by previous investigators.

It is shown that the stress-strain relations of a recent theory of plasticity provide a very convenient means of defining and studying effective stress and effective strain. The strong theoretical and practical limitations of such concepts are indicated and the calculation of specific plastic work is discussed for both isotropic and anisotropic metals.

One of the major objectives of the paper is to stimulate critical experimental examination of as yet unproved assumptions in the theory of plasticity and in the correlation of experimental data.

INTRODUCTION

THE relation between stress and strain for a work-hardening material is given for any one simple loading program (tension, shear, or any loading with constant ratios of the stress components) by a single curve. When the results obtained with different loading programs are to be correlated, or when the state and history of deformation for complex loading paths is to be described[1,2] it is again desirable to obtain a single curve. What is most often sought is a plot of some function of the stresses, termed the effective stress, against a function of the strain or strain history, termed effective strain. The related problem of equivalent proof stress has also been treated.[3]

The results of combined loading experiments have often been correlated by intuitively chosen stress and strain variables. Curves showing maximum shear stress *vs.* maximum shear strain are sometimes used. However, plots of octahedral shearing stress against octahedral shearing strain usually produce somewhat better correlation and are most often employed at present.

More recent definitions of effective stress $\bar{\sigma}$ and effective strain $\bar{\epsilon}$ have been developed in an entirely different manner to correlate not only simple loading programs but also those in which the directions and ratios of the principal stresses are not constant. Use is made of a stress-strain relation and a definition of effective strain based on the increment of specific plastic work, i.e. plastic work per unit volume, $dW^p = \bar{\sigma} d\bar{\epsilon}$. This approach has been employed for both isotropic and anisotropic materials.[4-7] If the effective stress $\bar{\sigma}$ in $dW^p = \bar{\sigma} d\bar{\epsilon}$ is taken to be the octahedral shearing stress, the increment of effective strain $d\bar{\epsilon}$ is found to be a function of the strain increments alone. For other definitions of $\bar{\sigma}$ it is by no means clear that the effective strain increment so defined will bear any simple relation to the measured or computed strain increments nor, in fact, have any direct physical significance.

The objective of this paper is to discuss these questions and to show how incremental stress-strain relations derived in terms of a criterion of yield or of further plastic deformation (termed a loading function) can be used in a systematic way to develop consistent and reasonable definitions of effective stress and effective strain. In this paper the loading function is chosen to be a function of the stress components only as is the current practice in experimental research. The choice of such a loading function, characteristic of the so-called "stress" theories of plasticity, leads directly to the definition of effective stress in terms of the stress com-

ponents and, after some manipulation, to effective strain in terms of the history of strain. It should be kept in mind, however, that experimental evidence shows that the loading function also depends explicity on the strain (see reference 16). Moreover, effective stress must, in general, include stress history or the path of loading rather than final values of stress only. Therefore, the concepts of effective stress and strain as now employed and discussed in the following pages can have only a limited, although very useful, range of validity.

SYMBOLS

Note that repeated letter subscripts denote summation and any dummy letter may be used. For example, $\sigma_{ii} \equiv \sigma_{kk} = \sigma_{11}+\sigma_{22}+\sigma_{33} \equiv \sigma_x+\sigma_y+\sigma_z$ and $\sigma_{ij}d\epsilon_{ij} \equiv \sigma_{mn}d\epsilon_{mn} = \sigma_{11}d\epsilon_{11}+\sigma_{12}d\epsilon_{12}+\cdots+\sigma_{31}d\epsilon_{31}+\sigma_{33}d\epsilon_{33} = \sigma_x d\epsilon_x+\frac{1}{2}\tau_{xy}d\gamma_{xy}+\cdots+\frac{1}{2}\tau_{zx}d\gamma_{zx}+\sigma_z d\epsilon_z$.

c, a constant chosen to make effective stress reduce to a standard stress in some special case.

f, the loading function or criterion of plastic deformation; here taken as a function of the stresses alone.

$g=g(f)$ or $h(f)$, the part of the proportionality factor G in the stress-strain relations which depends on f alone.

m, an arbitrary constant in the proportionality factor G.

n, Poisson's ratio.

r, degree of f in the stresses.

$s_{ij} = \sigma_{ij}-(\sigma_{kk}/3)\delta_{ij}$, the stress deviator tensor $s_x = \frac{1}{3}(2\sigma_x-\sigma_y-\sigma_z)$, $s_{xy} = \tau_{xy}$, etc.

$t_{ij} = s_{ik}s_{kj}-\frac{2}{3}J_2\delta_{ij}$, the deviation of the square of s_{ij}.

A_{ijkl}, coefficient of the stresses in an anisotropic quadratic loading function.

A_{ij}, constants in the general anisotropic quadratic loading function.

B_{ij}, the inverse of A_{ij}, i.e. $B_{ij}A_{jk}=\delta_{ik}$.

C_{ijkl}, anisotropic elastic constants in the generalized Hooke's law.

A, B, C, D, E, F, constants in an orthotropic loading function.

E, Young's modulus.

G, the factor of proportionality in stress-strain relations: here a function of stress.

$H=H[(K_2)^{\frac{1}{2}}, (|K_3|)^{\frac{1}{3}}]$, a function of K_2, K_3 used to define an increment of effective strain.

$I(f)=H/df$, a function of f alone used to define an increment of effective strain.

$J_1=\sigma_{kk}$, the first invariant of the stress tensor σ_{ij} equal to $\sigma_x+\sigma_y+\sigma_z$.

$J_2=\frac{1}{2}s_{ij}s_{ij}$, the second order invariant of s_{ij}, the stress deviator or $\frac{1}{6}[(\sigma_1-\sigma_2)^2+(\sigma_2-\sigma_3)^2+(\sigma_3-\sigma_1)^2]$ equal to $\frac{1}{3}\tau_0^2$.

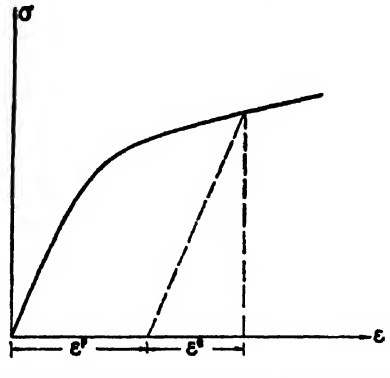

FIG. 1. Tension curve for a work hardening material.

$J_3=\frac{1}{3}s_{ij}s_{jk}s_{ki}$, the third order invariant of s_{ij}.

$K_2=de_{ij}^p de_{ij}^p$, second invariant of de_{ij}^p equal to $(de_x)^2+(de_y)^2+(de_z)^2+\frac{1}{2}(d\gamma_{xy})^2+\frac{1}{2}(d\gamma_{yz})^2+\frac{1}{2}(d\gamma_{zx})^2$.

$K_3=de_{ij}^p de_{jk}^p de_{ki}^p$, third invariant of de_{ij}^p.

$M_2=(\partial f/\partial\sigma_{ij})(\partial f/\partial\sigma_{ij})$, second invariant of $(\partial f/\partial\sigma_{ij})$, the gradient of f.

$M_3=(\partial f/\partial\sigma_{ij})(\partial f/\partial\sigma_{jk})(\partial f/\partial\sigma_{ki})$, third invariant of $(\partial f/\partial\sigma_{ij})$.

$R=(\frac{1}{2}M_2)^{\frac{1}{2}}/(\partial f/\partial\tau)$, the factor of difference between two stress-strain relations at a given value of f.

W^p, dW^p, specific plastic work and its increment.

δ_{ij}, the Kronecker delta equal to 0 for $i\neq j$, 1 for $i=j$.

$\bar{\epsilon}$, $\bar{\epsilon}^p$, effective strains, total and plastic.

$d\epsilon_{ij}=d\epsilon_{ij}^e+d\epsilon_{ij}^p$, increments of the total strain tensor ϵ_{ij} equal to the sum of the elastic and plastic increments with $d\epsilon_{11}=d\epsilon_x$, $d\epsilon_{12}=\frac{1}{2}d\gamma_{xy}$, $\cdots$, $d\epsilon_{33}=d\epsilon_z$.

ϵ_1, ϵ_2, ϵ_3, principal strains.

γ_0, octahedral shearing strain.

μ, ν, Lode's variables $\mu=(2\sigma_2-\sigma_1-\sigma_3/\sigma_1-\sigma_3)$, $\nu=(2d\epsilon_2-d\epsilon_1-d\epsilon_3/d\epsilon_1-d\epsilon_3)$.

$\bar{\sigma}$, effective stress.

σ_{ij}, stress tensor with components $\sigma_{11}=\sigma_x$, $\sigma_{12}=\tau_{xy}$, $\cdots$, $\sigma_{33}=\sigma_z$.

σ_1, σ_2, σ_3, principal stresses.

τ_0, octahedral shearing stress.

$\tau=\tau_{xy}$, shearing stress when $\tau_{yz}=\tau_{zx}=0$.

THE STRESS-STRAIN RELATION

The stress-strain relation to be used in this paper[8,9] is of the incremental or flow type which includes as special cases all explicit incremental laws now in use. A brief discussion of the development of the stress-strain relation will be given before the subject of effective stress and strain is treated. In this way the resulting definitions of effective stress and strain may be evaluated in the light of the assumptions made in deriving the stress-strain relation.

Figure 1 shows a typical tensile stress-strain curve for a work-hardening material. It is assumed that time and temperature effects are small enough to be disregarded. The stress-strain curve, which has positive slope, for the entire range considered represents then a series of states of stable static equilibrium. As no simple correlation between stress and strain exists for complex loading paths, the meaning of work-hardening for the general case requires consideration.

Work-hardening may be defined in the following manner: If for all additional sets of stresses which are slowly applied to and then removed from a block of stressed material in a given state of deformation by an external agency, the material remains in equilibrium and (a) positive work is done *by the external agency* during the application of the stresses and (b) the net work performed by it over the cycle of its application and removal is positive (or zero if no plastic deformation occurs), then the material is said to be work hardening. In other words, no work can be extracted in a cycle from the system including the block of material and the forces acting upon it.

The stress-strain relations which are derived in con-

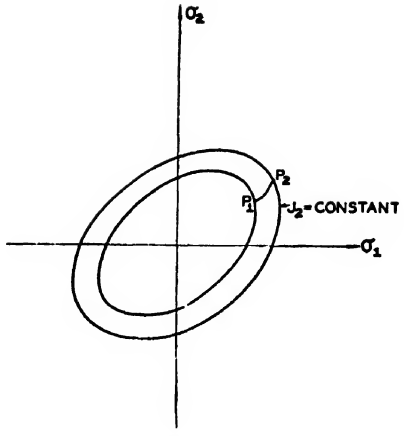

FIG. 2. A level curve of $f=J_2=\frac{1}{3}\tau_0^2$.

formity with the work hardening conditions are based on two assumptions:

(1) The relation between the increments of stress and strain is linear (all explicit stress-strain relations proposed so far adopt this assumption).

(2) A yield criterion or loading function f exists.

At any given state of plastic deformation a function of the stress components, $f(\sigma_{ij})=f(\sigma_x, \sigma_y, \cdots, \tau_{yz})$, exists such that further plastic deformation takes place only if f increases. In the general theory the value of the loading function f and also the form of f will depend on the plastic strain and plastic strain history.

In order to write the stress-strain relations compactly and to express basic ideas clearly, tensor notation will be employed. For example, the state of stress is represented by the single symbol σ_{ij} which stands for the stress tensor with the components $\sigma_{11}=\sigma_x$, $\sigma_{12}=\tau_{xy}$, $\cdots$, $\sigma_{33}=\sigma_z$. Moreover use of the tensor convention of summing over repeated subscripts, results in simplification of formulae and in case of manipulation, e.g. $a_ib_i=a_1b_1+a_2b_2+a_3b_3$, and $a_{ii}=a_{11}+a_{22}+a_{33}$.

The work-hardening conditions and the two assumptions lead to an expression for the plastic strain increments $d\epsilon_{ij}^p$ in terms of the gradient of the loading function $\partial f/\partial\sigma_{ij}$, a proportionality factor G, and the stress increments $d\sigma_{kl}$. In tensor notation the relation is

$$d\epsilon_{ij}^p=G\frac{\partial f}{\partial\sigma_{ij}}\left(\frac{\partial f}{\partial\sigma_{kl}}d\sigma_{kl}\right). \tag{1}$$

The factor G is in general a function of the stress, strain, and strain history. The positive quantity $(\partial f/\partial\sigma_{kl})d\sigma_{kl}$ is the increase in the loading function resulting from stress changes only; for example $d\tau_0$, if τ_0, the octahedral shearing stress, is the criterion of loading. The total increment of strain $d\epsilon_{ij}$ is obtained by adding $d\epsilon_{ij}^e$, the elastic increment, to the plastic increment $d\epsilon_{ij}^p$. A general anisotropic form of Hooke's law, $d\epsilon_{ij}^e=C_{ijkl}d\sigma_{kl}$, or the usual isotropic one may be used.

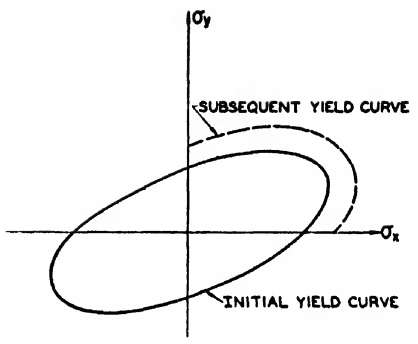

FIG. 3. Intrinsic anisotropy $f=f(\sigma)$, the flow stress in simple tension in the x-direction is not the same as for the y-direction.

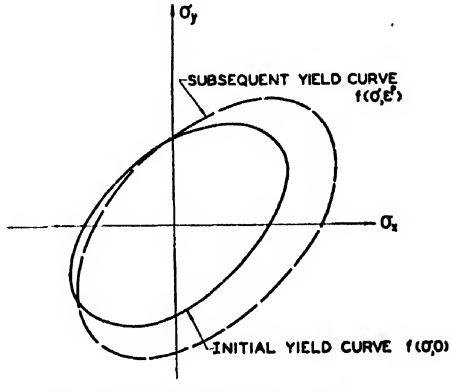

FIG. 4. Bauschinger effect—$f=f(\sigma, \epsilon^p)$.

The two resulting expressions are respectively

$$d\epsilon_{ij}=d\epsilon_{ij}^e+d\epsilon_{ij}^p=C_{ijkl}d\sigma_{kl}+G\frac{\partial f}{\partial\sigma_{ij}}\left(\frac{\partial f}{\partial\sigma_{kl}}d\sigma_{kl}\right) \tag{2}$$

and

$$d\epsilon_{ij}=\frac{(1+n)}{E}d\sigma_{ij}-\frac{n}{E}\delta_{ij}d\sigma_{kk}+G\frac{\partial f}{\partial\sigma_{ij}}\left(\frac{\partial f}{\partial\sigma_{kl}}d\sigma_{kl}\right), \tag{3}$$

where n is Poisson's ratio, E is Young's modulus, and δ_{ij} is the Kronecker delta, which is zero when $i\neq j$, unity when $i=j$. If the simplest loading function, the Mises' yield condition $f=J_2$ (shear strain energy or square of the octahedral shearing stress to within a multiplicative constant) is used, Eq. (3) in engineering notation is

$$\left.\begin{aligned} d\epsilon_x&=\frac{1}{E}[d\sigma_x-n(d\sigma_y+d\sigma_z)]\\ &\qquad+g(\tau_0)[\sigma_x-\tfrac{1}{2}(\sigma_y+\sigma_z)]d\tau_0\\ 2d\epsilon_{xy}=d\gamma_{xy}&=\frac{2(1+n)}{E}d\tau_{xy}+3g(\tau_0)\tau_{xy}d\tau_0 \end{aligned}\right\}. \tag{4}$$

These forms have been used by Nadai[10] and later by Dorn.[11]

Figure 2, a plot of Mises' loading function J_2=constant for a two-dimensional stress system, reveals many of the features of the more general loading functions. According to the postulates for the stress-strain relations, if the stresses change so as to move the point P_1 representing them outside of the ellipse J_2=constant on which the point is located, plastic deformation will take place and a new ellipse is established through the new point P_2. If the stresses change so as to move the point inside or on the ellipse, only elastic deformation can occur. In general, at any stage of plastic deformation, the loading function $f(\sigma_{ij})$ may be regarded as a surface in a multi-dimensional space with coordinates represented by all those stress components σ_{ij} which are not kept zero during the test. For a given state of stress at a point in the material, it is a surface which bounds all those states of stress which can be reached without additional plastic deformation taking place. As the increment of plastic work is necessarily positive, the surface f must be convex with respect to the origin as illustrated by Fig. 2.

An advantage of the general stress-strain relations Eqs. (2) and (3) is that anisotropic materials may be treated almost as easily as isotropic. Two types of anisotropy are (a) an initial anisotropy which is not altered appreciably by subsequent deformation, the loading function depending explicitly upon the stress components alone $f=f(\sigma_{ij})$, and (b) anisotropy produced by the plastic deformation being considered, the loading function depending explicitly on the components of plastic strain as well as stress, e.g. $f=f(\sigma_{ij}, \epsilon_{ij}^p)$. The first type of anisotropic loading function may be useful for a material which has been strongly cold worked prior to testing; the second for a material which is initially isotropic and exhibits a marked Bauschinger effect. Two-dimensional illustrations for particular examples of the two types of anisotropy are given in Figs. 3 and 4.

As f is here taken to depend explicitly on stress alone, the most general form of isotropy considered is that produced by using a loading function which is a function of the stress invariants J_1, J_2, and J_3. The octahedral shearing stress, $\tau_0=(\frac{2}{3}J_2)^{\frac{1}{2}}$, is a special case where $J_1=\sigma_{kk}$, the sum of the principal stresses, and J_3, which is a weighting factor for shearing stresses, are assumed to have no influence. The stress-strain relation (3) for $f=J_2=\frac{3}{2}\tau_0^2$ and $G=G(f)$ has been given in engineering notation, Eq. (4). In the simple tensor form, the plastic strain increment is

$$d\epsilon_{ij}^p=G(J_2)s_{ij}dJ_2=h(\tau_0)(\sigma_{ij}-(\sigma_{kk}/3)\delta_{ij})d\tau_0 \quad (5)$$

as s_{ij}, the stress deviator, is $\sigma_{ij}-(\sigma_{kk}/3)\delta_{ij}$. G and h are functions of J_2, or equivalently, of τ_0. A material obeying the relation (5) which uses J_2 as the loading function is called isotropic work hardening as it exhibits no directional properties when unloaded. There is no way of distinguishing the type of loading which produced the work hardening. All tensile specimens cut from the strained material will have the same yield point no matter what their orientation. Also, if the material is loaded a given amount in tension in any direction the extent of yielding or the value of f will be the same as for any other direction. Although the relation (5) is isotropic in the sense described, writing all the terms shows that when the material is under load (5) has the same form as a general anisotropic Hooke's law:

$$d\epsilon_x=G_1d\sigma_x+G_2d\sigma_y+G_3d\sigma_z+G_4d\tau_{xy}+G_5d\tau_{yz}+G_6d\tau_{zx}, \quad (6)$$

where the G's depend on stress alone. However, the anisotropy is produced entirely by the existing state of stress; it does not subsist after unloading.

Experimental evidence clearly indicates the need for more general stress-strain relations. The next extension is to retain the assumption of isotropic work hardening but include the third invariant of the stresses J_3 as well as J_2. The form of the relation (1) becomes then

$$d\epsilon_{ij}^p=G\left\{\frac{\partial f}{\partial J_2}s_{ij}+\frac{\partial f}{\partial J_3}t_{ij}\right\}df, \quad (7)$$

where t_{ij} is the deviation of the square of s_{ij}, $s_{ik}s_{kj}-\frac{2}{3}J_2\delta_{ij}$, and G is a function of stress.

If an intrinsically anisotropic stress-strain relation is needed, the loading function can no longer be a function of the stress invariants J_2 and J_3 but must depend directly on stress components referred to fixed axes. A simple convenient choice is the anisotropic quadratic form with constant coefficients $f=A_{ijkl}\sigma_{ij}\sigma_{kl}$ which reduces to J_2 in the isotropic case if the sum of the principal stresses is without influence. The stress-strain relation then obtained from Eq. (1) is

$$d\epsilon_{ij}^p=2GA_{ijkl}\sigma_{kl}df \quad (8)$$

where G is a function of stress. In expanded form using $\tau_{ij}=\tau_{ji}$

$$\left.\begin{aligned} d\epsilon_x^p&=2Gdf\{A_{1111}\sigma_x+2A_{1112}\tau_{xy}+A_{1122}\sigma_y \\ &\quad +2A_{1123}\tau_{yz}+A_{1133}\sigma_z+2A_{1131}\tau_{zx}\} \\ 2d\epsilon_{xy}^p=d\gamma_{xy}^p&=4Gdf\{A_{1211}\sigma_x+2A_{1212}\tau_{xy}+A_{1222}\sigma_y \\ &\quad +2A_{1223}\tau_{yz}+A_{1233}\sigma_z+2A_{1213}\tau_{zx}\} \end{aligned}\right\} \quad (9)$$

where the A's are just numbers. For a material in which there exist planes or axes with respect to which the anisotropy is symmetric, the general quadratic loading function and the corresponding stress-strain relation may be simplified. If for example the material is orthotropic and the principal axes of stress coincide with the lines of intersection of the three mutually orthogonal planes of symmetry taken as coordinate planes, the loading function is $f=a_{ij}\sigma_i\sigma_j$ $(i,j=1, 2, 3)$ where the stresses σ_i are principal stresses $\sigma_1=\sigma_x$ etc.

[10] A. Nadai, J. App. Phys. 8, 205–212 (1937).
[11] Cunningham, Thompson, and Dorn, Am. Soc. Test. Mat. 47, 546–553 (1947).

A typical plastic strain increment is then

$$d\epsilon_{ij}^{p} = 2Gdf(a_{11}\sigma_x + a_{12}\sigma_y + a_{13}\sigma_z). \quad (10)$$

Eqs. (9) and (10) are stress-strain relations used by Dorn, by Jackson, Smith, and Lankford, and by Fisher.

More elaborate forms of f may easily be written as required by experimental data.

EFFECTIVE STRESS AND EFFECTIVE STRAIN

Effective stress $\bar{\sigma}$ is by definition a quantity which determines whether or not further plastic deformation takes place. Since it must be defined consistently with the stress σ in a simple tension test of a work hardening material, Fig. 1, $\bar{\sigma}$ must be a positive increasing function of the stresses during plastic deformation. For stress theories of plasticity, $f=f(\sigma_{ij})$, the loading function f also by definition determines whether additional plastic deformation will occur. It too is a positive increasing function as long as plastic deformation continues, and if unloading occurs, plastic deformation is not resumed until the highest previous value of f is exceeded. For stress theories there is then no real choice in the definition of the effective stress $\bar{\sigma}$. The loading function f is the effective stress to some power and to within an arbitrary constant; for example $\tau_0=(\frac{2}{3}J_2)^{\frac{1}{2}}$ or $\bar{\sigma}=(3J_2)^{\frac{1}{2}}$.[10,11]

On the other hand the definition of an effective strain $\bar{\epsilon}$ related to the effective stress is not made so easily. The method now used is to arbitrarily define the permanent effective strain $\bar{\epsilon}^{p}$ by

$$dW^{p} = \bar{\sigma}d\bar{\epsilon}^{p}, \quad (11)$$

where dW^{p} is the increment of specific plastic work of deformation.[4-7] This definition is based on the belief that the plastic work is a fundamental measure of the amount of plastic deformation.

The definition (11) of $\bar{\epsilon}$ in terms of plastic rather than total work is made to avoid considering increases of total work in which plastic deformation plays no part. Such a situation arises when the loading path is one for which $f=$constant. In this case the plastic increments of strain (1) are zero whereas the elastic strain increments are not.

A second basic method is the use of the stress-strain relations, Eq. (1), to find an integral of the strain increments which is exactly or quite closely a function of the loading function f or effective stress $\bar{\sigma}$ only. The integral of the strain increments is then defined to be the effective strain.

The second method is an attempt to define an effective strain which has a direct physical meaning in terms of measured strain and strain history. The first method does not in general lead to an effective strain which is related to strain as ordinarily defined. The effective strain increment cannot be computed from the strains and their history only, as may be seen when Eq. (11) is expressed fully in terms of the stresses and strain increments by means of Eq. (1).

$$dW^{p} = \bar{\sigma}d\bar{\epsilon}^{p} = \sigma_{ij}d\epsilon_{ij}^{p} = \sigma_{ij}G\frac{\partial f}{\partial \sigma_{ij}}\left(\frac{\partial f}{\partial \sigma_{kl}}d\sigma_{kl}\right). \quad (12)$$

It should be kept in mind that the concept of effective stress $\bar{\sigma}$ and consequently of effective strain $\bar{\epsilon}^{p}$ as presented here is only valid for materials with negligible Bauschinger and similar effects, or the more usual case of paths of loading which do not reveal such effects directly. Figure 4 shows that to account for Bauschinger effect the loading function must depend on the plastic strains as well as on stress. An effective stress which depends on stress only is then no longer possible as consideration of alternating tension and compression clearly shows.

In the following sections the expressions for $\bar{\sigma}$ and $\bar{\epsilon}^{p}$ will be given explicit forms in accordance with certain other features of the loading functions and stress-strain relations dictated by experimental results.

ISOTROPIC THEORIES

The simplest form of stress-strain relation for a material which work hardens isotropically, Eq. (5), will be used first as an example of both methods for defining the effective strain $\bar{\epsilon}^{p}$ in terms of the effective stress $\bar{\sigma}$. In this case $\bar{\sigma}$ may be defined as $(f)^{\frac{1}{2}}$ or $(J_2)^{\frac{1}{2}}$ multiplied by any constant. Choosing $\bar{\sigma}=(3J_2)^{\frac{1}{2}}$ makes $\bar{\sigma}=\sigma_x$ for uniaxial tension in the x-direction. The resulting $\bar{\epsilon}^{p}$ is then the same as Dorn's.[11]

Using the first method and noting that $(\partial J_2/\partial\sigma_{ij})=s_{ij}$ and $(d\epsilon_{ij}^{p}d\epsilon_{ij}^{p})^{\frac{1}{2}}=G(2J_2)^{\frac{1}{2}}dJ_2$ gives

$$\begin{aligned}\bar{\sigma}d\bar{\epsilon}^{p} &= dW^{p} = \sigma_{ij}d\epsilon_{ij}^{p} = \sigma_{ij}G(J_2)(\partial J_2/\partial\sigma_{ij})dJ_2 \\ &= (3J_2)^{\frac{1}{2}}(\tfrac{2}{3}d\epsilon_{ij}^{p}d\epsilon_{ij}^{p})^{\frac{1}{2}} = \bar{\sigma}(\tfrac{2}{3}d\epsilon_{ij}^{p}d\epsilon_{ij}^{p})^{\frac{1}{2}}. \end{aligned} \quad (13)$$

Consequently the effective strain increment is

$$\begin{aligned}d\bar{\epsilon}^{p} = (\tfrac{2}{3}d\epsilon_{ij}^{p}d\epsilon_{ij}^{p})^{\frac{1}{2}} \equiv (\tfrac{2}{3})^{\frac{1}{2}}[&(d\epsilon_x^{p})^2+(d\epsilon_y^{p})^2 \\ &+(d\epsilon_z^{p})^2+\tfrac{1}{2}(d\gamma_{xy}^{p})^2+\tfrac{1}{2}(d\gamma_{yz}^{p})^2+\tfrac{1}{2}(d\gamma_{zx}^{p})^2]^{\frac{1}{2}}, \end{aligned} \quad (14)$$

as $d\gamma_{xy}=2d\epsilon_{xy}$, etc. and $d\epsilon_{xy}=d\epsilon_{yz}$.

On the other hand, the second method uses the stress-strain relation Eq. (5) directly to form an increment of effective strain. The simplest combination of the plastic strain increments which is positive increasing and has the correct dimension for an effective strain increment is $(d\epsilon_{ij}^{p}d\epsilon_{ij}^{p})^{\frac{1}{2}}$ so that with $(\frac{2}{3})^{\frac{1}{2}}$ inserted arbitrarily to make $\bar{\epsilon}^{p}=\epsilon_z^{p}$ for uniaxial tension in the x-direction

$$d\bar{\epsilon}^{p} = (\tfrac{2}{3})^{\frac{1}{2}}(d\epsilon_{ij}^{p}d\epsilon_{ij}^{p})^{\frac{1}{2}} = (\tfrac{2}{3})^{\frac{1}{2}}G(J_2)(2J_2)^{\frac{1}{2}}dJ_2 = G^{*}(\bar{\sigma})d\bar{\sigma} \quad (15)$$

which shows that the integrated effective strain $\bar{\epsilon}^{p}$ is a function of the effective stress $\bar{\sigma}$. Once the factor $G(J_2)$ has been found for a given material by matching the stress-strain relation, Eq. (5), to an experimental curve, the formula for $\bar{\epsilon}^{p}$ in terms of $\bar{\sigma}$ is completely determined. In this approach also the constant $\sqrt{3}$ in $\bar{\sigma}$ may be inserted if desired to make $\bar{\sigma}=\sigma_x$ for simple tension in the x-direction.

Before the definition of $\bar{\epsilon}^p$ is extended by means of each of the two methods to materials requiring more complicated loading functions, two features which account for the simplicity of the preceding result should be noted. The first is that the loading function $f=J_2=\frac{1}{3}\tau_0^2$ is homogeneous (quadratic) in the stresses; the second, that G is taken to depend on the loading function only. If these two properties are assumed to hold for other stress loading functions of degree r in the stresses and for the corresponding stress-strain relations, the expression for the specific plastic work is found to be a function of f

$$dW^p=\sigma_{ij}G(f)\frac{\partial f}{\partial\sigma_{ij}}df=rfG(f)df, \tag{16}$$

which, if true, would mean that when plastic deformation takes place the plastic work is independent of the path of loading.

Some evidence that f is a homogeneous function of the stresses exists in the results of Fraenkel's tube tests.[12] It was found that for a tube loaded in tension and internal pressure applied in constant ratio, $\mu-\nu$, the difference between Lode's variables, is quite constant for octahedral shear strains larger than 0.02 percent (see discussion[13]). Since ν is given by

$$\nu=\frac{2d\epsilon_2^p-d\epsilon_1^p-d\epsilon_3^p}{d\epsilon_1^p-d\epsilon_3^p}$$

$$=\frac{2(\partial f/\partial\sigma)_2-(\partial f/\partial\sigma)_1-(\partial f/\partial\sigma)_3}{(\partial f/\partial\sigma)_1-(\partial f/\partial\sigma)_3}, \tag{17}$$

homogeneity means constancy of ν as found in the experiment.

A lack of dependence of the dissipated work on the path of loading is a rather surprising result for a nonconservative system. However, Schmidt[14] has shown that, for tubes tested under tension and torsion applied in ratio, equally satisfactory correlation is obtained by plotting $f=\tau_0$ *vs.* work and $f=\tau_0$ *vs.* γ_0. On the other hand, a study of the results of Taylor and Quinney[15] indicates that, in their tests at least, the work dissipated is strongly path dependent and does not depend on the loading function alone. This is one of the most important questions still unanswered and much experimental work remains to be done.

When the effective stress $\bar{\sigma}$ and strain $\bar{\epsilon}^p$ of the simple J_2 or τ_0 isotropic theory do not give satisfactory correlation of experimental data,[16] definitions of $\bar{\sigma}$ and $d\bar{\epsilon}^p$ which depend on a stress-strain relation including the third stress invariant J_3, Eq. (7), should be tried. The necessity for including J_3 to fit experimental results is apparent from the fact that the J_2 theory gives straight μ *vs.* ν curves, i.e. $\mu=\nu$, whereas experiments show ν to be numerically less than μ except at special points. For isotropic loading functions this means that f depends on both J_2 and J_3. A possible inference is that the effective strain include not only the second strain increment invariant $K_2=d\epsilon_{ij}^p d\epsilon_{ij}^p$, as in the J_2 theory, but also the third invariant $K_3=d\epsilon_{ij}^p d\epsilon_{jk}^p d\epsilon_{ki}^p$. However, it will be shown that $(K_2)^{\frac{1}{2}}$ alone provides a satisfactory effective strain increment for many correlations of experimental data.

In the more general isotropic theory $f=f(J_2, J_3)$ where f is homogeneous of degree r in the stresses. Then $\bar{\sigma}=\bar{\sigma}(J_2, J_3)=cf^{1/r}$ where c is a constant which may be adjusted arbitrarily, as before, to make $\bar{\sigma}=\sigma_x$ in the case of simple tension. The first definition of the effective strain $\bar{\epsilon}^p$ by means of $dW^p=\bar{\sigma}d\bar{\epsilon}^p$ is useful but one without direct physical meaning as it is a function of stress as well as strain and cannot be computed from the measurement of strain and strain history along. This approach is equivalent to plotting plastic work against effective stress.[14] On the other hand, the second method for defining the effective strain using the stress-strain relations does not necessarily load to an $\bar{\epsilon}^p$ which is precisely dependent on the loading function f alone. Hence one may have to choose an $\bar{\epsilon}^p$ which is very closely related to, but is not truly a function of, $\bar{\sigma}$ alone. It will, in fact, be shown that for $f(J_2, J_3)$ the effective strain as defined for the simpler J_2 theory is satisfactory for experimental purposes providing, of course, that a J_2, J_3 theory is adequate for the data.

Consider the definition of $d\bar{\epsilon}^p$ by

$$\left(\frac{3}{2}\right)^{\frac{1}{2}}d\bar{\epsilon}^p=(d\epsilon_{ij}^p d\epsilon_{ij}^p)^{\frac{1}{2}}\equiv(K_2)^{\frac{1}{2}}$$

$$=G(f)\left(\frac{\partial f}{\partial\sigma_{ij}}\frac{\partial f}{\partial\sigma_{ij}}\right)^{\frac{1}{2}}df$$

$$=G(f)(M_2)^{\frac{1}{2}}df \tag{18}$$

where M_2 is the second invariant of $\partial f/\partial\sigma_{ij}$, the gradient of f. For the isotropic loading functions under consideration Eq. (18) may be written

$$\left(\frac{3}{2}\right)^{\frac{1}{2}}d\bar{\epsilon}^p=G(f)\left[2J_2\left(\frac{\partial f}{\partial J_2}\right)^2+6J_3\frac{\partial f}{\partial J_2}\frac{\partial f}{\partial J_3}\right.$$

$$\left.+\frac{2}{3}J_2^2\left(\frac{\partial f}{\partial J_3}\right)^2\right]df. \tag{19}$$

It is apparent from (19) that in general this choice of $d\bar{\epsilon}^p$ is not a function of f and df alone and cannot be integrated to give $\bar{\epsilon}^p$ as a function of f alone. Since this isotropic theory includes the effect of J_3, a definition of

[12] S. J. Fraenkel, J. App. Mech., Trans. ASME **70**, 193–200 (1948).

[16] D. C. Drucker, J. App. Mech., Trans. ASME **71**, 349–357 (1949).

$d\bar{\epsilon}^p$ may be tried which includes the third invariant K_3 as well as K_2, e.g.,

$$d\bar{\epsilon}^p = H([K_2]^{\frac{1}{2}}, [|K_3|]^{\frac{1}{3}}). \tag{20}$$

While neither K_2 nor K_3 are functions of f and df alone, the function $H([K_2]^{\frac{1}{2}}, [|K_3|]^{\frac{1}{3}})$ may be equivalent to a function I of f times df

$$d\bar{\epsilon}^p = H([K_2]^{\frac{1}{2}}, [|K_3|]^{\frac{1}{3}}) = I(f)df \tag{21}$$

and therefore may be integrated to give $\bar{\epsilon}^p = \bar{\epsilon}^p(f) = \bar{\epsilon}^p(\bar{\sigma})$. Although a relation of this type between H and I must always exist, $I(f)$ is given by an infinite series in J_2 and J_3, except in degenerate cases such as $f = J_2$. Definitions of $d\bar{\epsilon}^p$ of the type of Eq. (21) are therefore of little practical value. A restricted extension of the second method for defining $\bar{\epsilon}^p$ for $f = f(J_2, J_3)$ and $G = G(f)$

$$\bar{\epsilon}^p = \bar{\epsilon}^p\left(\int (K_2)^{\frac{1}{2}}dt, \quad \int (|K_3|)^{\frac{1}{3}}dt\right) = \bar{\epsilon}^p(f) \tag{22}$$

has the same defects as the definition of Eq. (21); a relation between the two integrals and f in (22) does exist but cannot generally be found in a simple, useful form.

These general procedures fail to give a useful $\bar{\epsilon}^p$, but a satisfactory $\bar{\epsilon}^p$ can be developed by means of the stress-strain relations Eq. (1) as the following example shows. Suppose that in Eq. (1) the function G is modified slightly to

$$G = g(f)/(M_2)^{\frac{1}{2}} \tag{23}$$

instead of $G = G(f)$ (as yet no conclusive experimental evidence exists for or against such a choice). The plastic strain increments are then

$$d\epsilon_{ij}^p = \frac{g(f)}{(M_2)^{\frac{1}{2}}} \frac{\partial f}{\partial \sigma_{ij}} df. \tag{24}$$

Squaring each term and adding gives

$$d\epsilon_{ij}^p d\epsilon_{ij}^p = g^2(f)(df)^2, \tag{25}$$

so that $(d\epsilon_{ij}^p d\epsilon_{ij}^p)^{\frac{1}{2}} = g(f)df$ when integrated will give a function of f alone. Thus any constant times $(d\epsilon_{ij}^p d\epsilon_{ij}^p)^{\frac{1}{2}}$ is an effective strain increment; its integral $\bar{\epsilon}^p$ depends on f or the effective stress $\bar{\sigma}$ alone. The function G is easily modified to produce more complicated definitions of the effective strain in which both K_2 and K_3 appear. If G is

$$G = h(f)/(M_2)^{\frac{1}{2}} + m(|M_3|)^{\frac{1}{3}} \tag{26}$$

where

$$M_2 = \frac{\partial f}{\partial \sigma_{ij}} \frac{\partial f}{\partial \sigma_{ij}}, \quad M_3 = \frac{\partial f}{\partial \sigma_{ij}} \frac{\partial f}{\partial \sigma_{jk}} \frac{\partial f}{\partial \sigma_{ki}},$$

and m is a constant, then the effective strain may be taken as any constant times

$$d\bar{\epsilon}^p = h(f)df = (K_2)^{\frac{1}{2}} + m(|K_3|)^{\frac{1}{3}}, \tag{27}$$

which again may be integrated directly. Still more general combinations, of course, may be derived.

These altered forms of the stress-strain relation are basically different from the previous ones for which $G = G(f)$. The work dissipated W^p is no longer dependent on the final state of stress or f alone. At present there is no definite indication as to which type of assumption is closer to physical reality. Experiment alone must decide, in each individual case, which stress-strain relation is best. As mentioned previously, the process of plastic deformation is irreversible so that even limited path independence $W^p = W^p(f)$ would be quite startling.

Fortunately, as the next section demonstrates, comparison of the results obtained with the various forms of G shows that the difference between $\bar{\epsilon}^p$ *vs.* $\bar{\sigma}$ curves in which $d\bar{\epsilon}^p$ is defined by means of the different factors is small. *Therefore $d\bar{\epsilon}^p$ can be chosen as $(\frac{2}{3})^{\frac{1}{2}}(d\epsilon_{ij}^p d\epsilon_{ij}^p)^{\frac{1}{2}}$ for materials which work harden isotropically in the range considered.*

THE DEPENDENCE OF THE EFFECTIVE STRAIN $\bar{\epsilon}^p$ ON THE FACTOR G

It having been demonstrated that the effective strain $\bar{\epsilon}^p = \int (\frac{2}{3})^{\frac{1}{2}}(d\epsilon_{ij}^p d\epsilon_{ij}^p)^{\frac{1}{2}}$ is a function of f or $\bar{\sigma}$ when the factor G in the stress-strain relation is given by $g(f)/(M_2)^{\frac{1}{2}}$ whereas $d\bar{\epsilon}^p$ is not in general a function of f along when $G = G(f)$, it is desirable to find a way of estimating the difference in $\bar{\epsilon}^p$ according to the two different types of G.

The two stress-strain relations may be written

$$d\epsilon_{ij}^{p(A)} = G(f) \frac{\partial f}{\partial \sigma_{ij}} df \tag{28}$$

$$d\epsilon_{ij}^{p(B)} = \frac{g(f)}{(M_2)^{\frac{1}{2}}} \frac{\partial f}{\partial \sigma_{ij}} df. \tag{29}$$

If the two relations are each matched to a given experimental shear stress *vs.* shear strain curve, τ *vs.* γ, it is readily found that, for an increment of f at any value of f, the increments of plastic strain for any loading path are related to each other quite simply by

$$d\epsilon_{ij}^{p(A)} = \frac{(\frac{1}{2}M_2)^{\frac{1}{2}}}{(\partial f/\partial \tau)} d\epsilon_{ij}^{p(B)} = R d\epsilon_{ij}^{p(B)}. \tag{30}$$

where $R = (\frac{1}{2}M_2)^{\frac{1}{2}}/(\partial f/\partial \tau)$. The maximum difference between the two strains can be computed for a given loading function and given types of loading by finding the deviation of R from unity.

For the extreme case of the particular loading function $f = J_2^3 - (9/4)J_3^2$ in which J_3, the shearing stress weighting factor, is much more prominent than ordinarily demanded by experimental data, the range of variation of the factor of difference R is only $0.935 \leq R \leq 1$. Figure 5 shows the maximum difference in the

tension curves for the two laws after they have been matched in shear. The curve A is obtained by multiplying the strain value for the B curve by $R=0.935$. If instead of a tension curve, the effective stress-strain curve $\bar{\sigma}$ *vs.* $\bar{\epsilon}^p$ is desired, the same method is applied since $d\bar{\epsilon}^{p(A)}=(\frac{2}{3})^{\frac{1}{2}}(d\epsilon_{ij}{}^{p(A)}d\epsilon_{ij}{}^{p(A)})^{\frac{1}{2}}=Rd\bar{\epsilon}^{p(B)}$ according to the second method of defining effective strain.

The difference between the plots of $\bar{\sigma}$ *vs.* $\bar{\epsilon}^p$ for any other loading path, no matter how complicated, is less than for simple tension. Therefore, if effective strain $\bar{\epsilon}^p$ is to be plotted as a function of $\bar{\sigma}$, one may use $\bar{\epsilon}^p=(\frac{2}{3})^{\frac{1}{2}}\int(d\epsilon_{ij}{}^p d\epsilon_{ij}{}^p)^{\frac{1}{2}}$ with the assurance that even for extreme cases a small variation only occurs between a plot for which Eq. (28) applies and one for which Eq. (29) is correct. The effective strain, so defined, may be used to calculate the plastic work done by $W^p=\int\bar{\sigma}d\bar{\epsilon}^p$ within close limits providing, of course, that the assumption of isotropic work hardening is sufficiently good for the path of loading studied.

It is interesting to note that in the customary tests on thin walled tubes in which all stresses are increased in ratio, the simple $\bar{\epsilon}^p$ defined above is a constant times the octahedral shearing strain. If the material of the tube is reasonably isotropic at the start, all such tests, no matter what the ratios chosen, will give very closely

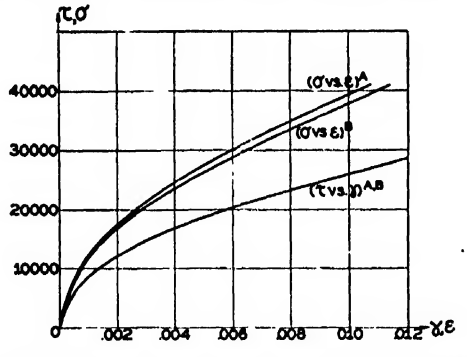

FIG. 5. Predicted σ *vs.* ϵ curves for A and B types of stress-strain relations based on a τ *vs.* γ curve of a severe test with the effect of J_3 overly prominent.

a single curve when the coordinates are chosen as $\bar{\sigma}(J_2, J_3)$ and $\bar{\epsilon}^p$ as the octahedral shearing strain.[16]

The expressions for effective stress $\bar{\sigma}=\bar{\sigma}(f)$ and effective strain $\bar{\epsilon}^p$ developed so far have been for isotropic work hardening and will not correlate experimental information from initially anisotropic materials. The general definitions of $\bar{\sigma}$ and $\bar{\epsilon}^p$, of course, also apply to the anisotropic case, but there the proper anisotropic stress-strain relations must be used.

ANISOTROPIC THEORY

As stated, the "stress" theories of plasticity $f=f(\sigma_{ij})$ with which this paper is concerned can only treat anisotropic materials which are free from Bauschinger effects for the loading being considered. The anisotropy is regarded as intrinsic in the material and is manifested in the loading function by asymmetry.

The work of Dorn,[6] of Fisher,[7] of Jackson, Smith and Lankford,[5] and of Hill[17] indicates that for many anisotropic materials, a loading function quadratic in the stresses is almost as satisfactory as J_2 is for the isotropic case. For such a loading function the stress-strain relation is given by Eq. (8)

$$d\epsilon_{ij}{}^p=2GA_{ijkl}\sigma_{kl}df. \tag{8}$$

As an example, the case of orthotropic symmetry in a material for which hydrostatic pressure does not influence plastic deformation and G is a function of f will be considered. The loading function f can be written as

$$\begin{aligned}2f=&A(\sigma_x-\sigma_y)^2+B(\sigma_y-\sigma_z)^2+C(\sigma_z-\sigma_x)^2+3D\tau_{xy}{}^2\\&+3D\tau_{yz}{}^2+3E\tau_{yz}{}^2+3E\tau_{zy}{}^2+3F\tau_{zx}{}^2+3F\tau_{xz}{}^2,\end{aligned} \tag{31}$$

where A, B, C, D, E, F are coefficients of anisotropy which become unity in the isotropic case. As f multiplied by any constant is just as satisfactory a loading function, one of the coefficients is not needed and can be taken as unity. The form (31) is employed purely for the sake of symmetry not generality.

The stress-plastic strain relations $d\epsilon_{ij}{}^p=G(\partial f/\partial\sigma_{ij})df$ become

$$\begin{aligned}d\epsilon_x{}^p&=G(\partial f/\partial\sigma_x)df=Gdf[A(\sigma_x-\sigma_y)-C(\sigma_z-\sigma_x)]\\d\epsilon_y{}^p&=G(\partial f/\partial\sigma_y)df=Gdf[B(\sigma_y-\sigma_z)-A(\sigma_x-\sigma_y)]\\d\epsilon_z{}^p&=G(\partial f/\partial\sigma_z)df=Gdf[C(\sigma_z-\sigma_x)-B(\sigma_y-\sigma_z)]\\d\epsilon_{xy}{}^p&=1/2d\gamma_{xy}{}^p=G(\partial f/\partial\tau_{xy})df=Gdf3D\tau_{xy}\end{aligned} \tag{32}$$

etc.

The ratios of the constants may be determined by simple tests. For example, under uniaxial tension, σ_z,

$$d\epsilon_y{}^p/d\epsilon_z{}^p=A/C, \quad \text{or} \quad d\epsilon_y{}^p/d\epsilon_x{}^p=-A/(A+C). \tag{33}$$

As f is quadratic the effective stress $\bar{\sigma}$ must be taken as $c(f)^{\frac{1}{2}}$ just as for the isotropic J_2. However, the choice of c which makes $\bar{\sigma}=\sigma_x$ for uniaxial tension in the x-direction does not make $\bar{\sigma}=\sigma_y$ for uniaxial σ_y.

A definition of effective strain corresponding to the anisotropic loading function (31) is obtained quite easily by either method considered. Here, in this special form, as in the J_2 isotropic quadratic theory, $dW^p=\bar{\sigma}d\bar{\epsilon}^p$ defines a $d\bar{\epsilon}^p$ in terms of the plastic strain increments alone. This is true because $dW^p=\sigma_{ij}d\epsilon_{ij}{}^p=G2fdf=(G(2/c)(f)^{\frac{1}{2}}df)\bar{\sigma}$, and $d\bar{\epsilon}^p=G(2/c)(f)^{\frac{1}{2}}df$ is a quadratic form in $d\epsilon_{ij}{}^p$. In engineering notation Eqs. (32) when solved for the stress differences and shearing stresses become

$$\begin{aligned}\sigma_x-\sigma_y&=\frac{Bd\epsilon_x{}^p-Cd\epsilon_y{}^p}{Gdf(AB+BC+AC)};\ \text{etc.}\\\tau_{xy}&=\frac{1}{2}\frac{d\gamma_{xy}{}^p}{Gdf3D};\ \text{etc.}\end{aligned} \tag{34}$$

Substituting (34) in (31) gives f as a quadratic function of the strains divided by $(Gdf)^2$. The effective strain

[17] R. Hill, Proc. Roy. Soc. A193, 281–297 (1948).

increment is thus a constant times the square root of $f(Gdf)^2$. Noting that

$$(d\epsilon_x^p)^2+(d\epsilon_y^p)^2+(d\epsilon_z^p)^2=-2d\epsilon_x^p d\epsilon_y^p-2d\epsilon_y^p d\epsilon_z^p-2d\epsilon_z^p d\epsilon_x^p \quad (35)$$

gives

$$d\bar{\epsilon}^p=2G(f)^{\frac{1}{2}}df/c$$

$$=\frac{(2)^{\frac{1}{2}}}{c}\left\{\frac{B(d\epsilon_x^p)^2+C(d\epsilon_y^p)^2+A(d\epsilon_z^p)^2}{AB+BC+AC}+\frac{(d\gamma_{xy}^p)^2}{6D}+\frac{(d\gamma_{yz}^p)^2}{6E}+\frac{(d\gamma_{zx}^p)^2}{6F}\right\}^{\frac{1}{2}} \quad (36)$$

which reduces to the isotropic form (14) where all constants including c are unity. The constant $(2/c)$ was chosen so that

$$dW^p=\sigma_{ij}d\epsilon_{ij}^p=\sigma_{ij}G\frac{\partial f}{\partial\sigma_{ij}}df=G2fdf$$

$$=\frac{2}{c}Gc(f)^{\frac{1}{2}}(f)^{\frac{1}{2}}df=\bar{\sigma}d\bar{\epsilon}^p.$$

Equation (36) can only be used if experiments verify the hypothesis that $G=G(f)$ or the plastic work done is path independent.

For completely general quadratic anisotropic loading functions the effective strain increment is found as in Eq. (36) to be the root of a quadratic in the plastic strain increments whose coefficients are simply related to the coefficients of the stresses in f. If f is written in terms of nine stress components

$$f=A_{ij}\sigma_i\sigma_j \quad (i,j=1,2,\cdots,9), \quad (37)$$

the stress-strain relations (8) become

$$d\epsilon_i^p=2GA_{ij}\sigma_j df \quad (38)$$

which may be solved for the stresses to give

$$\sigma_i=B_{ij}d\epsilon_j^p/2Gdf \quad (39)$$

where B_{ij} is the inverse of A_{ij}; i.e., $B_{ij}A_{jk}=\delta_{ik}$. As for Eqs. (34), (36), if the plastic volume change is zero, the inverse is not unique and a variety of equivalent forms is possible. Using the same definition of effective stress and strain as before, $\bar{\sigma}=c(f)^{\frac{1}{2}}$, $d\bar{\epsilon}=(2/c)G(f)^{\frac{1}{2}}df$, gives

$$d\bar{\epsilon}^p=(1/c)(A_{ij}B_{im}d\epsilon_m^pB_{jn}d\epsilon_n^p)^{\frac{1}{2}}$$

$$=(1/c)(B_{mn}d\epsilon_m^pd\epsilon_n^p)^{\frac{1}{2}}. \quad (40)$$

If experiments show that the quadratic anisotropic f of Eq. (37) is not satisfactory for experimental correlation, loading functions of higher degree in the stresses may have to be used. As in the isotropic case, if the assumption that plastic work is path independent, $G=G(f)$, is dropped, the effective strain may well be defined by the second method in the same form (40) as for the quadratic case, simply take

$$d\epsilon_i^p\propto\frac{g(f)}{[B_{ij}(\partial f/\partial\sigma_i)(\partial f/\partial\sigma_j)]^{\frac{1}{2}}}\frac{\partial f}{\partial\sigma_i}df, \quad (41)$$

so that

$$d\bar{\epsilon}^p\propto(B_{ij}d\epsilon_i^pd\epsilon_j^p)^{\frac{1}{2}}=g(f)df. \quad (42)$$

Little more can be said about the proper forms of $\bar{\sigma}$ and $\bar{\epsilon}^p$ as experimental data is very meager. It is hoped that this type of approach will serve as a useful guide in future experimental research.

CONCLUSION

Definitions of effective stress $\bar{\sigma}$ and effective strain $\bar{\epsilon}^p$ which offer the possibility of better understanding of tests on isotropic and anisotropic work hardening materials are given on the basis of stress-strain relations from the recent "stress" theories of plasticity.

The effective stress $\bar{\sigma}$ is defined in terms of the loading function f associated with the given material. A comparison is made between two fundamentally different definitions of the effective strain $\bar{\epsilon}^p$. One, now in use, assumes that the work dissipated depends on the final state of stress alone and not on the path, and the other presented here analyzes the stress-strain relations. For $f=J_2$ the two resulting definitions of $\bar{\epsilon}^p$ coincide and, for certain other loading functions, no matter how complicated the path of loading, agree within practical limits. For many purposes, therefore, the definition of effective strain given by Dorn

$$\bar{\epsilon}^p=\int_{\epsilon_p}(d\epsilon_{ij}^pd\epsilon_{ij}^p)^{\frac{1}{2}}$$

is entirely satisfactory even though $f=f(J_2,J_3)$. Fundamental differences exist, however, and the basic work assumption must be further examined as pertinent experimental data is obtained.

Although the several $\bar{\epsilon}^p$ and $\bar{\sigma}$ as defined here will correlate a variety of tests in a useful manner, the concepts of effective strain and stress must break down for loading paths in which Bauschinger and similar effects are present.

Formation of Crystal Nuclei in Liquid Metals

D. Turnbull
Research Laboratory, General Electric Company, Schenectady, New York
(Received April 13, 1950)

The known facts about nucleation phenomena in liquid metals are interpreted satisfactorily on the basis of the critical size and interfacial energy concepts. In large continuous masses nucleation is almost always catalyzed by extraneous interfaces. However, in very small droplets the probability that a catalytic inclusion is present is so much less that their minimum nucleation frequencies are reproducible and form a consistent set of values.

Interfacial energies, σ, between crystal nuclei and the corresponding liquids have been calculated from nucleation frequencies of small droplets on the basis of the theory of homogeneous nucleation. Energies of interfaces, σ_0, one atom thick and containing N atoms were calculated from the σ's. The ratio of σ_0 to the gram atomic heat of fusion, ΔH_f, was approximately 0.45 for most metals but $\sim$0.32 for H_2O, Bi, Sb, and Ge.

The effect of relative complexity of crystal structure upon the supercooling behavior of pure metals apparently is a reflection of its effect upon ΔH_f.

THE solidification of pure metals may be thought of as a sequence of two steps: nucleation of crystals and their subsequent growth. It is known that the growth of large metal crystals into their supercooled melts is very rapid and usually limited only by the rate at which the heat of solidification can diffuse from the interface. On the other hand the time preceding the appearance of "macroscopic" crystals may be very long relative to the duration of rapid growth and often controls the solidification rate. This time delay is known as the "nucleation" period. The reciprocal of the average nucleation period is the nucleation frequency or rate and is proportional to the volume of liquid or to the area of interfaces in the system that catalyze nucleation.

Nucleation rates measured on large continuous liquid metal masses are not reproducible. However, recent experiments[1,2] on the supercooling of small metal droplets have shown that the temperatures at which the rate of crystal nucleation becomes appreciable in them are consistent and reproducible to within about ± 5 percent.

Generalizations about the solidification behavior of small droplets have been made in a preceding paper.[2] By combining these generalizations with the known facts of the supercooling behavior of large masses, a theory of nucleation can be constructed that accounts qualitatively for the nucleation behavior of liquid metal masses of all sizes and surface conditions.

CRYSTAL NUCLEATION AND ITS CATALYSIS

In nearly all theories of homogeneous (non-catalyzed) nucleation of crystals in liquids it is supposed that the nucleation period is the time necessary for a crystal of a certain critical size to form by thermal fluctuations. The radius of a critical size nucleus is directly proportional to the interfacial energy between the liquid and crystal and inversely proportional to the difference in free energy between liquid and crystal phases of infinite volume. The free energy of a crystal of critical size is decreased by fluctuations that either add or subtract atoms to it; consequently, any crystal that is smaller than the critical size will usually disappear and any that becomes larger will usually grow.

On the basis of these concepts and absolute rate theory, the following expression has been derived[3] for the homogeneous nucleation frequency of crystals in supercooled liquids:

$$I = A \exp[-K\sigma^3/(\Delta F_V)^2 kT], \qquad (1)$$

where $A = n(kT/h) \exp[-\Delta F_A/kT]$ and the other symbols are defined as follows: I = number of nuclei/sec. $\times$cm^3, n = number of atoms in the mass of liquid, K = a factor determined by the shape of the nucleus, σ = interfacial energy/cm^2 between liquid and crystal, ΔF_V = difference in free energy/cm^3 between crystal and liquid phases of infinite volume, and ΔF_A = free energy of activation for transporting an atom across the liquid-crystal interface.

In Eq. (1) three parameters σ, K, and ΔF_A are not known. However, experience indicates that ΔF_A is very small, at least for large crystals, and there is reason to believe that it is of the same magnitude as the activation energy for viscous flow, $\Delta F_A'$. If $\Delta F_A \approx \Delta F_A'$ then $\exp(-\Delta F_A/kT)$ is of the order of 10^{-2} at the solidification temperature for most metals. Therefore, it is expected that $A \approx 10^{33\pm1}$ sec.$^{-1}$ cm^{-3}. A can be evaluated from measurements of the homogeneous nucleation frequency as a function of temperature and its value compared with the predictions of theory. If the theory is thus approximately verified, Eq. (1) can be used to calculate σ (assuming some shape for the nucleus) from the nucleation frequency measured at a single temperature.

There is convincing evidence that nucleation of crystals in large continuous masses of liquid metals is almost always catalyzed by accidental inclusions and container walls.[4-6] The theory of nucleation catalysis is

[1] D. Turnbull, J. Metals 188, 1144 (1950).

[6] J. H. Hollomon, A.S.M. Symposium on Thermodynamics, Cleveland (1949).

also based upon the critical size concept. When crystals form on the surfaces of catalytic interfaces the total increase in free energy due to forming the crystal surfaces is less than the increase that would accompany the formation of the same mass of crystal without the aid of extraneous interfaces. Catalysis requires that interfaces be present such that the equilibrium contact angle, θ, made by the crystal and the interface in the presence of liquid be less than 180°. An expression can be written for the frequency of heterogeneous (catalyzed) nucleation analogous to the expression for homogeneous nucleation as follows:[7]

$$I_s = A' \exp[-K\sigma^3\{f(\theta)\}/(\Delta F_V)^2 kT], \qquad (2)$$

where $A' = n_s(kT/h)\exp[-\Delta F_A/kT]$, $f(\theta) = (2+\cos\theta)\times(1-\cos\theta)^2/4$, I_s = nuclei/sec. cm^2, n_s = number of atoms in the interface/cm^2, and A' is estimated to be $\approx 10^{25\pm1}$ sec.$^{-1}$ cm^{-2}. Thus a clear distinction can be made between homogeneous and heterogeneous nucleation on the basis of the coefficient A evaluated from data on the nucleation frequency as a function of temperature. However, in large masses of liquid the nucleation frequency usually follows no regular relation such as (2) because accidental catalysts of varying degrees of effectiveness (i.e. different θ values) are liable to be present in different samples. Due to these difficulties adequate testing of the nucleation theory with data on large masses of liquid metals is almost impossible.

One approach to the problem of measuring the rate of homogeneous nucleation is to pass the liquid through fine filters prior to the rate studies in order to remove catalytic particles. It is known that the frequency of nucleation in filtered samples often is much smaller than in unfiltered ones.[8,9] However, the method is not promising for the investigation of nucleation in metal samples. Because of the relatively rapid growth rate of metal crystals, a nucleus originating at a single catalytic site can quickly transform a very large mass of liquid.

A method of eliminating the effects of nucleation catalysis that appears more promising for liquid metals is to break the sample into a number of non-communicating droplets that is large in comparison with the number of catalytic sites. This technique has recently been used to study the solidification behavior of a large number of pure metals.[1,2]

Data on the isothermal rates of solidification of small droplet aggregates of tin[10] and mercury[11] at several temperatures are now available. The temperature dependence of the nucleation frequency is so great that it was easily measurable only in narrow ranges of temperature corresponding to 59 to 63° supercooling for mercury and 100 to 115° for tin. Analysis of the data showed that $A = 10^{30.4}$ for tin and $10^{30.9}$ for mercury. Considering the theoretical and experimental uncertainties these numbers are in good agreement with the value for $A \approx 10^{33}$ calculated from the theory of homogeneous nucleation but considerably larger than the value 10^{25} to be expected if nucleation were catalyzed by a film coating the entire surface of all the droplets. Thus it appears that the conditions for homogeneous nucleation were closely approached in these experiments.

Because of the sharp temperature dependence of the nucleation frequency shown in these experiments (for mercury, I changed by a factor of 10 in 1½°C), it is possible to specify a narrow range, δ, of supercooling ΔT_- such that the nucleation frequency is practically zero when $\Delta T_- < \delta$ and immeasurably fast when $\Delta T_- > \delta$. On the basis of these results it is expected that crystals would be formed at a measurable rate in small droplets of other metals within a comparatively narrow temperature band characteristic of the metal. Microscopic observations of the solidification of small droplets (10 to 100 micron diameter) of many other metals confirmed this expectation.[2]

A maximum supercooling $(\Delta T_-)_{max}$ was found for each pure metal corresponding to a temperature at which the nucleation frequency becomes appreciable. Not all droplets supercool as much as $(\Delta T_-)_{max}$ but under suitable conditions a large fraction do. For most metals $(\Delta T_-)_{max}$ is of the order of 0.18 times the absolute melting temperature, T_0. Also, it is found that $(\Delta T_-)_{max}$ is reproducible (±5 percent) and not dependent upon the source of the metal in cases where this factor was varied.

SIZE EFFECT IN NUCLEATION

According to the critical size concept, the frequency of homogeneous nucleation of crystals, I_v, in droplets of volume v is

$$I_v = Iv, \qquad (3)$$

where I is given by Eq. (1). From the results on mercury and tin I_v may be calculated for any volume of liquid metal or alternatively the amount of supercooling (ΔT_-) at which the rate of nucleation becomes appreciable in droplets of a given size can be calculated as a function of the volume. For example, mercury droplets 4 microns in diameter were found to solidify[11] with a frequency of about 10^{-5} sec.$^{-1}$ at $\Delta T_- = 60$. From the rate equation it was calculated that nuclei should form with the same frequency in a mercury droplet 1 cm^3 in volume at a supercooling $\Delta T_- \sim 49°$. Since similar relations for the rate of nucleation are expected to be valid for other substances it is inferred that large continuous masses of liquid metals (of the order of 1 cm^3 in volume) *completely free of catalytic inclusions* and *not subjected to mechanical vibration* should supercool about

[11] D. Turnbull, J. Chem. Phys. 18, 768 (1950).

0.8 of the maximum supercooling observed in small droplets $(\Delta T_-)_{max}$, before solidification.

In agreement with this view, large continuous masses of liquid have been supercooled occasionally almost as much as small droplets. For example, comparatively large masses of gallium,[1] water,[12] and iron[13] have been supercooled more than 0.73 $(\Delta T_-)_{max}$.

The fact that continuous liquid masses 1 cm³ or more in volume rarely supercool more than ~ 0.05 $(\Delta T_-)_{max}$ is consistent with the viewpoint that the probability of finding accidental inclusions effective in promoting crystal nucleation is much greater in large than in small masses. This probability should increase either as the volume or surface area of the droplet so that, for example, the chances of finding one accidental inclusion in a 1 cc mass of mercury is about 10^{11} times greater than the chance of finding an inclusion in a 4 micron droplet separated from it. Thus, it appears that the known facts about the supercooling of small droplets and large masses of liquid metals are adequately accounted for on the basis of the critical size concept.

THERMAL HISTORY EFFECT IN SOLIDIFICATION

It has been fairly well established that the thermal history dependence of the nucleation frequency usually observed in the solidification of large continuous liquid masses is due to catalytic inclusions and container walls.[4,5] It follows that the nucleation frequency of small droplets should not be thermal history dependent provided that the catalysts responsible for the effect are in fact segregated in a small proportion of the droplets. This prediction has been verified by experiments on bismuth.[1] The nucleation frequency in large continuous masses of bismuth has been shown to be very dependent upon thermal history[14] but in small droplet aggregates it is independent of thermal history.[1]

From the facts that the nucleation frequency of lead crystals in sulfate-coated droplets, though increased by the catalytic effect of the film, is apparently not dependent on thermal history, it may be inferred that the presence of nucleation catalysts is a necessary but not a sufficient condition for thermal history dependence. On the basis of the micro-cavity theory of the effect,[5] the following conditions should be fulfilled in order for a thermal history effect to be observed:

1. Suitable microcavities be present in the catalytic surface. These microcavities retain small crystals above the melting temperature, but in order to be effective their diameter has to be very small (*ca.* 10^{-6} cm).
2. The substance must penetrate and fill the microcavities.
3. The contact angle θ made by the crystal with the catalytic surface when immersed in liquid should be less than 90°.

ALTERNATIVE INTERPRETATIONS OF THE SUPERCOOLING OF SMALL DROPLETS

In the foregoing it has been established that the known facts about nucleation of crystals in liquids can be explained satisfactorily on the basis of the "critical size theory." It remains to be considered whether any alternative hypotheses might explain the phenomena as well.

The basic fact to be accounted for is the long waiting period prior to the rapid growth of large crystals. Apart from the critical size hypothesis such a result might be explained if very small crystals, assumed to be stable, grow into supercooled melts at a rate many orders of magnitude less than do large crystals.

Two hypotheses that could lead to such an effect are thought worthy of serious consideration. First, it might be assumed that crystals need to have some type of imperfections in their surface in order to grow rapidly. Conceivably the probability that small crystals contain such imperfections might be much smaller than for

* Heats of fusion and absolute melting points used in the computations summarized in Tables I and II are those recommended by K. K. Kelley ["Contributions to the Data on Theoretical Metallurgy. V. Heats of Fusion of Inorganic Substances," Bureau of Mines Bulletin No. 393 (1936)] with the exception of the heat of fusion of germanium (6100 cals/g atom) that was calculated by R. A. Oriani of this Laboratory from equilibrium data on the binary systems Ge-Au, Ge-Pb, Ge-Ag.

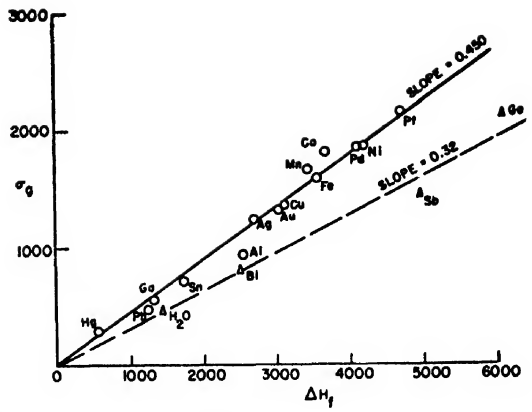

FIG. 1. Gram-atomic interfacial energy as a function of the gram-atomic heat of fusion for various substances.

large crystals so that ΔF_A would be larger for the former. However, it is not easy to construct a model that would account for such a marked effect of imperfections upon growth rate unless the interfacial energy between liquid and crystal is quite large. Thus, dissociation of the imperfection and critical size hypotheses is difficult. A further difficulty with the imperfection hypothesis is that it does not account for the effect of specimen volume upon nucleation frequency.

The other hypothesis considered is that minute amounts of soluble impurities inhibit nucleation in some way. In the experiments on the solidification of small droplets[1,2] impurity concentrations were usually of the order of 0.001 to 0.1 atomic percent. It does not seem likely that such small concentrations of impurity could inhibit nucleation by causing the liquid-crystal interfacial energy to be increased. However, it is well known that minute quantities of impurity sometimes profoundly affect the macroscopic growth rate of crystals so it is conceivable that the growth of very small metal crystals in supercooled melts is practically stopped by such impurities.

Nevertheless, there are convincing arguments against this interpretation of nucleation during solidification. A mechanism whereby impurities effectively inhibit the growth of microcrystals but not macrocrystals is possible but complicated. In the small droplet experiments $(\Delta T_-)_{max}$ was found to be independent, within experimental error, of the source and purity (within limits) of particular metals. Also it is important that the $(\Delta T_-)_{max}$ values obtained by Turnbull and Cech[2] and Mendenhall and Ingersoll[15] on the metals common to both investigations are in close agreement. This consistency in the experimental data would not be expected if the rate controlling factor were inhibition by soluble impurities. Finally it appears that the wide difference in nucleation frequency for large and small masses of liquids cannot be explained on the basis of the inhibition hypothesis unless the critical size theory is also used. There is no reason why minor amounts of soluble impurities should be more effective in inhibiting crystal growth in small droplets than in large continuous liquid masses unless it is supposed that in the latter crystals are formed by a different mechanism such that their continued growth is not inhibited. It appears that the only other reasonable mechanism involves the catalytic action of insoluble impurities.

In view of these arguments it seems that the known facts about nucleation of crystals in liquids can be interpreted much more satisfactorily on the basis of the critical size theory than in terms of either of the slow-growth hypotheses examined. The excellent correlations of the small droplet supercooling data to be presented in the following sections constitute a further decisive argument in favor of the critical size interpretation.

CORRELATIONS OF DATA ON SUPERCOOLING OF SMALL DROPLETS

The ratio of the maximum supercooling observed in small droplets to the absolute melting temperature, $(\Delta T_-)_{max}/T_0$, is nearly a constant for many metals. These ratios for 50 micron diameter droplets of various metals are given in Table I. In calculating $(\Delta T_-)_{max}/T_0$ for iron and manganese there is the problem that the metals solidify in temperature ranges in which the most stable crystal phase is different from that in equilibrium with the liquid at the normal melting point. It is not known which phase nucleates most rapidly in the liquid at the solidification temperature but it was assumed arbitrarily that the solid phase stable at the normal melting point nucleates first. The assumption can cause little error in the iron calculation since the difference in free energy between the face centered and body centered cubic phases is very small.

For all but six of the substances $(\Delta T_-)_{max}/T_0$ is

[15] C. E. Mendenhall and L. R. Ingersoll, Phil. Mag. 15, 205 (1908).

≈ 0.185 with maximum deviations of ± 0.02. Considering all the data, the ratio ranges from 0.133 for lead to 0.250 for gallium.

When the implications of the approximate constancy of $(\Delta T_-)_{max}/T_0$ are examined in terms of the theory of homogeneous nucleation (see Eq. (1)) it is found that the ratio would be constant if σ were proportional to the gram atomic heat of fusion, ΔH_f, and if the entropy of fusion $(\Delta H_f/T_0)$ were constant. Entropies of fusion of metals are approximately 2.3 cal./deg.×g atom but there are some marked deviations from this value (e.g. 4.4 for Ga). These considerations suggested that a deeper insight into the phenomena might be gained by comparing σ directly with ΔH_f.

Values of σ were calculated from the nucleation frequency at one temperature and Eq. (1) with the aid of the following assumptions:

1. Crystal nuclei are spherical in shape so that $K = 16\pi/3$.

2. $\mathrm{Exp}(-\Delta F_A/kT) = 10^{-2}$.

3. The entropy of fusion is independent of temperature.

The validity of these assumptions has been discussed elsewhere.[7] It follows from 3 that

$$\Delta F_V = \lambda \Delta T/T_0, \tag{4}$$

where λ = heat of fusion/cm^3 and $\Delta T = T - T_0$. It is believed that the available data are in general not sufficiently accurate to justify the use of a more precise free energy function. From the assumptions and Eq. (1)

$$\sigma = [\{3 \times 2.303 \lambda^2 (\Delta T)^2 kT/16\pi T_0^2\} \times \log(nkT \exp\{-\Delta F_A/kT\}/Ih)]^{\frac{1}{3}}. \tag{5}$$

I is estimated to be $10^{-(1\pm1)}$ sec.$^{-1}$ per 50-micron particle at the maximum supercooling. Although the uncertainty in I is very large, a factor of 10 error in its value introduces an error of only 1 percent in the calculated σ.

Since ΔH_f is a gram-atomic quantity it should be compared with a gram-atomic surface energy σ_g, which may be defined as the free energy of an interface containing Avogadro's number, N, atoms. If the area of such an interface is A,

$$\sigma_g = \sigma A. \tag{6}$$

Let it be assumed arbitrarily that the interface is one atom thick and let V be the gram-atomic volume; then,

$$A = N^{\frac{1}{3}} V^{\frac{2}{3}}, \tag{7}$$

where a structure factor of the order of unity is neglected. This treatment is analogous to that of Skapski[16] on liquid-vapor interfaces. Substitution of (7) into (6) gives:

$$\sigma_g = N^{\frac{1}{3}} V^{\frac{2}{3}} \sigma. \tag{8}$$

σ_g has been calculated for all of the substances whose solidification was studied by the small particle technique and the resulting values expressed in calories/gm atom are given in Table II.

Calculated ratios of σ_g to ΔH_f (see Table II) are fairly constant, ranging from about 0.31 for antimony to 0.53 for mercury. It is interesting that $\sigma_g \approx \frac{1}{2}\Delta H_f$ for one class of substances and $\approx \frac{1}{3}\Delta H_f$ for a smaller class. This difference is shown in Fig. 1 where σ_g is plotted against ΔH_f. The points for the more metallic substances (Class I) fall (within the experimental error) on a straight line of slope 0.45. Points corresponding to water and the semimetallic elements (antimony, bismuth, and germanium) (Class II) fall on a second line of slope 0.32.

Correct evaluation of σ_g depends upon the validity of the theory of homogeneous nucleation. There is an empirical correlation upon which the success of the correlation of σ_g with ΔH_f is based. This relation is:

$$[(\Delta T_-)_{max}/T_0]^{\frac{1}{3}}[\{T_0 - (\Delta T_-)_{max}\}/\Delta H_f]^{\frac{1}{3}} = M, \tag{9}$$

where M is constant for a class. M is equal to (see Table I) 0.222 ± 0.01 for Class I and 0.158 ± 0.01 for Class II.

The greater success of the $\sigma_g/\Delta H_f$ correlation relative to that of $(\Delta T_-)_{max}/T_0$ is in part illusory since the most important empirical factor (see Eq. (9)) leading to the success of the former is $[(\Delta T_-)_{max}/T_0]^{\frac{1}{3}}$. However, when this is corrected for, the $\sigma_g/\Delta H_f$ correlation is still the better of the two and in addition it appears to be more promising from a theoretical standpoint.

It is noted that the point for aluminum (see Fig. 1) on the σ_g *vs.* ΔH_f curve falls considerably below the Class I line on which it would seem to belong. Probably the most reasonable explanation of this disagreement is that surface films that may have catalyzed nucleation of aluminum crystals were not completely eliminated in the experiments.[2]

INTERPRETATION OF GRAM-ATOMIC INTERFACIAL ENERGIES

It is not surprising that mercury, tin, and the metals having cubical crystal structures fall into a distinct class with respect to solidification behavior. The four substances in Class II have the property of expanding upon solidification. In addition, their crystal structures are relatively more complex than the substances of I and excepting water over certain ranges of temperature they are all semiconductors. However, gallium exhibits all these properties yet it certainly falls in Class I. It is, of course, possible that the separation into two classes is more apparent than real. Perhaps the elements of Class II did not supercool the maximum amount for some unknown reason (in order to belong to Class I bismuth droplets should supercool 130° compared to the 90° observed) or approximations necessary in calculating σ_g may have caused misleading results. Nevertheless, the separation may be intrinsic for reasons not now apparent.

The parameter σ can be identified with the interfacial

[16] A. S. Skapski, J. Chem. Phys. 16, 386 (1948).

energy between small crystal nuclei and liquid but it is important to know whether or not it corresponds to the interfacial energy between large crystals and their melts. Any such correspondence or lack of it can only be established by measurement of σ for large crystals. However, there is some indirect evidence that σ may not be markedly dependent on crystal size. The interfacial energies between liquid nuclei and vapor calculated from the nucleation rates[17, 18] measured by Volmer and Flood[19] are in good agreement with the values measured directly on extensive liquid surfaces. Apparently decreasing the size of liquid droplets to the dimensions of nuclei has little effect upon vapor-liquid interfacial energies.

Consider now the interfacial energy between adjacent crystals of widely different orientation σ_B (i.e., grain-boundary free energy). It follows that at equilibrium $\sigma_B \leqslant 2\sigma$ at the melting point of the substance. Fisher[20] has found σ_B between adjacent copper crystals of very different orientation to be about 535 ergs/cm^2 at 800°C. σ for copper solid-liquid is calculated from nucleation data to be 177 ergs/cm^2. Considering the experimental and theoretical uncertainties the numbers are not inconsistent with the condition that $\sigma_B \leqslant 2\sigma$.

It has been assumed in making the calculations that the nuclei are spherical i.e., that σ is independent of crystal orientation. There is some experimental justification of an indirect nature supporting this assumption. It has been found[21] that the microstructures of two phase lead-copper alloys equilibrated at relatively high temperatures can be interpreted satisfactorily by assuming that the liquid lead-solid copper interfacial energy is independent of the orientation of copper crystals. A number of other microstructures in two-phase alloys have been explained on the basis of analogous assumptions.

Recently it has been shown[22] that the interfacial energy between differently oriented adjacent crystals of silicon ferrite is practically independent of the orientation difference providing it is not very small or not of such magnitude that the orientations approach a twin relationship. When the orientations are very different it appears that the grain boundary should be highly disorganized so that the transition region between the grain boundary and adjacent crystal should be somewhat similar in nature to a liquid-crystal boundary. Thus, independence of grain boundary energy upon the orientation of the abutting crystals is a point in favor of the hypothesis that liquid-crystal interfacial energies for metals are isotropic.

Although the facts that have been presented do not prove that σ or σ_0 values calculated from nucleation rates can be identified positively with the free energy of extended liquid-crystal interfaces it is believed that they afford substantial credibility for this identification.

EFFECT OF CRYSTAL STRUCTURE

It is well known that large masses of liquid metals that crystallize to close packed structures rarely can be supercooled more than 3 to 10 degrees while large masses that crystallize to more complex structures often can be supercooled much more. These facts have led to the concept[9] that the failure of large masses of the former class to supercool is an inherent property that is explained by the similarity in structure between close-packed crystals and their melts.

However, in view of the evidence that crystallization in large masses of all liquid metals is catalyzed by impurities, the facts are accounted for as well when it is assumed that effective catalysts for the nucleation of close-packed crystals occur much more frequently than those effective in the nucleation of crystals having more complicated structures.

Experiments on the supercooling of small droplets seem to have verified the latter theory. Small droplets of metals such as cobalt, silver, or nickel that crystallize to a cubical close-packed structure have been supercooled about as much relative to their melting points as have droplets of substances such as bismuth or tin that crystallize to more complex structures.

The arguments in favor of the concept that liquids crystallizing to close-packed structures should supercool much less than those crystallizing to more complicated structures hinge upon the idea that because of the structural similarity between the liquid and crystal[23] the interfacial energy between them should be small. This idea is quite reasonable, but by the same argument the heat of fusion, and therefore the free energy decrease in forming close-packed crystals should be and is small relative to that accompanying the formation of non-close-packed crystals.

Since it appears that σ_0 is directly proportional to ΔH_f for most metals the effect of crystal structure upon supercooling behavior is but a reflection of its effect upon ΔH_f within one class of substances. However, additional insight into the effect of crystal structure upon σ_0 can be gained by comparison of the σ_0/T_0 values listed in Table II. These ratios are roughly in the order of complexity of crystal structure and range from 1.91 for gallium to 0.80 for lead.

FURTHER IMPLICATIONS OF SMALL DROPLET RESULTS

The relation between σ_0 and ΔH_f that has been found is analogous to similar relations between liquid-vapor

[23] C. S. Barrett, *Structure of Metals* (McGraw-Hill Book Company, Inc., New York, 1943), pp. 224–229.

interfacial energies and heats of vaporization.[16] It suggests that analogous relations exist for liquid-crystal interfacial energies of classes of substances other than those studied in these investigations and in other types of phase transformations. For example, the interfacial energy between two solid phases in solid-state transformations of a certain class might turn out to be proportional to the heat of transformation. Unfortunately, not much effort has been made to minimize possible nucleation catalysis in solid-solid reactions so it is not known to what extent the results now available have been affected by this factor. It may be possible in some instances to minimize this factor by applying the small particle technique to solid-state reactions.

Finally, it appears that one of the most promising fields of further research in phase transformations will be that of seeking what generalizations can be made about the chemical and structure relations between nucleation catalysts and the phase that is nucleated. Already considerable progress has been made in this direction by Vonnegut[24] and Schaefer[25] on the catalysis of ice nucleation.

ACKNOWLEDGMENT

The writer has benefited from conversations with Drs. J. C. Fisher and J. H. Hollomon on some of the subjects herein discussed. He has also been helped by the encouragement of Dr. J. H. Hollomon throughout the investigations on the supercooling of small droplets.

Hot-Cathode Arcs in Cesium Vapor * †

RICHARD K. STEINBERG
Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received April 21, 1950)

A hot-cathode arc in cesium vapor has been studied by the use of a plane Langmuir probe to investigate the potential distribution, electron temperature and electron density in the plasma. The range of arc currents and vapor pressures over which satisfactory probe measurements may be made are determined.

In some cases it was possible to maintain the discharge with a total arc drop of less than the ionization potential of cesium (3.87 volts). Potential "humps" along the arc are shown to be absent, and ionization by the high energy electrons of a Maxwellian electron velocity distribution is found unsatisfactory as a possible mechanism for positive ion production in the arc. The mechanism of successive electron collisions can account for the observed ionization on the assumption that the effective lifetime in the excited state is increased by the process of the imprisonment of resonance radiation.

I. INTRODUCTION

THE principal purpose of this work was to obtain information which would lead to a better understanding of the mechanism by which positive ions are produced in an electric arc in cesium vapor, particularly when the total voltage across the arc is less than the ionization potential of cesium. Although various explanations for low voltage arcs have been advanced, none of them seems to enjoy universal acceptance.

Of these explanations, at least four appear to be plausible. One is that the potential gradient is not uniform along the length of the arc, but instead, a potential "hump" may exist somewhere in the arc, and there may be two points or regions with a potential difference at least as great as the ionization potential. Another explanation involves the existence of oscillations in the arc. These oscillations may be of the relaxation type at frequencies of the order of kilocycles per second, or they may be, crudely speaking, bunches of electrons or positive ions vibrating in the electric fields produced by their own displacements from their equilibrium positions. The frequencies of the latter type of oscillations may be as high as thousands of megacycles per second. With oscillations in the arc, there is the possibility that potential differences greater than the ionization potential of the gas will be present even when the average total arc drop is much less. A third explanation is based on the fact that probe measurements on the plasma of an arc usually indicate that the velocity distribution of the electrons is reasonably close to Maxwellian, at least over the range of energies for which probe measurements can be made. Without attempting to give a detailed explanation of how the high electron energies are attained, this velocity distribution function is assumed to be obeyed for all energies. Then from the probability of ionization function of the gas under consideration, it is ascertained that the number of electrons with energies greater than the ionization potential is sufficient to create ions as fast as they diffuse from the plasma to the walls. The fourth explanation does not require that a single electron deliver the entire amount

It has appeared as Technical Report No. 128, Research Laboratory of Electronics, Massachusetts Institute of Technology.

TABLE I. Cesium vapor pressure and atom density.

Temperature °C	Vapor pressure mm Hg	Atom density per cc
30	0.0000023	$(7.3)10^{10}$
100	0.00054	$(1.4)10^{13}$
150	0.0089	$(2.0)10^{14}$
200	0.079	$(1.6)10^{15}$
250	0.45	$(8.3)10^{15}$
300	1.9	$(3.2)10^{16}$

of energy necessary for ionization; rather, it suggests that it is possible for an electron to deliver only enough energy to excite an atom, with the remainder of the ionization energy coming from one or more successive collisions with other electrons. For reasons to be explained, this last mentioned mechanism is believed to be the one by which the cesium vapor arc is maintained.

Only a small amount of work on cesium vapor arcs has been reported. A series of papers by Mohler[1] is probably the most outstanding.

II. THE EXPERIMENTAL TUBES

Two tubes were constructed. The first, which will be referred to as tube No. 1, contained a plane nickel cathode and a plane tantalum anode, both 2.5 cm in diameter, mounted in a glass tube with an inside diameter of 5.3 cm. The cathode and anode were mounted on a glass and quartz assembly which could be moved along the axis of the tube by tilting the tube and shaking it slightly. The cathode-to-anode separation was 12.7 cm. Both the anode and cathode were constructed with built-in tungsten heaters capable of raising their temperatures to at least 1000°C. Low resistance, flexible, copper wire was used for making connections between the movable assembly and the lead-ins through the glass envelope. Actually, for most of the measurements, the cathode heater was turned off entirely because the arc itself caused sufficient heating to maintain the required thermionic emission.

A plane tantulum probe with a diameter of 0.25 cm was installed in tube No. 1 about 1 cm from the tube wall and with the plane of the probe parallel to the tube axis. The variation in position of the probe with respect to the arc was obtained by moving the cathode-anode assembly. A small glass tube was placed over the probe lead and the edge of the probe so that only the front surface of the probe "faced" the discharge. The same material was chosen for the anode and the probe to eliminate the uncertainty in the potential measurements which would otherwise arise from the contact difference of potential between different materials. In the case of cesium vapor, this difference would be particularly difficult to evaluate because cesium condenses on various surfaces to a thickness of the order of one atomic layer even when the temperature of the surface is hundreds of degrees centigrade higher than the temperature of the cesium supply. This layer of cesium lowers the work function of the surface by as much as 3 ev in some cases. The amount of lowering is strongly dependent on the fraction of a monatomic layer present and therefore dependent on the temperature.

Although annoying when making potential measurements, the cesium layer could be put to good use at the cathode. Thermionic currents of at least 2 amp. per cm² were attainable at cathode temperatures lower than 800°C because of the lowering of the work function of the cathode surface by the cesium. A text by Reimann[2] includes a more extensive discussion of the phenomenon together with references to original literature.

The cesium supply was contained in an appendix to the tube which consisted of a glass tube about 6 in. long. The cesium temperature, and therefore the vapor pressure, was controlled by the temperature of an oven which enclosed the appendix. To prevent bulk condensation of the cesium on the glass walls where it would cause low resistance leakage paths between the various

leads, a separate oven which could be maintained at a temperature higher than the temperature of the cesium was constructed for the main body of the tube. A glass window was installed in one side of the oven to provide a means for viewing the arc.

Tube No. 2 contained a series of probes in line as a means for measuring various plasma properties as functions of distance along the arc. In tube No. 2, the diameter of the front face of the cathode was 4.3 cm and the inside diameter of the glass tube was 4.6 cm. The anode was simply a disk 4.3 cm in diameter. The material for both the cathode and anode was tantalum. Four plane probes, each similar to the one used in tube No. 1, were mounted in a line along the length of the tube, and the distances from the center of the probes to the anode were 0.5, 2.5, 12.5, and 14.7 cm. The cathode-to-anode separation was 15.2 cm.

Both tubes were baked at 500°C for one hour, and the cathode and anode of each were heated to a bright red for several minutes either by means of their heaters or by radiofrequency induction heating. The pressure at the time the tubes were sealed off the vacuum system, as indicated by an ionization gauge, was about $(3)10^{-6}$ mm Hg. This reading corresponds roughly to the vapor pressure of cesium at room temperature and is the highest vacuum that could be expected.

III. CESIUM VAPOR PRESSURE AND ATOM DENSITY

The most recent and probably the most accurate vapor pressure data which were found were those of Taylor and Langmuir.[3] They measured the vapor pressure up to a temperature of 73°C by utilizing a method which makes use of the fact that practically every cesium atom which strikes a hot tungsten surface leaves as a positive ion. From their data, they derived the following formula for the vapor pressure of cesium in equilibrium with the liquid state:

$$\log_{10} p = 11.0531 - 1.35 \log_{10} T - (4041/T), \qquad (1)$$

where p is the pressure in millimeters of mercury, and T is the temperature of the cesium in °K. They claim an accuracy of 3 percent up to 327°C and 8 percent up to 727°C when extrapolating the curve beyond the range over which data were taken. Table I shows the cesium vapor pressure and atom density at various temperatures as determined from Eq. (1) and the equation of state.

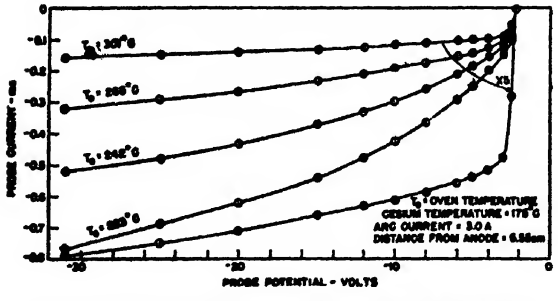

FIG. 3. Negative current portion of probe characteristic curves (tube No. 1).

IV. PLASMA POTENTIAL

The usual Langmuir technique was used for making measurements of the plasma potential. A text by Loeb[4] includes a discussion of the method and its limitations.

It was found that there was a rather limited range of arc currents over which reliable probe measurements could be made. Oscillations with frequencies in the range from 1000 to 10,000 c.p.s. would occur in the arc when the arc current was reduced below a certain critical minimum value. This minimum was a function of vapor pressure (cesium temperature) and was lower at the higher pressures, as shown in Fig. 1. The amplitude of these oscillations depended upon several parameters including vapor pressure, cathode temperature and arc current, but they usually had an amplitude of the order of 1 volt as indicated by an oscilloscope connected across the anode and cathode. The oscillations could not be eliminated by circuit modifications. Probe data were taken only at those values of arc current for which no oscillations existed.

The upper limit to the arc current at which reliable probe measurements could be made was set by the fact that at the higher arc currents the probe characteristic curve did not have a well-defined bend in it, or it had no bend at all, at plasma potential. Instead, the probe current would continue to rise as the probe voltage was increased until the probe was drawing the entire arc current. Also, the probe currents obtained at the higher arc currents were sufficient to cause probe heating, which, because of the cesium layer, changed the work function of the probe and introduced another source of error in the measurements. With tube No. 1, good probe characteristic curves were obtained with arc currents up to 3 amp. and up to 1.9 amp. with tube No. 2. The limitations just described were such that no reliable probe measurements at all could be made at cesium temperatures below about 150°C. Measurements were not made at cesium temperatures higher than 250°C because of possible damage to the tubes by chemical attack by cesium.

Sample logarithmic plots of probe characteristic curves are shown in Fig. 2.

Probe data taken at potentials negative with respect to floating potential were found to be of little value. Figure 3 shows the negative portion of the probe characteristic curves taken with the plane probe in tube No. 1 when the cesium temperature and arc current were held constant at 175°C and 3 amp. respectively, but when the main oven was at various temperatures from 223°C to 301°C. The lower oven temperatures appear to cause a much greater positive ion current to the probe. Similar sets of curves were obtained at cesium

[3] J. B. Taylor, I. Langmuir, Phys. Rev. 51, 753 (1937).

[4] L. B. Loeb, *Fundamental Processes of Electrical Discharge in Gases*, (John Wiley and Sons, Inc., New York, 1939), pp. 232–257.

temperatures of 125°C and 250°C. It was discovered that even when the oven temperature was much higher than the cesium temperature, enough cesium would condense on the glass surfaces in the tube to cause leakage which, although small, was great enough to cause substantial errors in the measurement of positive ion currents. Thus, since the plane probe was doubtlessly in contact with its glass shield, the shield could have acted as a part of the probe, with the effect of increasing its area. The increase in leakage resistance with temperature would then account for the smaller probe currents found at the higher oven temperatures. The negative probe currents that were obtained at an oven temperature of 300°C were possibly a reasonably good measure of the positive ion current present, but, again because of the cesium layer on the surface, thermionic emission from the probe surface is of the same order of magnitude at this temperature.

From kinetic theory the relationship

$$I = n(kT/2\pi M)^{\frac{1}{2}} \qquad (2)$$

may be obtained, where I is the random current of gas particles crossing unit area in unit time, n is the number of particles per unit volume, k is Boltzmann's constant, T is the absolute temperature and M is the mass of the particle. This equation indicates that if the electron and positive ion densities and temperatures were equal, the ratio of random electron current to random positive ion current would be equal to the square root of the ratio of the ion to electron masses. The square root of this ratio is approximately 500 in the case of cesium. In order to determine plasma potential more accurately, the positive ion current was assumed to be 1/500 of the random electron current and this correction was applied to the measured values of probe current. The logarithmic plots so obtained (of which those in Fig. 2 are examples) were substantially linear in the region of rapidly varying electron current to the probe. The utilization of the data obtained at probe potentials more negative than floating potential was not attempted except to confirm, as near as could be ascertained, the fact that 500 was a reasonable value for the electron-ion current ratio.

Experimental work on mercury vapor by Robert Howe at the Massachusetts Institute of Technology, and by others, has indicated that the random electron-ion current ratio is actually less than the square root of the mass ratio in spite of the fact that the electron temperature is usually found to be quite high. In the plasma potential determination, a considerable variation in the ratio which is used causes only a small variation in the potential measurement.

TABLE II. Total arc drop (tube No. 1)

Cesium temperature °C	Arc current amp.	Arc drop volts
150	3.0	3.0– 9.0
200	3.0	6.6– 7.8
200	1.0	6.0–10.4
250	3.0	5.5–10.7
250	1.0	8.2–13.5
250	0.3	21.5

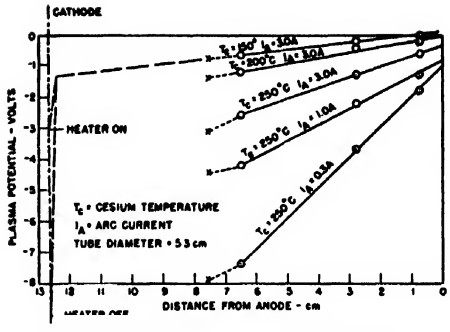

FIG. 4. Plasma potential (tube No. 1).

For tube No. 1 the plasma potential, referred to the anode as a function of distance from the anode, is shown plotted in Fig. 4 for various cesium temperatures and arc currents. It was intended to take data with the probe at positions close to the cathode but the movable assembly became damaged before this was accomplished. However it happened to be possible to take some data using the tantalum electrode as the cathode and the nickel electrode as the anode, with a cathode-to-anode separation of 8.5 cm and with the probe 0.9 cm from the cathode. The data so taken are represented by crosses and dotted lines in Fig. 4. The indication is that the plasma potential is at least a reasonably linear function of distance to within 0.9 cm from the cathode. Most of the data were taken with the cathode heater current turned off entirely and the arc itself was used as a source of cathode heating power. In order to obtain electrons for starting the arc it was necessary to use the cathode heater.

The total arc drop was a function of cathode temperature, and by using the heater, this total arc drop could be reduced to a value several volts below the value obtained without the heater. Excessive heating caused the cesium layer to evaporate faster than it was deposited, so that in spite of the increased temperature, the resulting increase in work function of the cathode surface caused a reduction in the available thermionic emission and an increase in arc drop. At a cesium temperature of 150°C and an arc current of 3 amp., for example, the total arc drop was 9 volts with the heater off. By using the heater, the drop could be reduced to a value as low as 3 volts. This example is shown graphically in Fig. 4.

The results, to be described later, obtained with tube No. 2 indicate that a linear extrapolation of the plasma potential to within 0.5 cm of the cathode is justified. Table II indicates the arc drops which were recorded at the times the probe data were taken.

With the tantalum cathode and nickel anode, the arc drop could be made as low as 2 volts. It was possible, though difficult, to reproduce these minimum values; the difficulty arose from the fact that it was necessary

that a large portion of the cathode be at the optimum temperature for thermionic emission and that the cathode heating by the arc tended to make the temperature non-uniform. The important point here, however, is that the potential of any point in the plasma when referred to the anode was found to be independent of cathode temperature and total arc drop. Several readings of potential were made under different conditions of arc drop and in each instance, even though the arc drop varied as much as 6 volts (the largest variation recorded), the potential of the plasma with respect to the anode stayed the same within experimental error, which was estimated to be about 0.1 volt. If the 150°C-3 amp. curve is considered again, it is seen that the negative anode fall is no greater than about 0.2 volt, and that with a total arc drop of only 3 volts there are no

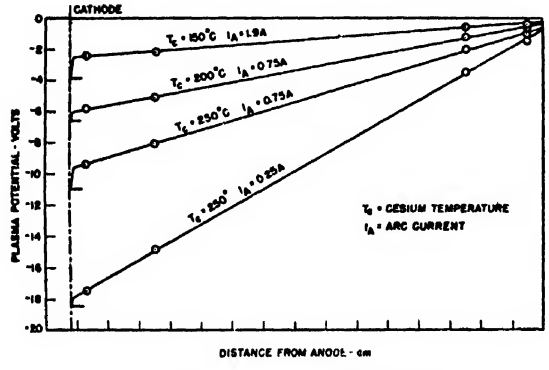

FIG. 5. Plasma potential (tube No. 2).

two points in the discharge with a potential difference as great as the ionization potential of cesium (3.87 volts).

The plasma potential measurements obtained from tube No. 2 are shown plotted in Fig. 5. It can be seen that they agree both qualitatively and quantitatively with those obtained from tube No. 1 if consideration is given to the fact that the cross-sectional area of tube No. 2 was only 0.75 times as great as that of No. 1.

Most of the data taken with tube No. 2 were taken with the cathode heater turned on and adjusted to yield minimum obtainable total arc drop. The total arc drop is indicated for each curve at the left edge of Fig. 5. The curve corresponding to a cesium temperature of 150°C and an arc current of 1.9 amp. shows no indication that there are two points in the tube with a potential difference greater than the ionization potential of cesium, a result similar to that obtained from tube No. 1. Cathode falls of from 0.8 to 1.5 volts were found.

The total arc drop as a function of arc current for tube No. 2 at the three vapor pressures studied is shown plotted in Fig. 6. For each curve the points represent the lowest drop which was attainable with the particular cathode which happened to be in use. For the higher arc currents, i.e., above about 3 amp., the heating of the cathode by the arc itself was sufficient to cause the cathode temperature to rise above optimum value for thermionic emission. Therefore it was necessary, in obtaining these data, to measure the arc drop immediately after starting the arc. Within a few seconds the arc drop would rise by as much as a volt or more above its initial value. If the cathode had been capable of emitting even greater thermionic currents the total arc drop might have been less because there was no apparent lower limit to the cathode fall other than zero.

The random electron current as a function of distance along the arc for two typical cases is shown in Fig. 7. The random current near the cathode was high, as shown, when the cathode heater was used to enable the cathode to emit a copious supply of thermionic electrons. When the heater was turned off, making it necessary for the arc itself to heat the cathode through the high cathode fall thus created, the random electron current near the cathode was as much as an order of magnitude less. This effect was in spite of the fact that no measurable difference in the space potential was noted.

An indication of the electron temperature may be obtained from the slope of the curve representing the logarithm of the electron current to the probe as a function of probe potential. Actually, the term "temperature" does not have a well-defined meaning when applied to the particles in the plasma of an arc; nevertheless, the temperature obtained in this manner is plotted as a function of distance along the arc in Fig. 8. Both of these sets of data were obtained with the four plane probes in tube No. 2. Similar results were obtained with tube No. 1.

V. OSCILLATIONS

Except for the low frequency oscillations, previously mentioned, which occurred when the arc current was reduced below a certain critical value, no oscillations were found. During all of the runs an oscilloscope which was responsive to frequencies up to 2 Mc was connected across the anode and cathode of the tube to check for the existence of oscillations, and data were taken only when no oscillations were indicated.

A search was made under various conditions of arc current and vapor pressure for oscillations at frequencies higher than might have been indicated on the oscilloscope. To carry out the search, a radio communications receiver, a radar search receiver and a crystal detector were employed in conjunction with various tuned circuits and Lecher wires connected in the arc circuit. A failure to find oscillations, no matter how thorough the search, does not establish the fact that no oscillations were present; however it is believed to have been reasonably well established that no oscillations were present at frequencies below an upper limit of about 10,000 Mc/sec. According to a derivation given by Tonks and Langmuir,[5] it is possible for electron oscillations in a plasma to occur at a frequency of $(8980)n^{\frac{1}{2}}$ where n is the number of electrons/cm³. The highest electron density found in the range of arc currents and

[5] L. Tonks, I. Langmuir, Phys. Rev. 33, 195, 990 (1929).

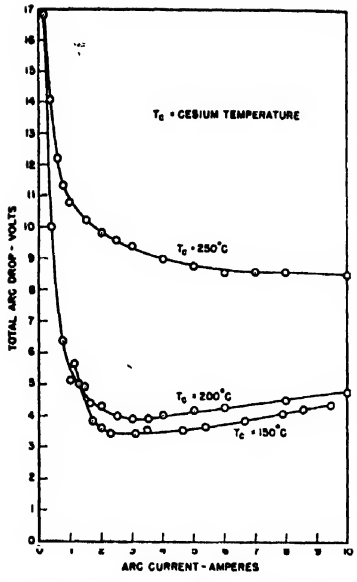

FIG. 6. Arc voltage *vs.* arc current (tube No. 2).

vapor pressures over which data were taken was $(1.6)10^{12}$ electrons/cm³. This density was obtained near the cathode of tube No. 2 when the cesium temperature was 150°C and the arc current was 1.9 amp., and it would imply a frequency of 12,000 Mc which might have been higher than the crystal was capable of detecting. However, 12,000 Mc is an upper limit to the possible frequency, and even under the same arc conditions the electron density near the anode was $(1.6)10^{11}$ electrons/cm³. This density would indicate a frequency of 3600 Mc, which was known to be within the range over which the detecting instruments would function.

High frequency oscillations have been reported occasionally in connection with tubes containing arcs, and certainly can be obtained with tubes of special design. The existence of the oscillations so found is usually not assured by the mere presence of the arc but is critically dependent on such factors as arc current and potentials of the various electrodes that may be present in the tube.

It is believed that there is little evidence to support a theory of ionization based on oscillations, particularly since, even if their existence were established with certainty, it would yet remain to be shown that they had sufficient amplitude to produce ionization. On the other hand, the present failure to detect oscillations is an indication that the ionization could not have been dependent upon them.

VI. IONIZATION BY ELECTRONS WITH A MAXWELLIAN VELOCITY DISTRIBUTION

The number of ions lost to the walls per centimeter-length of tube may be obtained experimentally and is given by the expression $2\pi Ri_+/e$, where R is the radius of the tube in centimeters, i_+ is the positive ion current in amp./cm² as determined by probe measurement, and e is the electronic charge expressed in coulombs. For the range of atom density for which the discharge fills the whole tube, the number of ionizing collisions per electron per sec. is then

$$\alpha = 2\pi Ri_+/e\pi R^2 n = 2i_+/eRn, \qquad (3)$$

where n is the number of electrons per cm³, and, for the examples to be considered, it will be assumed that n is not strongly dependent on distance from the axis of the arc. If their velocity distribution is Maxwellian, the number of electrons per cm³ with velocities between v and $v+dv$ cm per sec is

$$nf(v)dv = 4\pi n\left(\frac{m}{2\pi kT_e}\right)^{\frac{3}{2}} v^2 \exp\left(-\frac{mv^2}{2kT_e}\right)dv, \qquad (4)$$

where m is the mass of the electron in grams, k is Boltzmann's constant expressed in ergs per degree, and T_e is the electron temperature in °K. The number of ionzing collisions per sec. that will be produced by an electron of velocity v is (PvN/N_0) where N is the number of atoms per cm³ present, N_0 is equal to $(3.5)10^{16}$ and is the number of atoms per cm³ when the temperature and pressure are 0°C and 1 mm Hg respectively, and P is the probability of ionization per centimeter-length of path when N_0 atoms per cm³ are present. Note that P is the product of the atomic cross section for ionization and N_0. The number of positive ions per cm³ produced per second by electrons with velocities between v and $v+dv$

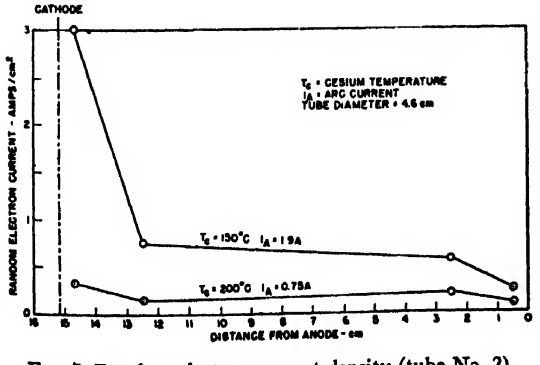

FIG. 7. Random electron current density (tube No. 2).

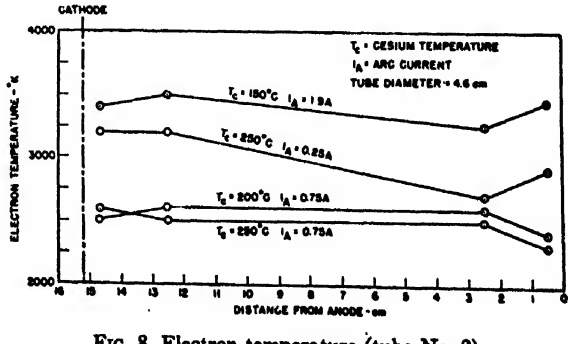

FIG. 8. Electron temperature (tube No. 2).

is then

$$4\pi n\left(\frac{m}{2\pi kT_e}\right)^{\frac{1}{2}} P\frac{N}{N_0} v^3 \exp\left(-\frac{mv^2}{2kT_e}\right)dv. \quad (5)$$

If the substitution

$$v=(2Ve10^7/m)^{\frac{1}{2}} \quad (6)$$

where V is the electron energy expressed in electron volts, is made, expression (5) takes the form

$$(8)10^{14}\pi n\left(\frac{m}{2\pi kT_e}\right)^{\frac{1}{2}} \frac{e^2}{m^2} P\frac{N}{N_0} V \exp\left(-\frac{eV10^7}{kT_e}\right)dv. \quad (7)$$

The probability of ionization for cesium is not known, but it will be assumed for the purpose of this calculation that it is zero for electron energies less than the ionization potential V_i, and is constant with a value P_i, at all energies above V_i. After dividing by n, an integration of expression (7) from $V=V_i$ to $V=\infty$ yields the number of positive ions α' formed per second per electron. The result is

$$\alpha'=(2.0)10^{-7}\frac{P_iN}{T_e^{\frac{1}{2}}}\exp\left[-\frac{(1.16)10^4V_i}{T_e}\right] \times\left(V_i+\frac{T_e}{(1.16)10^4}\right), \quad (8)$$

where V_i is in volts.

By using the data obtained from tube No. 2 when the cesium temperature was 150°C and the arc current was 1.9 amp., for example, it was found that α, as computed from Eq. (3), was approximately 16,700 ionizing collisions per electron per sec. Although i_+ and n vary along the length of the plasma, they vary in approximately the same fashion so that α is reasonably constant. As described previously, i_+ was taken as 1/500 of the random electron current. Upon using 3.87 volts for V_i and 3400°K for T_e, it was found by equating α to α' that P_i must be at least 3000 ions per electron per cm of path. Data for the probability of collisions taken by Brode[6] indicate that it is 650 collisions per cm at V_i and drops off considerably at higher electron energies. Brode's probability of collision includes elastic and exciting collisions as well as ionizing collisions. From these results it is concluded that the number of electrons with sufficient energy for ionization which is made available from the Maxwellian distribution is not adequate to sustain the plasma. The results of additional examples are shown in Table III.

By working along similar lines Killian[7] concluded that, for mercury vapor, the ionization produced by this mechanism was sufficiently great in some cases to make up for the loss of ions caused by diffusion to the walls. However he obtained values for electron temperature up to 38,000°K, which is rather high. Because of the exponential term, α' is a rapidly varying function of temperature, and if the true temperature were even slightly less the mechanism would have been found insufficient in all cases.

TABLE III. Data taken from tube No. 2.

Cesium temperature, °C	150	200	250	250
Atom density, per cc	$(2.0)10^{14}$	$(1.6)10^{15}$	$(8.3)10^{15}$	$(8.3)10^{15}$
Arc current, amp.	1.9	0.75	0.75	0.25
Electron temperature, °K	3400	2600	2500	3000
Electron density, per cc	$(4.8)10^{11}$	$(1.4)10^{11}$	$(9.5)10^{10}$	$(1.9)10^{10}$
Necessary P_i, per cm (see Section VI)	3000	18,000	66,000	380
Necessary P_e, per cm (see Section VII)	130	410	290	72

It should be noted that oscillations do not necessarily afford an explanation for the presence of high energy electrons or the existence of a high electron temperature, as is sometimes implied.[7,8] It is easy to see, though, why oscillations might cause probes to indicate, erroneously, high energy electrons or high electron temperatures. The explanation lies in the fact that, over a portion of the oscillation cycle, the probe at any potential setting is more positive with respect to the plasma than it would be in the absence of oscillations, and an increased electron current to the probe is produced. Because of the exponential current-probe potential relationship, the decrease in electron current that occurs over the opposite portion of the cycle does not cancel the effect. Thus at all probe potentials negative with respect to the average plasma potential, the electron current to the probe could be misleadingly large in the presence of oscillations.

An additional difficulty with the theory which assumes a Maxwellian velocity distribution of electrons lies in the inability to explain how the supply of high energy electrons is maintained in view of the fact that the number of high energy electrons would be expected to be diminished because of the inelastic (exciting and ionizing) collisions which occur. It is somewhat surprising that probe measurements indicate conformance to a Maxwellian distribution over as wide a range as they do, but this conformance is not a good reason to extrapolate the results beyond the range of measurements, which seldom extend to energies much higher than that corresponding to ionization potential. Further, measurements on the high energy electrons are subject to considerable error because of the uncertainties involved in extrapolating that portion of the probe characteristic curve which supposedly represents positive ion current.

VII. IONIZATION BY SUCCESSIVE COLLISIONS

The successive-collision hypothesis was suggested as far back as 1925,[9–11] but unless certain other phe-

nomena are taken into consideration, which was not always done, ionization by successive collision appears unlikely. The reason is that the lifetime of an excited state is so short compared with the average time between collisions that there is only a small probability that an excited atom will still be excited by the time a second electron strikes it. If the case of an arc current of 1.9 amp. and a cesium temperature of 150°C is taken as an example, and if Eq. (8), which assumes zero probability at energies below a certain critical value and a constant probability at higher energies, is employed, it is found that the number of excited atoms created per second per electron is $(8.1)10^3P_e$. The probability of excitation is P_e and the first critical potential of 1.48 volts was used. If $(4.8)10^{11}$ electrons per cm^3 is taken as the electron density and if the average lifetime of an excited state is 10^{-8} sec., it is found that the density of excited atoms is approximately $(3.9)10^7P_e$ per cm^3, which is about $(1.9)10^{-7}P_e$ times the density of unexcited atoms. Since an additional 2.39 ev are required to ionize an atom which has already been excited to the lowest excitation level, a second application of Eq. (8) indicates that the number of ions produced per second per electron is about $(1.1)10^{-4}P_eP_i'$, where P_i' is the probability of ionizing an excited atom if all the atoms were excited. In correspondence with the units used above, the atomic cross section for ionization of an excited atom is equal to P_i'/N_0. When the result just obtained is compared with α, the necessary number of ions per sec. per electron (16,700 for this example), it is seen that the product P_eP_i' must be at least $(1.6)10^8$ which is rather high. The assumption of a Maxwellian distribution of electron energies is possibly more justified in this case because the energies under consideration are not so great.

The phenomenon of imprisonment of resonance radiation is yet to be considered, and according to Holstein[12] the lifetime of an imprisoned light quanta in cesium vapor over a pressure range of 0.01–1 mm Hg is $(1.2)10^{-5}R^{\frac{1}{2}}$ sec., where R is the radius in centimeters of an infinitely long tube. Since it makes no difference which atom is excited, the passing of resonance radiation back and forth among the atoms has the effect of increasing the lifetime of an excited state by over 10^3 in the present case.

Also, according to Klarfeld,[11] the probability of ionization for excited atoms may be at least 10 times the probability for ionization from the ground state. The higher probability seems feasible when it is remembered that the wave function of an excited atom is much more spread-out than the wave function of an atom in the ground state. Thus when these two factors are considered it is found that P_e need not be greater than the square root of $(1.6)10^4$ or approximately 130 collisions per cm. This result causes ionization by successive collisions to appear more plausible. Additional examples are included in Table III.

VIII. CONCLUSION

Various properties of hot-cathode arcs in cesium vapor have been measured. In an effort to determine the mechanism by which the plasma of the arc is maintained it has been observed that no potential "humps" exist in the plasma, and, under certain conditions, no oscillations could be found. Sufficient ionization by the high energy electrons of a Maxwellian distribution appears unlikely. If the phenomenon of imprisonment of resonance radiation is taken into consideration, it has been shown that ionization by successive collisions is a plausible mechanism for plasma maintenance in spite of the short lifetimes of the excited states.

IX. ACKNOWLEDGMENT

I wish to thank Professor W. B. Nottingham, under whose direction the work was carried out, for the many helpful suggestions received. I also wish to thank Dr. A. W. Hull of the General Electric Company Research Laboratory, Schenectady, New York, for suggesting the problem and for assistance received in the preparatory phase of the work.

Allotropy of Beryllium*

S. S. Sidhu and C. O. Henry
University of Pittsburgh, Pittsburgh, Pennsylvania
(Received April 24, 1950)

The allotropy of beryllium has been confirmed by employing different alloying properties of allotropic forms of metallic elements. Alloys of beryllium and gold, studied by x-ray diffraction methods, showed that the limit of solubility of gold in beryllium is between two and three atomic percent, and practically all of it is dissolved in the β-form. The lattice parameters of the two forms observed here are: $a_0=2.286$A, $C_0=3.588$A, and $C_0/a_0=1.570$ for the α-form, and $a_0=6.93$A, $C_0=11.35$A, and $C_0/a_0=1.638$ for the β-form. The volume of the unit cell of the β-form is about 29 times that of the α-form.

SOME investigators[1–3] have reported allotropy of beryllium while others[4] have failed to observe it. As a result a considerable uncertainty[5] exists regarding it. The object of this investigation was to obtain definite information in favor of or against such an existence.

EXPERIMENTAL PROCEDURE

The allotropic forms of metallic elements differ in their crystalline structures, and hence possess different alloying properties. These properties may be employed to prove or disapprove the allotropy of an element. If heavy atoms, such as of gold, can be dissolved, even to a limited solubility, in one of the allotropes of a light element as beryllium, noticeable changes may occur in the intensities of its diffraction lines due to a large difference in the atomic scattering factors of the two atoms. With this in view four alloys having compositions as given in Fig. 1 were prepared in an evacuated induction furnace with maximum pressure of the order of 10^{-4} mm Hg. Weighted mixtures of gold and beryllium metals were melted in BeO crucibles covered with BeO lids and enclosed in graphite heaters and ZrO_2 insulators. The maximum temperature varied between 1400° and 1480°C, and the solidification of the melts took place in the furnace. Powder x-ray diffraction patterns were made of stress relieved beryllium and representative samples of each alloy with a cylindrical camera of 114.6 mm diameter and copper $K\alpha$-radiation. The diffraction pattern of Be was repeated with a flat film and a specimen to film distance of 60 mm.

RESULTS

As given in Table I the diffraction data obtained from the pattern of a sample of beryllium contained diffraction lines of the usual form of beryllium (α-form), and in addition several weak lines at relatively small Bragg angles. The interplanar spacings corresponding to the latter lines alone were not sufficient to determine a crystal structure but they could be fitted into an hexagonal structure with Miller indices as given under $\beta-$Be, and the lattice parameters as given below. These

lines could not be attributed to impurities as determined by the spectrographic and x-ray diffraction analyses.

X-ray diffraction data obtained from patterns of alloys B, C, and D showed that there was no observable effect on the diffraction lines of the $\alpha-$Be with the increasing atomic percent of gold. The relative intensities and the interplanar spacings of these lines remained identically the same as those observed in the sample of beryllium. The diffraction lines of the $\beta-$Be on the other hand showed marked changes. The intensities of some of the original lines increased without any apparent change in their interplanar spacings, and additional lines appeared in increasing numbers as the atomic percent of gold increased. A few of the original lines appeared to be resolved into two lines. As given in Table II the diffraction data of sample D contained many more lines than those obtained from the sample of beryllium. These lines, however, were not due to gold or to the phase $AuBe_5$.

As shown in pattern *E*, Fig. 1, a definite transformation takes place at about 3 atomic percent of gold. The diffraction data, given in Table III, show conclusively that the alloy contained mostly $AuBe_5$ phase, which crystallizes in a face-centered cubic structure with $a_0=6.083$A, and a small percentage of $\alpha-$Be.

SUMMARY

The results obtained here showed that beryllium crystallizes in two hexagonal structures. The lattice parameters of the α-form are: $a_0=2.286$A, $C_0=3.588$A, and $C_0/a_0=1.570$, and of the β-form, $a_0=6.93$A, $C_0=11.35$A, and $C_0/a_0=1.638$. The volume of the unit cell of the β-form is about 29 times of the α-form. These parameters compare favorably with those reported by other investigators. The amount of crystalline material in the β-form appears to be very small and hence can be confused with impurities.

The limit of solubility of gold in beryllium is between 2 and 3 atomic percent, and practically all of it is dissolved in the β-form. Since this amount of gold in beryllium produces no observable effects in the α-form, but marked changes in the β-form, it would seem that the unit cell of one form is not related to that of the other and the two forms crystallize independent of each other.

Most of the prominent lines of the β-form, as seen in Table I, appear at relatively small Bragg angles; therefore, they are beyond the range of measurements made with the back-reflection method.[4]

The technique of employing different alloying properties of allotropic forms of metallic elements to prove their existence seems to work very well as demonstrated in this investigation.

The cooperation of Dr. Frank Foote and Mr. James Schumar of Argonne National Laboratory for getting alloys made for us is gratefully acknowledged.

Single Wave-Length X-Rays for Powder Diffraction

L. K. Frevel and P. P. North
The Dow Chemical Company, Midland, Michigan
(Received May 10, 1950)

WL_α radiation filtered through a Cu-Zn foil is essentially monochromatic and has the advantage over filtered CuK_α or MoK_α radiation in that the $WL_{\alpha 1}$ line is approximately ten times as intense as the $WL_{\alpha 2}$ line. Moreover the comparatively wide $\Delta\lambda$-spread ($WL_{\alpha 2}-WL_{\alpha 1}$) results in very sharp powder lines at those Bragg angles where the CuK_α doublet or MoK_α doublet is unresolved.

THE geometrical factors deciding the resolution of a Debye-Scherrer-Hull pattern are: R, radius of the camera; r, radius of the powder specimen; h, length of the specimen; δ, divergence of the impinging x-ray beam; and σ, difference in wave-length of the K_α doublet. For a fixed camera radius the optimum resolution corresponds to the limiting condition: $r, h, \delta, \sigma \to 0$. The geometrical resolution for a camera of radius R can be expressed approximately as the sum of δ, the divergence of the diffracted beam due to the divergence or convergence of the impinging primary beam, and $\omega(r, h)$, the angular spread of the diffracted beam due to the dimensions of the powder specimen [$\omega(r, 0) = 2r/R$ radian, for parallel x-rays].[1-3] Accordingly, two powder reflections d and $(d+\Delta d)$ will be resolved if

$$(\theta_{\alpha 2}-\theta_{\alpha 1})_d < (\theta_d - \theta_{d+\Delta d})_\alpha > (\delta+\omega)_\theta,$$

or

$$(\delta+\omega)_\theta < |(\theta_{d+\Delta d})_{\alpha 1} - (\theta_d)_{\alpha 2}|$$

where θ is the Bragg angle for the interplanar spacing d, and α denotes the wave-length under consideration. For example, with $MoK_{\alpha 1}$ radiation the two powder reflections corresponding to 2.260A and 2.274A will be separated by 3.4′, which interval is equal to the MoK_α doublet separation, $(\theta_{\alpha 2}-\theta_{\alpha 1})_{2.26}$. Evidently the use of very narrow slits does not aid greatly in the resolution of a non-cubic powder pattern because of the disturbing doublet separation. The utility and precision of powder diffraction work would be greatly enhanced if an intense source of strictly monochromatic $L_{\alpha 1}$ radiation could be made available (see Table I). Crystal-monochromatized $L_{\alpha 1}$ radiation should be quite excellent for single crystal diffraction techniques; however, for powder diffraction work such a source of monochromatic x-rays would be too weak for most analytical applications. To circumvent this limitation it was decided to use filtered L_α radiation. An examination of Table I reveals that tungsten offers the most convenient source of L_α radiation because of the general availability of x-ray tubes with tungsten targets and because of the absence of target contamination by sputtering or evaporation from

Camera radius:	207.3 mm	71.7 mm	88.8 mm
Slit dimensions:	0.15 × 5 × 50 mm	0.4 mm rad. × 70 mm	0.1 × 3 × 50 mm
Specimen radius:	0.2 mm	Wedge method	0.4 mm

For very absorbing materials such as $BaSO_4$, the wedge technique with CuKα gives very sharp lines because only the topmost part of the wedge is effective for diffraction. Pyrex capillary tubing was used to hold the powder sample for the MoKα pattern, and polystyrene capillary for $WL_{\alpha 1}$. Since the sample radius was excessively large in the latter case, only the top-half of the sample was bathed in the x-ray beam, this arrangement being comparable to the wedge technique.

* Resolved reflections.

the tungsten filament. A brass filter, 0.025 mm thick, was used to absorb the WL_β and WL_γ lines. The WL_α doublet thus transmitted has a decided advantage over filtered K_α doublets because the $WL_{\alpha 2}$ line is only one-tenth as intense as the $WL_{\alpha 1}$ line; so that for all practical purposes powder patterns taken with this filtered radiation will correspond to patterns taken with $WL_{\alpha 1}$. The comparatively wide $\Delta\lambda$-spread ($WL_{\alpha 2} - WL_{\alpha 1} = 0.0111$A) has the further advantage of registering very sharp powder lines at those Bragg angles where the CuKα doublet or MoKα doublet is unresolved.

Legend: Filtered CuKα and WL_α x-rays were used to obtain the powder diffraction patterns of Ag_2HgI_4. {hkl} are the indices of the various reflections based on the unit cell $a = c = 12.62 \pm 0.02$A. The complex iodide Ag_2HgI_4 was prepared by the dropwise addition of $AgNO_3$ solution to an agitated solution of K_2HgI_4. Chemical analysis of the washed and vacuum-dried precipitate showed 23.51 percent Ag (23.35 percent theor.), 53.25 percent I (54.94 percent theor.), and 20.52 percent Hg (21.71 percent theor.). The sample for the WL_α exposure had been aged for five years in a closed vial.

* Reflections requiring larger unit cell than $a = c = 6.35$A.

Table II compares the powder patterns of $BaSO_4$ obtained with filtered CuKα, MoKα, and WL_α. It will be noted that six reflections were resolved with $WL_{\alpha 1}$ that appeared as unresolved lines with CuKα. Only two reflections out of fifty were attributable to $WL_{\alpha 2}$. For indexing non-cubic substances or reducing the superposition of powder lines in complex mixtures the use of $WL_{\alpha 1}$ radiation is to be recommended. To minimize continuous background radiation the tungsten x-ray tube with line focus should be operated at ~20 kv and ~40 ma.

The complex iodide, Ag_2HgI_4, is reported by Ketelaar[4] to be tetragonal with $a = c = 6.34kX$. Patterns were taken of this substance with CuKα and $WL_{\alpha 1}$ radiation to ascertain if any splitting could be detected for pyramid reflections. Whereas no splitting was revealed (see Table III), a sufficiently large number of weak reflections were observed to require a larger unit cell. Extensive grinding of the complex iodide diffuses these additional sharp reflections into faint broad bands. It is quite likely that one is dealing with an order-disorder system in Ag_2HgI_4 and that the $E3_1$ structure will have to be reexamined in the light of the present findings.

Shielding Properties of the Concrete Wall of the M.I.T. Cyclotron

VICTOR DELANO* AND CLARK GOODMAN
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received May 15, 1950)

The shielding properties of the four-foot concrete wall of the M.I.T. cyclotron have been studied, using foils for neutrons and x-ray films for gammas. Fast neutrons were measured by counting the beta-active products of $Al^{27}(n, p)Mg^{27}$, $Fe^{56}(n, p)Mn^{56}$, and $Al^{27}(n, \alpha)Na^{24}$ reactions, thermal activation being eliminated by Cd holders. Resonance (1.44 ev) and thermal neutron distributions, measured by Cd-In-Cd and In, with suitable corrections, were reduced to absolute intensities by comparison with a known flux. Measurements were made with cylindrical concrete blocks fitted into a 4½" diameter hole which extended through the concrete wall. The results indicate an attenuation factor of 8.3 per foot for the fast neutron component and 10 per foot for thermal neutrons. An estimate of the fast neutron flux above 4.5 Mev showed a transmitted intensity slightly higher than the presently accepted tolerance value when bombarding Be. The absolute thermal neutron flux was below the tolerance level. The r.m.s. distance and the diffusion length for thermal and resonance neutrons in concrete were estimated by considering the distributed source to be equivalent to a point source at the inner face of the wall. The gamma-ray measurements were not convertible to roentgens. A mean energy of 2.7 Mev was obtained for the gamma-radiation within the wall. The attenuation factor for total gamma-radiation in the wall at large distances from the inner face was 5.9 per foot.

INTRODUCTION

THE occurrence of radiation cataract among the Japanese survivors at Hiroshima and Nagasaki and among cyclotron workers in this country has emphasized the importance of adequate neutron shielding. The problem is complicated by the invariable presence of gamma-rays which arise both from the reactions producing the neutrons and from the absorption and scattering of neutrons within the shield. The latter effect imposes important limitations on the choice of shielding material. What is needed is a combination of heavy and light atoms which are effective for attenuating gamma-rays and neutrons respectively. Of the many materials and combinations of materials investigated in the search for an ideal shield, concrete is one of the most satisfactory especially when cost is a major consideration and where size and bulk are not of too great concern.

While concrete has found wide use for the shielding of particle accelerators, there is only a limited amount of published information regarding its effectiveness.[1] Since the radiations from the M.I.T. cyclotron are representative of a number of existing sources and of others being built, the results of the tests made on this four-foot concrete shield may be of general interest.

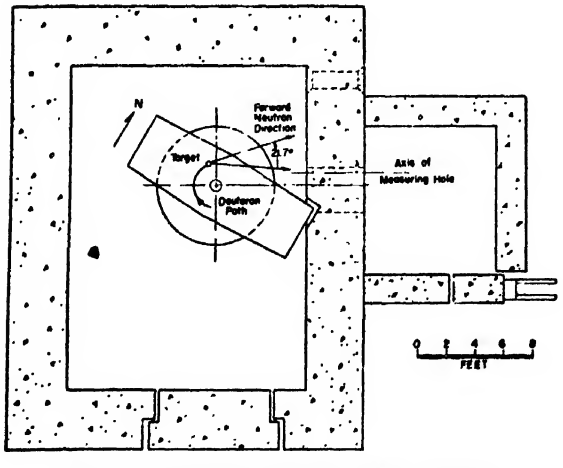

FIG. 1. Plan view of cyclotron shield, showing location of measuring hole.

EXPERIMENTAL ARRANGEMENTS AND PROCEDURES

Description of Cyclotron Shield and Measuring Hole

The M.I.T. cyclotron is shielded by a four-foot concrete wall topped with a three-foot concrete roof. Through the northeast wall of the shield, of which a plan view is shown in Fig. 1, a rectangular opening three feet wide and one foot high is provided for emergent beam experiments. When this beam is not in use, the opening can be closed with an array of concrete blocks of three sizes: 6"×6"×11½", 3"×6"×11½" and 6"×6"×6". These sizes are approximate because of slight surface irregularities.

Because of these irregularities and the relatively large dimensions, another set of blocks was constructed which formed a smooth, horizontal hole through the wall into which one could slide close-fitting cylindrical blocks for intensity measurements with foils and films. Since the center of the rectangular opening is below the central plane of the cyclotron dees, these blocks were designed to fit in the upper left-hand corner of the rectangular opening (see Fig. 2). By this arrangement the measuring foils could be exposed to the most energetic portion of the neutron beam.

As seen in Fig. 1, the axis of the measuring hole was displaced from the direction of the deuteron beam at the cyclotron target. For 15-Mev deuterons on Be, the maximum energy of neutrons to which the measuring hole was exposed was calculated as 18.8 Mev.

* Lieutenant Commander, U. S. Navy, now at Los Alamos Scientific Laboratory.

[1] M. S. Livingston, J. App. Phys. 15, 2–19, 128–147 (1944); E. Creutz and K. Downes, J. App. Phys. 20, 1236–1240 (1949); P. C. Gugelot and M. G. White, Phys. Rev. 74, 1215 (1948); P. Jensen and O. Ritter, Zeits. f. Naturforschung 2a, 376–384 (1947).

As shown in Fig. 3, three *C* blocks formed a base along the bottom of the rectangular opening for the *A* and *B* blocks. The measuring hole was formed using two pairs of *A* blocks, placed end to end. Two *B* blocks were set alongside these (see Fig. 2). All blocks were arranged to eliminate, as completely as possible, any continuous cracks or slits through the opening. Because of the small dimensional discrepancies in the latter, it was necessary to use wooden wedges between the blocks and the left-hand edge of the rectangular opening in order to force the hole-forming blocks tightly against the cyclotron wall. The original rectangular blocks were installed with their surfaces flush with the cyclotron wall in the cyclotron vault but they failed to complete the rectangular opening by about three-quarters of an inch along the outer side of the wall.

Each cylindrical *D* block has a $\frac{3}{16}''$ recess in one end in which were placed foils for neutron measurements or films for gamma-radiation measurements. By using two different lengths (2″ or 4″), measurements could be taken at two-inch intervals through the wall. "*A*" runs, as they are henceforth called, used twelve four-inch blocks. "*B*" runs used one two-inch block followed by eleven four-inch blocks and, at the end of the hole, another two-inch block. All the four-inch blocks were numbered and the two-inch blocks lettered to insure that successive "*A*" and "*B*" runs would have the same sequence of blocks.

The cylindrical blocks were always inserted with their recessed ends toward the cyclotron. The blocks were inserted by hand and removed with piano wire attached in a manner allowing half the blocks to be removed from the front of the hole and half from the back. Clearance between the top of the cylindrical blocks and the roof of the hole was $\frac{1}{16}''$ or less. Flake graphite was used as a lubricant.

Composition of Concrete

All the blocks used in the rectangular opening of the cyclotron wall were made from a concrete mix consisting of 1 part cement, $1\frac{1}{2}$ parts sand and 2 parts gravel (pea stone, $\frac{1}{2}''$ gravel), with about 5–$5\frac{1}{2}$ gallons of water per 100 lb. bag of cement. Composition of the cyclotron wall was slightly different, being made from a mix of 1 part cement, 2 parts sand and 4 parts gravel (1″ grated to $\frac{1}{4}''$), by weight. The difference in the mixes was necessitated by the relatively small size of the blocks which required more cement to insure adequate strength and proper shape. Table I gives chemical analyses of the two cements. Table I also includes the assumed composition of the cement used in the work of Jensen and Ritter.[2] The composition of the sand and gravel given in Table I is based on typical analyses of the sand and gravel from glacially deposited pits near Scituate, Massachusetts. Jensen and Ritter considered their sand and gravel combination to be pure SiO_2.

[2] P. Jensen and O. Ritter, see reference 1.

FIG. 2. Photograph of measuring hole showing insertion of foil and film-holding blocks.

An analysis of a sample block very kindly made by the Oak Ridge National Laboratory gave an average water content of 7.6 percent by weight. Using this value we have calculated the weight percentages of elements present as given in Table II.

The average density of the concrete in the cyclotron wall was measured as 2.20 g/cc, slightly less than Jensen and Ritter's value of 2.26 g/cc.

Counters and Counting Circuits

The beta-activities of the foils were measured with a Victoreen, mica-window, counter (Model VG-Special) mounted in a $1\frac{1}{2}''$ lead shield. The end-window of the counter was 2.0 mg/cm^2; the foils were inserted on brass trays with a $\frac{1}{8}''$ deep recess, 3.18 cm in diameter centered directly below the counter window. The distance from the bottom of the tray to the center of the window was 1.0 cm. Circuitry consisted of a one-stage amplifier, a discriminator stage with adjustable bias and a scale-of-64, followed by a mechanical register.

For standardizing the counting rates, a brass slide was provided containing a small amount of RaD+E covered with 6 mils of aluminum which allowed only the 1.17-Mev beta-rays of RaE to emerge. The counter was shown to be linear up to at least 20,000 counts per

minute. Active foils were allowed to decay below 15,000 counts per minute, although less than 10,000 counts per minute was generally used. The average of backgrounds taken before and after each set of measurements was used, and counting rates less than twice the average background were discarded.

Fast Neutrons—Aluminum and Iron Foils

As calculated from Bethe's penetrability function,[3] the (n, p) reaction reaches half its maximum cross section for Al and Fe at 4.5 and 7.6 Mev, respectively. Al also has an (n, α) reaction reaching half the maximum cross section at 8.3 Mev. A single set of Al foils gives results for both energy intervals. Reynolds 24-mil (165 mg/cm^2) Al sheets, with a purity of 99.8 percent, were die-cut into disks $1\frac{3}{16}''$ in diameter. Fe foils were die-cut from Armco Magnetic Ingot Iron into disks of the same diameter from sheets hand-rolled to 10 mil (200 mg/cm^2). After activation, the Al foils exhibited only the 10.2 min. half-life from $Al^{27}(n, p)Mg^{27}$ and the 14.8 hr. half-life[4] from $Al^{27}(n, \alpha)Na^{24}$, indicating that any impurities were negligible. The 2.59 hr. activity[5] from $Fe^{56}(n, p)Mn^{56}$ was observed but in addition there was an apparent half-life of about 28 hr. A correction was made for the 28 hr. period.

To reduce the effect of (n, γ) reactions, the Al and Fe foils were encased in 1 mm thick Cd holders. In the Fe foils, no (n, γ) activation was detectable. By waiting 20 min. before counting, the 2.4 min. activity in Al became negligible.

Thermal and Resonance Neutrons—Indium Foils

Indium foils were used for measuring thermal and resonance neutron distributions by the Cd-difference method. Foils 1 cm in diameter were cut from 99.97 percent in sheets hand-rolled to a thickness of 3 mil (56 mg/cm^2). Activation indicated impurities were negligible. Because the In foils were bombarded only short lengths of time, the 4.5 hr. activity was relatively weak, and correction was made only when it was significantly above background. In foils were counted front and back after bombardment, since the sum of the front and back activity is proportional to the flux for thermal and 1.44-ev resonance neutrons.

Indium Foil Calibration and Corrections

Attempts were made to calibrate the indium foils with the cyclotron as a source, but, owing to nonhomogeneity of the neutron distribution in the cyclotron vault, this was unsuccessful. Instead, a 1-gram Ra-Be source in a 4-foot cubical water tank was used. In addition to corrections for variations in individual foils, two other factors were considered before the foil activities could be interpreted in terms of absolute neutron flux. These factors were (1) the attenuation of 1.44-ev resonance neutrons by the 1-mm Cd holder used for resonance measurements and (2) the distortion of the thermal neutron flux by the detector. Both factors are thoroughly discussed by Bothe[6] and his results are adapted to this work. Bothe develops an expression for the absorption of a neutron striking a detector in any direction:

$$\alpha = 1 - e^{-\mu\delta}(1 - \mu\delta) + \mu^2\delta^2 E_i(-\mu\delta)$$

where α = average absorption probability for a neutron striking in any direction, δ = linear thickness of absorbing material, $\mu = N\sigma$, and E_i = exponential integral.

With this absorption factor, the correction factor to be applied to all resonance runs (Cd holders) becomes:

$$f_a = 1/(1 - \alpha).$$

Inserting the appropriate values for Cd, $\delta = 0.1$ cm, $N = 0.0463 \times 10^{24}$ nuclei/cc,[7] and $\sigma_{1.44} = 11.5$ barns,[8] we obtain $f_a = 1.11$.

[6] W. Bothe, Zeits. f. Physik 120, 437–449 (1943).
[7] H. R. Kroeger, Nucleonics 5 (No. 4), 51–54 (1949).
[8] Goldsmith, Ibser, and Feld, *The Science and Engineering of Nuclear Power*, Vol. I, p. 456 (1947).

To correct for distortion, the depression factor for foils which are small compared with the scattering path length in the medium was taken from Bothe's work using λ_{tr} instead of λ_s:[9]

$$f=\frac{1}{1+0.23\alpha R_K/\lambda_{tr}}$$

where f=depression factor, α=absorption factor, previously described, R_K=radius of foil, λ_{tr}=transport mean free path.

Inserting appropriate values for In, $\alpha=0.100(\sigma_{th}=190$ barns), $R_K=0.5$ cm, $\lambda_{tr}=1.95$ cm, we obtain $f=1/1.00590$, or the correction factor equals 1.00590.

After applying these factors to the resonance and Cd difference results, the corrected, saturated initial activities were converted to absolute neutron flux.

Gamma-Ray Measurements

Measurements of total gamma-radiation proved considerably more difficult than neutron measurements. X-ray films (duPont 552) were used. This film is paper-wrapped in dental-size packets, each containing two films, one sensitive and one insensitive, such that 0.02 to 20 roentgens can be measured. The exposed films are examined with an Ansco-Sweet Densitometer and the density is converted to dosage by means of calibration charts. These charts are based on a 1-mm layer of Cd surrounding the film.

The film has two major undesirable characteristics. The bare film is severely blackened by beta-rays and electrons. Furthermore, the blackening is constant for gamma-radiation above 300 kev. Below 300 kev, the blackening per roentgen rises sharply. When only alpha-, beta- and gamma-radiations are present, 1 mm of Cd is sufficient to attenuate the charged radiations and has been shown to be adequate for reducing the blackening from the soft gamma-radiation. When there is a high thermal neutron flux, as in most of the present measurements, the secondary gammas from radiative capture of neutrons in Cd produce serious extraneous blackening. Kikuchi, Aoki and Husimi[10] found that of 32 elements studied, Cd is outstanding in its production of capture gammas.

Summary of Runs

In order subsequently to refer to runs by number those providing useful data are listed in Table III.

RESULTS AND DISCUSSION

Fast Neutron Distribution

For the fast neutrons we assume a point source at the cyclotron target and an exponential attenuation through the wall, i.e., a $(1/r^2)\exp(-r/L_r)$ distribution,[11] where r is the distance of the foil from the target and L_r is the relaxation length at large distances.

Figure 4 shows one set of measurements of fast neutron attenuation through the concrete wall for Al and Fe detectors. We would expect the relaxation lengths for these curves to be the same for the three activities observed since the energies involved are nearly the same. At large distances in the wall, it would appear that the fast, resonance, and thermal neutrons should have the same relaxation length, since the higher energy feeds into the lower energies and the diffusion length of low energy neutrons is quite small. Table IV shows the results.

Values for both thresholds of the Al foils agree and are considered the most acceptable for the threshold range covered. The attenuation factor corresponding to a relaxation length of 14.4 cm is 8.3 per foot.

Dementi and Timoshuk's[12] cross section for the Al(n, p) reaction is 15 millibarns and the extrapolated short-lived activity at the wall's outer surface is 5.75 c.p.m. for Run 14. This run is used because its average beam current was the strongest of the Al runs, 164 μamp., and its relaxation length the same as the average, 14.4 cm.

The flux is estimated from the following relation:

$$(nv)_f=A/(\sigma_p NV),$$

where $(nv)_f$=flux in neutrons/cm^2/sec., A=absolute foil activity in disintegrations per second, σ_p=reaction cross section in cm^2, N=nuclei per foil volume, and V=foil volume.

This gives a flux of 243 neutrons/cm^2/sec. above the Al(n, p) threshold and gives an interesting comparison with the tolerance flux of 190 n/cm^2/sec. for 4.5-Mev neutrons determined from:[13]

$$(nv)_f=1.45\times10^{-21}/\sigma_H E,$$

TABLE III. Summary of runs.

Run no.	Detector	Type run	Length	Av. beam current (μ amp.)	Target	Remarks

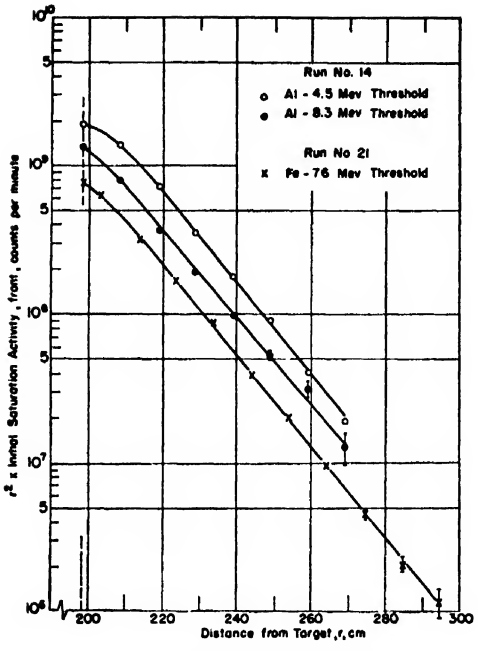

FIG. 4. Fast neutron distributions in concrete.

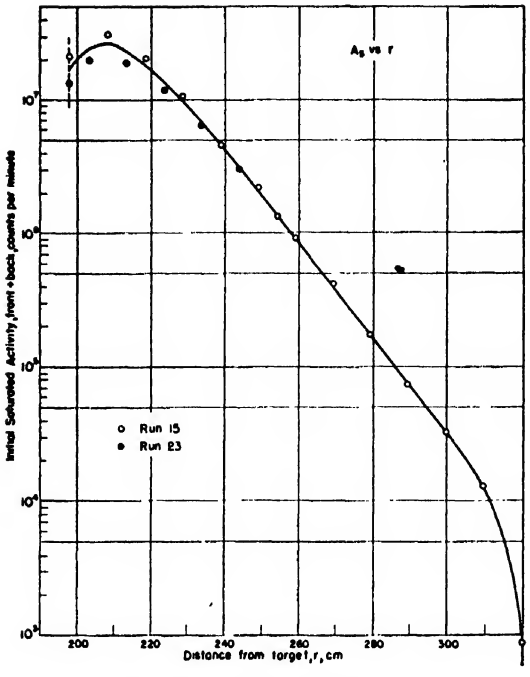

FIG. 5. Thermal plus 1.44 ev resonance neutron distributions in concrete.

where σ_H = scattering cross section for hydrogen and E = neutron energy in Mev. Our approximate value can also be compared with the tolerance flux of 85 n/cm²/sec. for 2–20 Mev neutrons reported by Mitchell.[14]

Our estimate is probably low, due to the decrease in reaction cross section as the Al(n, α) reaction begins to compete.

Thermal and Resonance Neutron Distributions

Since the cyclotron is non-reproducible, it was necessary to establish a relation between the resonance and thermal resonance distributions in order to provide a basis for normalization.

Table III shows that 15 and 23 were thermal+resonance runs and 16 and 24 were resonance runs. A foil was placed 5½″ to the right of the measuring hole axis on the inner face of the wall; on Runs 15 and 23, the foil was Cd covered, on Runs 16 and 24, paper covered. Between each of these specially placed foils and the regular foil nearest the cyclotron, thermal+resonance/resonance ratios were established. Since only one foil was covered with Cd on Run 23, with the depressive effect consequently less, the thermal+resonance/resonance ratio of this run (2.594) was selected to be applied to the mean values of the thermal+resonance and resonance runs in order to relate them.

Figure 5 shows a plot of the results of Runs 15 and 23, with 15 corrected to an average beam current of 170 μamp. by assuming the neutron yield to be linearly proportional to the beam current for small increments of current, together with the mean curve for the two runs. Figure 6 shows a plot of the results of Runs 16 and 24, with 24 corrected to 170 μamp. beam current and the resulting mean curve. The thermal+resonance/resonance ratio of 2.594 was applied to the initial point of the mean resonance curve of Fig. 6 to determine the starting point of the corresponding thermal+resonance curve. A point-by-point subtraction was carried out next and the foil depression correction applied to this result, giving the thermal distribution shown in Fig. 6.

Mean Square Distances and Diffusion Length

One of the first results obtainable from the thermal resonance data is the calculation of the mean square distance for thermal and resonance neutrons. Before reasonable values can be determined, however, an initial assumption is necessary for which no justification can be found in theory. The primary source of neutrons is naturally the cyclotron target, and at first glance it seems correct to consider a distribution based on the actual distance of each foil from the target, following

the usual $(1/r^2)\exp(-r/L_r)$ attenuation, where r is the distance from the target and L_r the relaxation length. Figure 7 shows such a plot. Amaldi and Fermi's equation can then be used to calculate mean square distance:[15]

$$\bar{r}^2=\frac{\int_0^\infty r^4 A dr}{\int_0^\infty r^2 A dr},$$

where r is the distance of the foil from the target and A is the foil activity as a function of distance.

Values determined by this method for the mean square distance for thermal and resonance neutrons are absurdly high, 5×10^4 cm^2, and have no significance, being obviously overweighted by the effect of the 200-cm distance in air between the target and the front face of the wall. By assuming that the thermal and resonance neutron source is located at the inner face of the wall, but continuing to treat it as a point source (as plotted in Fig. 8), reasonable values are obtained:

$$\bar{r}_{th}^2=2148 \text{ cm}^2 \text{ and } \bar{r}_{res}^2=1818 \text{ cm}^2.$$

The root mean square distance for the resonance neutrons, $\bar{r}_{res}=42.7$ cm, compares closely with Jensen and Ritter's value of 44.9 cm,[16] which is corrected for boundary disturbance and also is based on the use of a Ra-Be neutron source. Our result suggests a lower mean energy for the neutron spectrum of the cyclotron than for a Ra-Be source.

Continuing, we estimate the diffusion length L from the relation:[17]

$$\bar{r}^2_{thermal}=\bar{r}^2_{thermal\ source}+6L^2.$$

Although $\bar{r}^2_{thermal\ source}$ is required by the equation, we can accept the value of $\bar{r}^2_{res}$ as a close approximation. From this we obtain a diffusion length of 7.4 cm.

We can compare this with the calculated results: $L^2=\lambda_{tr}\lambda_a/3$, where λ_{tr} and λ_a are the transport and absorption mean free paths, respectively. Table V lists the cross sections used in computing λ_a, λ_s and λ_{tr}. The Mg and S in the concrete were neglected.

Table VI lists the calculated values of absorption, scattering and transport mean free paths, and the diffusion length. The value of the latter, 7.7 cm, is in good agreement with the experimental observed value of 7.4 cm given in Table VI.

Relaxation Lengths for Thermal and Resonance Neutrons

Assuming a thermal and resonance source at the inner face of the wall, we obtain relaxation lengths of

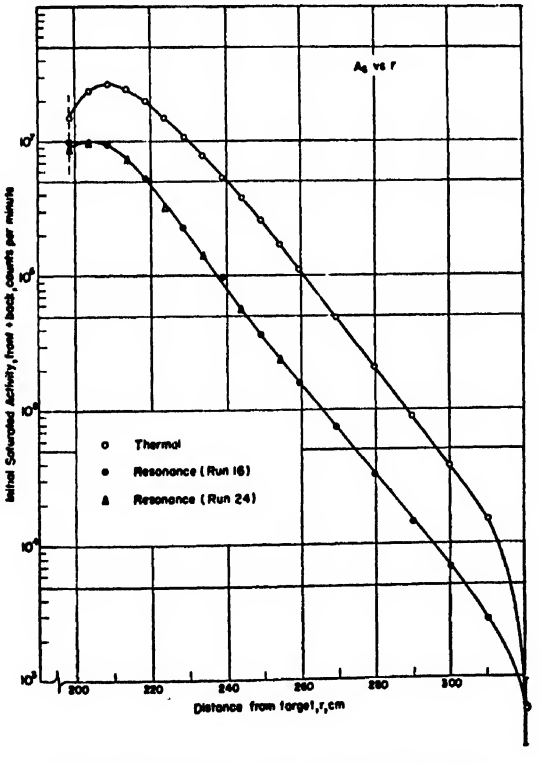

FIG. 6. Thermal and 1.44 ev resonance neutron distributions in concrete.

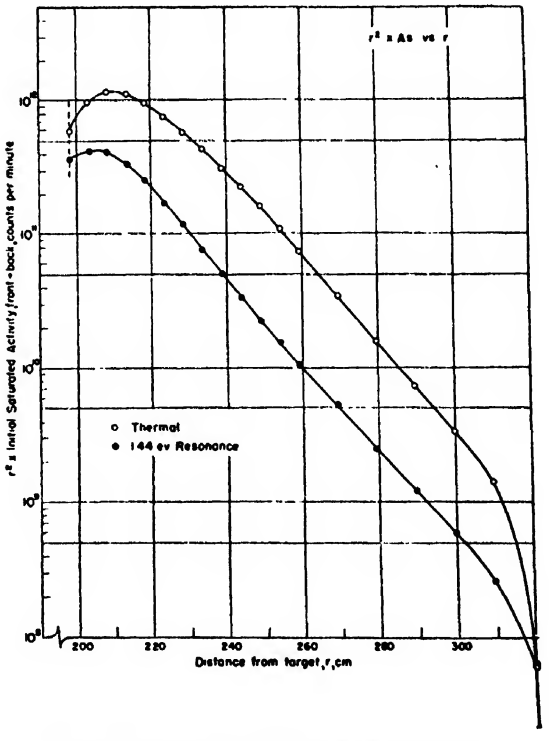

FIG. 7. Thermal and 1.44-ev resonance neutron distributions in concrete.

[17] A. M. Munn and B. Pontecorvo, Can. J. Research 25A, 157 (1947).

$L_{\tau(th)} = 16.9$ cm and $L_{\tau(res)} = 18.0$ cm. Jensen and Ritter[18] embedded their source in the center of a concrete block and reported relaxation lengths of 20.4 cm and 24 cm for thermal and 1.44-ev resonance neutrons, respectively. It should be noted that they used a half-life for In of 57 minutes, which would account for some of the discrepancy between our measurements and theirs. Their experimental arrangement was close to ideal, making it unnecessary to adopt the assumption of the source at the surface of the wall.

In order to compare our work with recent observations by Gugelot and White,[19] we consider our source as the cyclotron target and the thermal and resonance relaxation lengths thus obtained are 13.1 and 14.0 cm, respectively. Gugelot and White, using Ag detectors, report a half-value thickness of 9.5 cm for ordinary concrete with 8.5 percent water content. This corresponds to a relaxation length of 13.7 cm.

The relaxation length for thermal neutrons, based on the cyclotron target as the source, is equivalent to an attenuation factor of 10 per foot for slow neutrons, distinctly larger than the 8.3 per foot obtained for fast neutrons. Since the former is based on the observed thermal distribution, which is considerably more uncertain, a value of 9 per foot is considered a reasonable average for future design purposes.

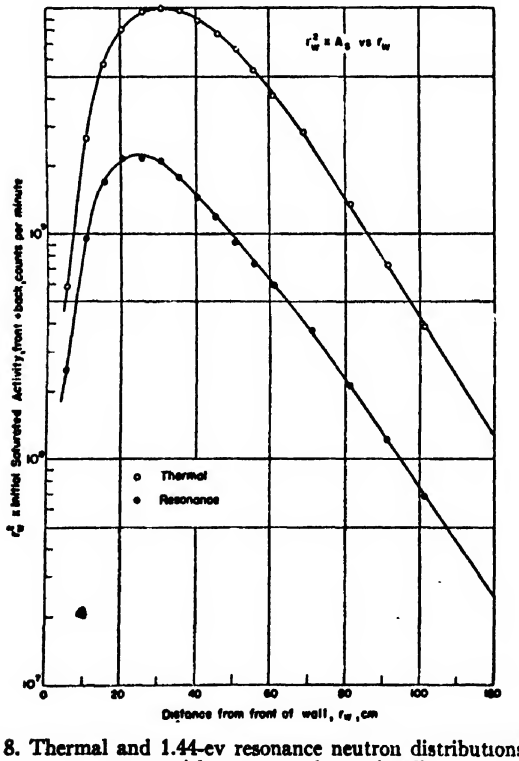

FIG. 8. Thermal and 1.44-ev resonance neutron distributions in concrete, with respect to front of wall.

Absolute Thermal and Resonance Neutron Fluxes

In the same four-foot water tank used for In foil calibration, Dacey and Paine[20] have accurately established the thermal and resonance flux at a point 14 cm from a 1-gram Ra-Be source. From the activities of In foils at this point, we obtain the following ratios for converting In foil activity from a cyclotron bombardment to neutron flux:

$$\frac{(nv)_{th}}{(A_s)_{th}} = \frac{8613}{6082} = 1.416,$$

$$\frac{(nv)_{res}}{(A_s)_{res}} = \frac{124.2}{483.5} = 0.2569.$$

These are then applied to the mean values for the thermal and resonance distributions, respectively, to obtain the thermal flux in neutrons/cm²/sec. and the resonance flux in neutrons/cm²/sec. per unit logarithmic energy interval.

It is interesting to compare the thermal flux at the outer surface of the wall with values calculated by Wende[21] and by Mitchell[22] as biologically equivalent to the *former* tolerance dosage of 0.1 *r*/8 hour day.[23] Considering only the effect on body tissue of gamma-rays from the $H'(n, \gamma)$ reaction, Wende estimates the tolerance flux to be 15,000 n/cm²/sec. for thermal neutrons. Mitchell, in a more realistic calculation, includes the

effects of the $N^{14}(n, \gamma)$ and $N^{14}(n, p)$ reactions as well as the gammas from neutron capture by hydrogen and estimates the tolerance flux to be 12,500 n/cm²/sec. Our data indicate the thermal flux at the wall's outer surface to be 830±540 n/cm²/sec. It is evident, therefore, that for 170 μamp. average beam current and a Be target, the cyclotron shield has reduced the thermal flux more than an order of magnitude below either of these estimated tolerance levels and well below the recent more conservative level of 1500 n/cm²/sec.[24]

Gamma-Radiation

Figure 9 is typical of radiation measurements using bare film. The plot is in terms of $r^2 \times I$ as a function of r, where r is the distance in cm from the cyclotron target to the film and I the apparent ionization intensity in roentgens per hour. The values for I are determined as previously described. These intensities are somewhat uncertain because of the possible blackening caused by low energy gamma-rays (<300 kev) and by capture gammas from the cadmium cover.

Two prominent features of all the curves obtained are the increase in apparent ionization intensity in the first 10 cm of the wall because of secondary and capture gammas from neutron interaction within the wall and also the tendency toward linearity beyond 40–45 cm of wall distance.

At large distances in the shield three processes combine to produce the total gamma-radiation: (1) attenuation of primary gammas from the target (2–8 Mev); (2) capture gammas from thermal neutron capture by hydrogen (2.18 Mev); (3) secondary gammas from radioactive products of fast neutron reactions (0.5–2.8 Mev).[25] The relative weights of these effects cannot be determined, although (1) and (2) appear more important than (3).

From the curves, an average absorption coefficient of 0.058 cm^{-1} is obtained. Hirschfelder and Adams[26] have reported mass absorption coefficients for monoenergetic gamma-rays in concrete. Converting their results for 1- and 3-Mev gamma-rays into linear absorption coefficients, we obtain values of 0.0856 and 0.0517 cm^{-1}. Assuming the ionization intensity is directly proportional to the flux intensity over the energy range with which we are concerned, the absorption coefficient from our data suggests a "mean" gamma-ray energy of about 2.7 Mev. Gugelot and White,[27] using 18-Mev protons on Be, have reported a half-value thickness of 13.3 cm for gamma-rays in concrete of slightly higher density (2.35 g/cc) than used here. This corresponds to an absorption coefficient of 0.052 cm^{-1} and, according to Hirschfelder and Adams,[26] to a "mean" energy of about 3 Mev. The attenuation factor for the gamma-radiation in concrete, measured in the linear portion of the curves, is 5.9 per foot.

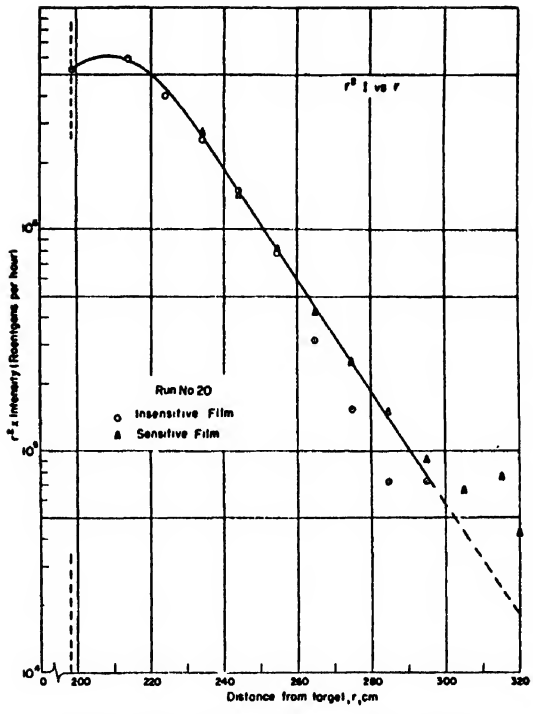

FIG. 9. Apparent ionization intensity distribution through concrete.

Average gamma-radiation from the cyclotron is probably about 5 Mev. The capture and secondary gammas, with lower average energies, appear sufficiently abundant to result in a lower mean energy for the total gamma-radiation in the wall. This seems to agree with Gugelot and White's[27] results.

This effect should be an important consideration in designing future cyclotron shields. With better information, the apparent importance of the capture and secondary effects may be verified. If so, cyclotron shield design should emphasize the importance of lower energy gamma-rays as much as those of higher energies produced at the target.

ACKNOWLEDGMENTS

The authors appreciate discussions of this work with Dr. M. Stanley Livingston and our colleagues in the Nuclear Shielding Group. The facilities of the cyclotron were made available by Dr. R. D. Evans with the assistance of Mr. J. B. Bulkley. The painstaking assistance of Miss Joan Sullivan in the analysis of data is gratefully acknowledged. This work was performed in the Laboratory for Nuclear Science and Engineering and was supported by the Bureau of Ships and the Office of Naval Research.

Storage of Small Signals on a Dielectric Surface

JOHN V. HARRINGTON
Air Force Cambridge Research Laboratories, Cambridge, Massachusetts
(Received May 29, 1950)

A mathematical analysis is presented which is believed to be applicable to a general class of storage tubes where signal storage is accomplished by depositing through secondary emission a charge pattern on a dielectric surface. The assumptions made to linearize and simplify the problem are outlined and plots are given of the predicted output signals for writing, reading, and cancellation operations when the input signal is a step function. Experimental evidence is presented to substantiate the analytical results.

INTRODUCTION

AN increasing amount of material has appeared in recent literature concerning the general class of vacuum tubes called storage tubes, in which signal storage is accomplished by depositing, through secondary emission, a charge pattern on a dielectric surface.[1–5] The material published on these storage tubes thus far has emphasized more or less the physics of the storage process—an emphasis which is to be expected in view of the admittedly complicated process of charge transfer by secondary emission and the difficulty in collecting the secondary current to give a useful output signal. To the engineer using these storage tubes, as opposed to the tube designer, somewhat different characteristics are of primary interest. As in ordinary vacuum tubes, these are external or equivalent characteristics and are defined primarily on the basis of the device's behavior as a circuit element; i.e., on the basis of its effect on the amplitude or shape of a signal passed through it.

The analysis which follows attempts to explain quantitatively some of the external characteristics of the *barrier-grid storage tube*, and a substantial portion of the introductory discussion concerns this particular model. The results which are obtained, however, are believed to be sufficiently general as to apply to the general class of tubes under discussion.

A simplified sketch of the *barrier-grid tube* is shown in Fig. 1. A complete description of this device and its operation appears in the literature.[1] In operation the dielectric surface will be charged, in the absence of a signal, to some potential V_0 at which the effective secondary emission ratio, δ, equals 1 and equilibrium exists. Thereafter when a signal is applied to the back plate, the emission ratio is changed; this results in a charge, different from the equilibrium charge, being deposited on the dielectric at the point of beam impingement. Thus, for a linear beam motion a signal varying in time would be stored as a charge distribution varying in distance along a line of the dielectric surface. In reading, when no signal is applied to the back plate, the beam in sweeping over this same line acts to restore the charge distribution to the equilibrium value, and in so doing the secondary emission current (as observed at the collector) will regenerate essentially a counterpart of the stored signal.

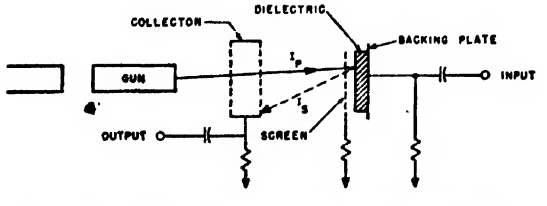

FIG. 1. Barrier grid storage tube, simplified sketch.

BASIS OF ANALYSIS

A rigorous mathematical analysis of a device such as this is extremely difficult if not impossible to make. Consequently certain assumptions and simplifications must be made to bring the problem within the range of available analytical methods. In this case the following assumptions have been made:

(1) The loss of resolution due to the redistribution of secondaries is neglected. The screen action is assumed to reduce such losses to negligible proportions.

(2) Not all of the secondary beam leaving the dielectric gets to the collector. It is assumed, however, that the fraction of the secondaries which are intercepted by the screen and other electrodes is constant; thus the collector or signal current is a "scaled-down" version of the total secondary current.

(3) A linear relationship is assumed between small voltage changes about the second crossover, or equilibrium, point of the secondary emission characteristic, and the corresponding secondary emission ratio (Fig. 2).

(4) The current in the electron beam is assumed to follow an even distribution curve in the direction of motion of the beam and

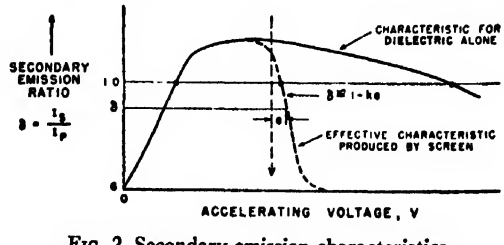

FIG. 2. Secondary emission characteristics, with and without screen.

to be uniformly distributed in the transverse direction. The effect of this assumption is to reduce what would be a three-dimensional problem to one of two dimensions—distance and time. This may be done with small sacrifice of generality, since it is primarily the lateral and not the transverse distribution of the beam current which influences the signal response. For purposes of presenting the results of this analysis graphically a normal beam distribution is assumed.

(5) Effects such as unevenness or non-uniformity of the dielectric, secondary emission from the screen material, etc., which contribute primarily to the background noise level of the tube, are ignored.

The foregoing assumptions allow us to reduce the problem to that of evaluating the current-voltage relationships in the equivalent network shown in Fig. 3. $e_0(t)$ is the signal voltage on the back plate applied at time $t=0$; C_x is the capacitance of the dielectric per unit area; and δ is the effective secondary emission ratio and is given by $\delta=1-ke$ for small values of e.

The quantity I_x is the primary beam-current density at point x; if we assume that the beam is scanning with constant lateral velocity v, then I_x as a function of x

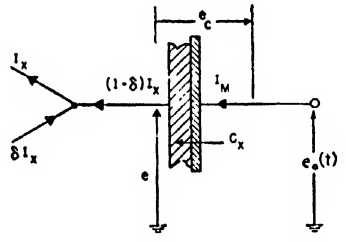

FIG. 3. Storage-tube input circuit.

and t is given by:

$$I_x=\frac{I_b}{w}F\left(\frac{x-x_0-vt}{w}\right)=\frac{I_b}{w}F(x'-t')$$

where $F(x')$ is an even function of x' and meets the conditions:

$$\int_{-\infty}^{\infty}F(x')dx'=1 \text{ so that } \int_{\infty}^{\infty}Idx=I_b$$

and for $|x'|\gg 1$, $F(x')\to 0$.

I_b is the total beam current per unit line width and w is a measure of a half beam width. The primed variables are normalized or dimensionless units of distance and time are given by

$$x'=(x-x_0)/w, \quad t'=vt/w.$$

For the circuit of Fig. 4 we may write the following equations

$$e=e_0(t)-e_c, \tag{1}$$

$$C_x(de_c/dt)=(1-\delta)I_x. \tag{2}$$

Then the basic differential equation obtained by combining the foregoing relationships is

$$de_c/dt'+\gamma F(x'-t')e_c=\gamma F(x'-t')e_0(t)$$

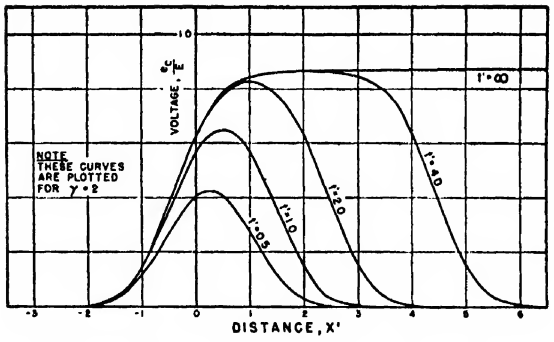

FIG. 4. Build-up of voltage distribution along scan line during storage of step voltage.

where

$$\gamma=[kI_b/vC_x]. \tag{3}$$

Since the signals to be stored in any practical case are most always pulsed signals, it is useful to carry out the analysis on the assumption that $e_0(t)$ is a step function of magnitude E applied at $t=0$. From these results one can easily deduce the tube performance for pulsed signals. Under these conditions (3) has the general solution

$$e_c(x', t')=E+C_1(x')\epsilon^{\gamma[B(x'-t')-B(x')]}, \tag{4}$$

where

$$B(x')=\int_0^{x'}F(x')dx'$$

and $C_1(x')$ is a constant of integration (the integration having been performed with respect to t') to be determined by the initial conditions.

The varying component of the collector current which generates the output signal will be the negative of the dielectric charging current I_M; it is calculated as follows:

$$I_M=\int_{-\infty}^{\infty}(1-\delta)I_xdx=\int_{-\infty}^{\infty}C_x\frac{de_c}{dt}dx=vC_x\int_{-\infty}^{\infty}\frac{de_c}{dt}dx. \tag{5}$$

In setting the limits for which this integration is to be performed, the implication is made that the length of a scan line is infinite. This is a valid assumption so long as the scan line is very long compared to one beam width.

ANALYSIS

It is both convenient and useful to obtain solutions for the charging current and for the voltage distribution along a scan line for three general cases. The first case will correspond to the so-called writing operation in which a voltage step is to be stored with no signal initially in storage; the second case will correspond to a multiple writing or cancellation operation in which a second-step voltage is to be stored over one initially in storage; the third case corresponds to a reading operation in which no external signal is applied but a stored signal is present.

Case I. Writing Operation

For this case the initial conditions are at $t=0$, $e_c=0$, $e_0(t)=E$, when these are used to evaluate $C_1(x)$, the desired expression for e_c is:

$$e_c(x', t')=E[1-\epsilon^{-\gamma[B(x')-B(x'-t')]}]. \quad (6)$$

It is interesting to plot this (Fig. 4) for an assumed[6] normal beam current distribution in order to observe the changing charge pattern laid down by the electron beam as the applied step voltage is stored. In interpreting these curves it is helpful to consider t' as a distance giving the center of the beam. For very large values of t', the voltage distribution especially in the vicinity of $x'=0$ becomes essentially independent of time and is given by

$$\operatorname*{Lim}_{t'\to\infty} e_{c1}(x', t')=e_{c1}(x', \infty)=E_1[1-\epsilon^{-\gamma[\frac{1}{2}+B(x')]}]. \quad (7)$$

This expression represents the "stored" signal.

Case II. Multiple Writing Operation

By using (7) as the initial voltage distribution for the second writing operation in which a step of magnitude E_2 is to be stored, it is found that

$$e_{c2}(x', t')=E_1[1-\epsilon^{-\gamma[\frac{1}{2}+B(x')]}]\epsilon^{-\gamma[\frac{1}{2}-B(x'-t')]}; \quad t\leq 0 \quad (8)$$

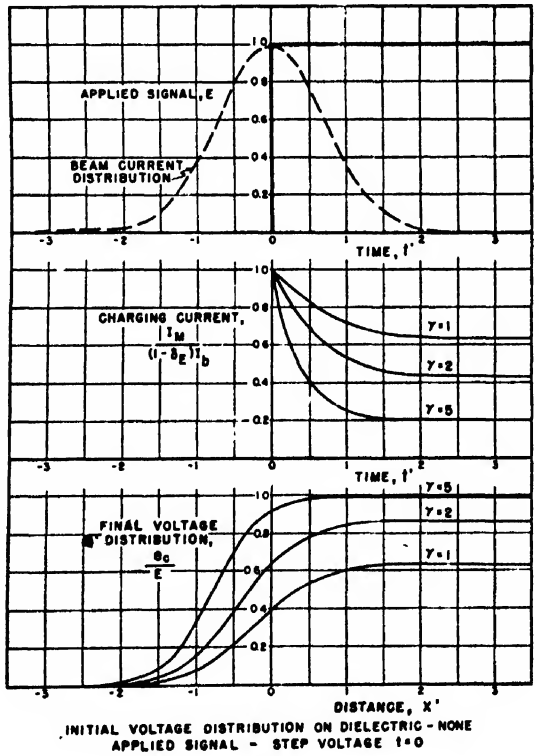

FIG. 5. Signal storage on a dielectric surface, Case I.

[6] That is, in the curves, $F(x')=[I_b/(\pi)^{\frac{1}{2}}w]e^{-x'^2}$, and $B(x')=\frac{1}{2}\operatorname{erf}(x')$.

$$e_{c2}(x', t')=E_2[1-\epsilon^{-\gamma[B(x'-t')-B(x')]}]+E_1\epsilon^{-\gamma[\epsilon^{\gamma[\frac{1}{2}+B(x')]}-1]}\times\epsilon^{\gamma[B(x'-t')-B(x')]}; \quad t\geq 0. \quad (9)$$

The final "stored" signal obtained by letting $t'\to\infty$, is then

$$e_{c2}(x', \infty)=(E_2+\epsilon^{-\gamma}E_1)[1-\epsilon^{-\gamma(\frac{1}{2}+B(x'))}]. \quad (10)$$

From (8), (9) and (5) one finds that the charging current is given by

$$I_M=kE_1I_b\cdot\epsilon^{-\gamma}\left[I(\gamma, t')-\left(\frac{\epsilon^{\gamma}-1}{\gamma}\right)\right]; \quad t\leq 0 \quad (11)$$

$$I_M=kI_b\cdot\left[(E_2+E_1\epsilon^{-\gamma})I(\gamma, t')-E_1\left(\frac{1-\epsilon^{-\gamma}}{\gamma}\right)\right]; \quad t\geq 0 \quad (12)$$

where the function $I(\gamma, t')$ is given by:

$$I(\gamma, t')=\int_{-\infty}^{\infty}\epsilon^{\gamma[B(x')-B(x'-t')]}F(x')dx'. \quad (13)$$

Equations (11) and (12) are rather general expressions for the dielectric charging current and as special cases of these one may obtain by setting $E_1=0$, $E_2=E_1=E$, or $E_2=0$, the expression for I_m for cases I, II, or III,

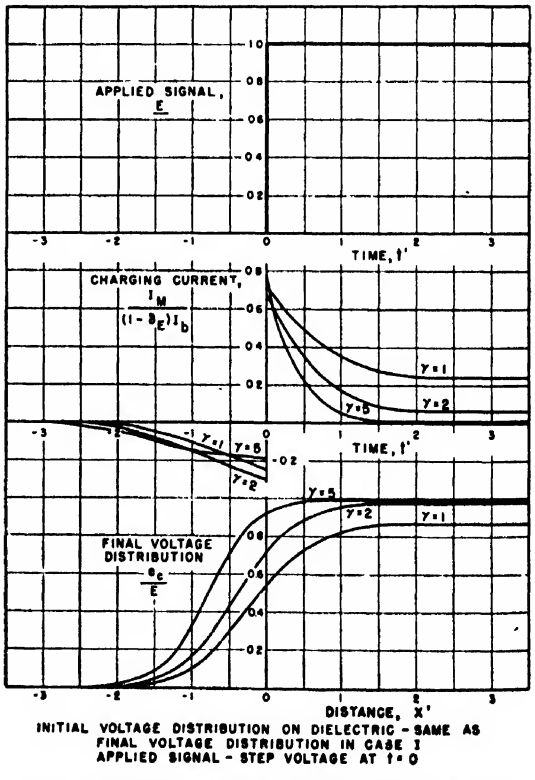

FIG. 6. Signal storage on a dielectric surface, Case II.

respectively. It is interesting to note that while a simple relation giving $I(\gamma, t)$ is in general impossible to obtain because of the difficulty encountered in integrating (7), its values at $t=0$, and $t=\pm\infty$ can be calculated.

$$I(\gamma, 0)=1$$
$$I(\gamma, \infty)=(1-\epsilon^{-\gamma})/\gamma$$
$$I(\gamma, -\infty)=(\epsilon^{\gamma}-1)/\gamma. \quad (14)$$

Thus we may conclude that the particular beam distribution, i.e., the particular $F(x')$; only influences the shape of the response within a few beam widths travel from the point of application of the signal.

Even within this region the $I(\gamma, t')$ functions for different assumed beam current distributions are very much alike. Beyond this region, the response (a sort of steady state response) is independent of $F(x')$ and depends principally on γ. This is to be expected since for a flat or uniform response only the total beam current and not its distribution should be significant.

The charging current and final voltage distribution for selected values of γ and an assumed normal beam current distribution for cases I and II are plotted[7] in Figs. 5 and 6. The typical "spike" for the writing signal is indicated, and it is seen that the effect of the finite width of the electron beam is to slope the leading edge of the stored signal such that two modified distance units (roughly, one beam width) are required to go from initial to final values.

Case III. Reading Operation

The expressions for charge distribution and charging current for the reading operation may be easily obtained from (10)–(12), by setting $E_1=E$ and $E_2=0$. A comparison of (10) and (7) indicates that for the reading operation the initial and final voltage distributions would be identical except for a scale factor $\epsilon^{-\gamma}$. Thus the reading operation is also an erasing operation in which the stored signal is reduced by $\epsilon^{-\gamma}$ or $8.68\gamma db$.

Typical curves for the Case III charging current are plotted in Fig. 7 along with the corresponding voltage distribution curves for the reading operation. It is seen that the output current wave rise time has been limited to about 3-to-4 modified time units or to the time it takes the beam to sweep through 1.5 to 2 beam widths.

EXPERIMENTAL RESULTS

As intimated previously the purpose of this section is to present some experimental evidence obtained with the STE barrier-grid storage tube which will support the preceding analysis. To obtain this evidence it is first necessary to choose a write-read schedule which on a continuous or repetitive basis will yield signal shapes corresponding to those predicted for Cases I, II and III.

[7] For selected values of γ and for an assumed normal beam current distribution, numerical values of $I(\gamma, t')$ in the range $-4<t'<4$ have been calculated at the M.I.T. Center of Analysis, Cambridge, Massachusetts.

It turns out that about the simplest schedule to do this is two writing followed by two reading operations, ad infinitum (Fig. 8). Because of the repeated application of the signal and the improbability of complete erasure, the initial charge distribution prior to the application of the first writing pulse will not be zero as assumed in Case I but will have some finite value $AE(x)$. It is desirable to calculate the magnitude of A as a function of γ so that our results may be properly interpreted. Thus, from the preceding analysis,

if before *first write*, stored signal is $A\cdot E(x')$ (15)

then before *second write*, stored signal is
$$(1+\epsilon^{-\gamma}A)\cdot E(x') \quad (16)$$

and before *first read*, stored signal is
$$[1+\epsilon^{-\gamma}(1+\epsilon^{-\gamma}A)]\cdot E(x') \quad (17)$$

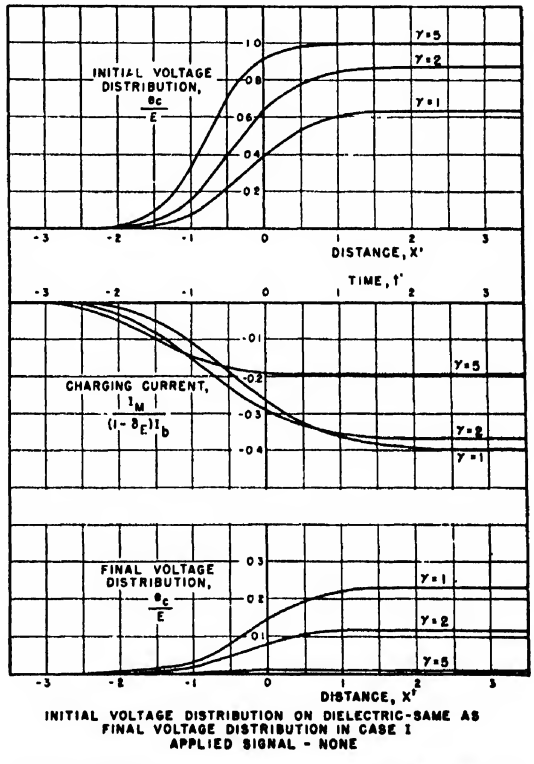

FIG. 7. Signal storage on a dielectric surface, Case III.

and before *second read*, stored signal is
$$\epsilon^{-\gamma}[1+\epsilon^{-\gamma}(1+\epsilon^{-\gamma}A)]\cdot E(x') \quad (18)$$

and after *second read*, stored signal is
$$\epsilon^{-2\gamma}[1+\epsilon^{-\gamma}(1+\epsilon^{-\gamma}A)]\cdot E(x'). \quad (19)$$

Then for a sustained sequence of such operations equilibrium will be reached when (15)=(19), or when

$$A=\epsilon^{-2\gamma}\frac{(1+\epsilon^{-\gamma})}{(1-\epsilon^{-4\gamma})}. \quad (20)$$

Using this to determine the initial values of the charge distribution, one can utilize the results of the previous

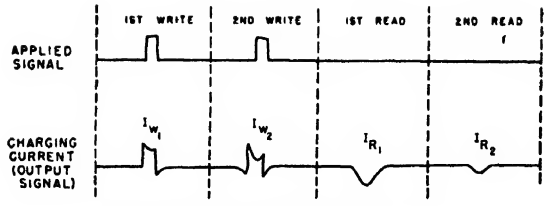

FIG 8 Two write two read schedule.

section, Eq. (12), to find the steady-state responses of the write-read signals of Fig. 8. When this is done one finds that

$$I_{w1}(\infty)=I_{R1}(\infty)=(1-\delta_E)I_b\cdot\frac{(1-\epsilon^{-\gamma})}{\gamma(1+\epsilon^{-2\gamma})} \qquad (21)$$

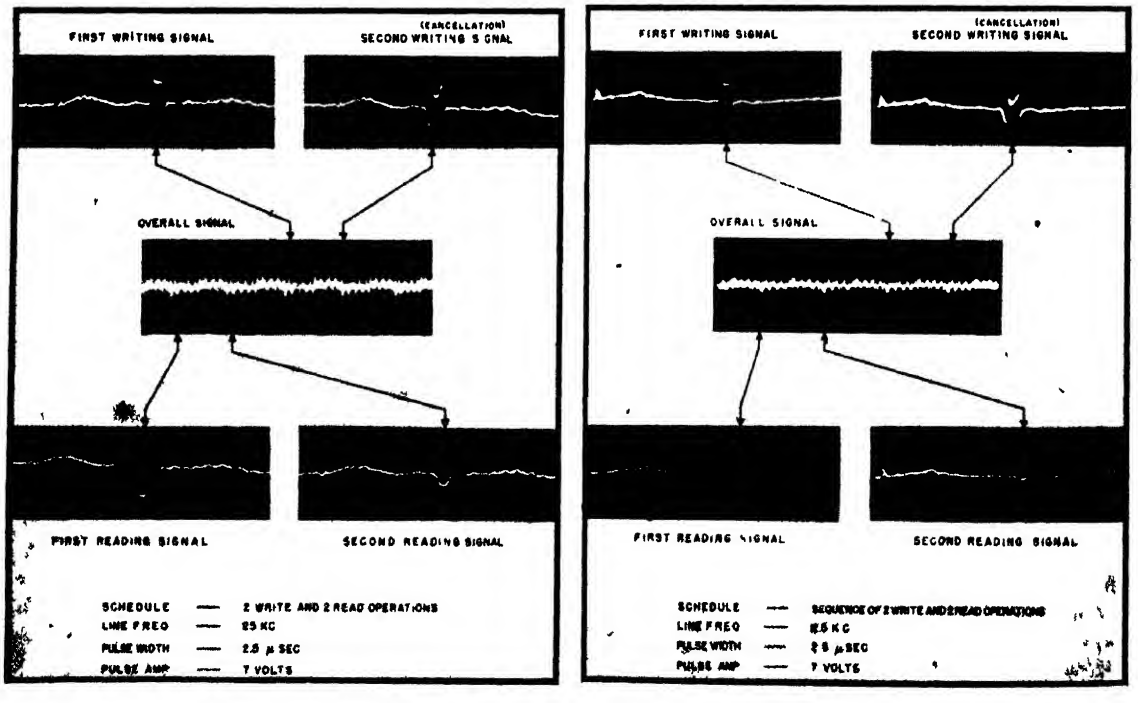
and

$$I_{w2}(\infty)=I_{R2}(\infty)=(1-\delta_E)I_b\,\frac{\epsilon^{-\gamma}(1-\epsilon^{-\gamma})}{\gamma(1+\epsilon^{-2\gamma})}. \qquad (22)$$

For a value of γ in the neighborhood of unity, the magnitude of A will be small, and hence the initial conditions for the first writing operation will be essentially the same as those assumed in Case I. Similarly, the basis for comparison of the second writing signal and the reading signal with Cases II and III, respectively, is also established.

Oscillograms of the writing and reading signals for a schedule as outlined above are shown (Figs. 9(a) and (b)) for $\gamma_{avg}=0.8$ and $\gamma_{avg}=1.6$. In general, a very good agreement is noted between these signals and their predicted counterparts in Figs 5–7 It was necessary here to define the term γ_{avg} as the average of the writing and reading decrements, since for a 7-volt signal the effective secondary emission characteristic is not too linear or even symmetrical. This may be seen from Fig. 10, in which the initial amplitude of a writing signal (followed by three reading operations to insure essentially complete erasure for $\gamma\cong 1$) is taken as a measure of $(1-\delta)I_b$ and is plotted, in arbitrary units, *versus* the input voltage. The assumption of linearity is evidently valid over a range of about ± 5 volts. This is further substantiated by a plot of the *first* reading signal against the input pulse amplitude, which gives a sort of input-output characteristic for the tube. Here again it is seen that for small input signals ($<\pm 5$ volts) one may consider the operation to be approximately linear.

While these oscillograms give a fair measure of confirmation to our analysis, it is desirable to obtain more quantitative support for this theory. This may be obtained by comparing observed steady-state signal amplitudes with the theoretical amplitudes given by (21) and (22). (See Fig. 11.) It will be noted that the experimentally observed amplitudes agree fairly well with the calculated amplitudes. It should be mentioned that the sets of points were obtained by some rather inaccurate measurements of write and read signal amplitudes on a synchroscope as the average γ was changed by varying the velocity of the storage-tube sweep or scan. Furthermore, in order to provide a basis of comparison the first reading in each set was scaled to agree with the theoretical value for that particular γ and the same scale factor applied to the remaining



(a) $\gamma_{avg}=0.8$ (b) $\gamma_{avg}=1.6$

FIG. 9. Storage-tube output signals.

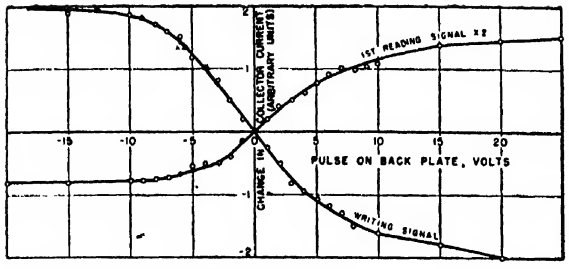


FIG. 10. Amplitude of writing signal and first reading signal *vs.* input pulse amplitude.

observations in the set. Thus, no comparison of absolute values is made here, but rather a comparison of the patterns or curves along which these points fall; from these results one then draws the conclusion that a rather good correlation between predicted and observed curves exists. It might be mentioned again that these amplitudes are difficult to measure with any great degree of accuracy, especially when the applied signal is kept low (at about three-volt peak) to insure good linearity since the base-line disturbance or background "noise" generated by the tube thus appears proportionately larger. Hence, the data of Fig. 11 indicate that the analysis is correct to at least a good first approximation.

Further support for the analysis is obtained by plotting experimentally observed values[9] of γ *versus* the reciprocal of the scanning velocity for various values of collector current (Fig. 12). It will be noted that the linear relationship between γ and $1/v$ is confirmed and also to a more approximate degree the direct variation of γ with I_b.

SUMMARY AND CONCLUSIONS

It will be noted that the shape of the stored voltage distribution in each of the three cases considered is the same, differing only in magnitude, the effectiveness of the erasing action in Case III being measured by the factor $\epsilon^{-\gamma}$ and the scale factor in Case II being the sum of those in I and III. This is a very useful result, since it means that for sufficiently high values of γ (say, above 2) the final value of the stored voltage distribution is dependent only upon the applied signal and is practically independent of the initial charge distribution on the dielectric. Therefore, under these conditions the signal being stored takes precedence over any previously in storage and no separate erasing operation is required.

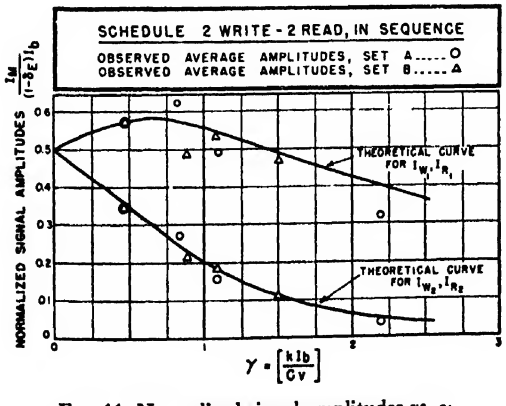

FIG. 11. Normalized signal amplitudes *vs.* γ.

[9] This data was obtained by T. F. Rogers and J. Dumanian.

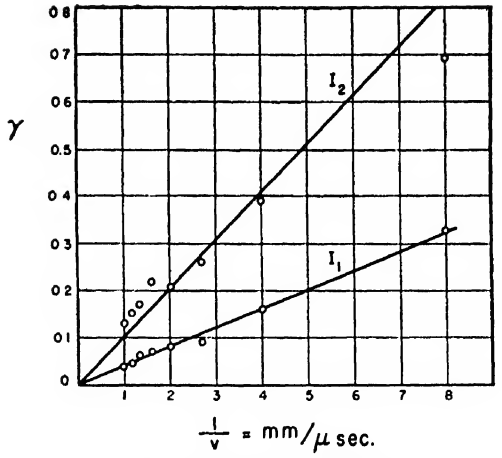

FIG. 12. γ *vs.* $(1/v)$ (for two values of collector current).

The factor $\gamma = kI_b/vC_x$ is evidently an extremely important quantity in governing the tube operation; the reason for this may be surmised from an understanding of its physical meaning. The expression for γ may be written as

$$\gamma = \frac{kI_b}{vC_x} = \frac{(1/v)}{(C_x/kI_b)} = \frac{(1/v)}{R_eC_x},$$

where $R_e = 1/kI_b$. This interpretation is dimensionally valid since k, the slope of the secondary emission curve, has the dimensions of $(\text{volts})^{-1}$; therefore $1/kI_b$ will have the dimensions of ohms multiplied by length. R_eC_x may be interpreted to be the time constant for charging the dielectric in the absence of beam motion and hence, γ is seen to be the ratio of the time it takes the beam to traverse a given spot to the time it would take the beam to charge the same spot if the beam were stationary. For reasonably successful charging action it would be expected that these times should be somewhere near equal, or that the important range of γ-values should be in the vicinity of unity; this expectation is borne out by the foregoing analysis.

Graphical Representation of Particle Trajectories in a Moving Reference System

M. GARBUNY
Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania
(Received April 17, 1950)

A graphical method is derived for the analysis of microwave electron tubes, ion accelerators etc., which refers particle positions and velocities to a moving reference system. If the forces are dependent on time only, the trajectories are transformed into straight lines. For inhomogeneous fields an approximation procedure applies. To demonstrate the capabilities of this method a brief treatment of the transit time phenomena in cavity triodes is outlined.

I. INTRODUCTION

THE analysis of transit time phenomena of particles under the influence of varying forces, as in electron tubes, leads often to complicated transcendental equations. Usually cumbersome graphical methods are employed to arrive at such kinematic values as arrival velocities, transit angles, and current distribution.[1] A typical example is the simple case of linear electron motion between two electrodes which produce superimposed homogeneous static and radiofrequency fields, i.e. a type of acceleration $a(t)$ described by

$$a(t)=A\sin t+B, \tag{1}$$

t being measured in electrical radians. An electron leaving the first electrode at time t_1 with a velocity v_0 arrives at a distance s at time t with a velocity v. One obtains by successive integrations:

$$v=A(\cos t_1-\cos t)+B(t-t_1)+v_0, \tag{2}$$

$$s=A[(t-t_1)(\cos t_1+v_0/A)+\sin t_1-\sin t]+B(t-t_1)^2/2. \tag{3}$$

The usual problem is then to evaluate transit times $(t-t_1)$ and velocities for a given electrode distance s with various starting times t_1 as parameter, and it is evident that in such representation elaborate graphical methods are called for such as a point-by-point construction of all the trajectories $s(t)$ with various values t_1.

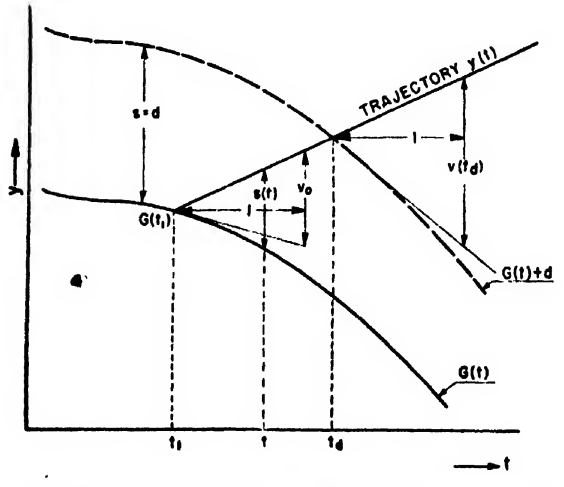

FIG. 1. Method of obtaining straight lines as trajectories.

In the following a graphical method will be described which in essence amounts to referring all trajectories to a coordinate system which moves along with one of the particles which is chosen arbitrarily for greatest simplicity of the procedure. If the force is a function only of time, as in case of homogeneous fields, all trajectories become straight lines. This means in terms of expediency that instead of constructing a great number of complicated trajectories or performing equivalent graphical operations one has to use only one relatively simple trajectory as a reference system, and all the others appear as straight lines, permitting a simple evaluation of such values as were mentioned above.

II. DERIVATION OF METHOD

Let us assume a particle enters a field at time t_1 with a velocity v_0, and the forces acting on it depend only on time so that the resulting acceleration is

$$a=f(t). \tag{4}$$

Let the motion be one-dimensional for reasons of simplicity, although the three-dimensional case can be obtained by considering the components $f_x(t)$, $f_y(t)$, $f_z(t)$ separately. We now define:

$$F(t)=-\int_p^t f(t)dt;\quad G(t)=\int_q^t F(t)dt, \tag{5}$$

where the lower limits p and q of the integrals can be chosen arbitrarily or preferably so that the simplest expressions for F and G result. One obtains then for velocity and distance reached at time t:

$$v=F(t_1)-F(t)+v_0=v_0+G'(t_1)-G'(t), \tag{6}$$

$$s=G(t_1)-G(t)+(v_0+G'(t_1))\cdot(t-t_1). \tag{7}$$

If one writes (7) in the following form as two equations

$$G(t)+s(t)\equiv y(t)=(v_0+G'(t_1))(t-t_1)+G(t_1) \tag{8}$$

one obtains two statements. The left side of (8) defines $y(t)$ as a transformed trajectory of position *vs.* time by the stipulation that

$$s(t)=y-G, \tag{9}$$

[1] A notable exception is R. Kompfner's method, Wireless Engr. 19, 2, (1942), which for a special case overlaps with the method described here.

i.e. that the distance traveled equals the vertical distance between the trajectory and the reference curve $G(t)$. The right side of (8) states that the trajectory $y(t)$ is a straight line of slope $m=v_0+G'(t_1)$ through the point with the coordinates t_1, $G(t_1)$. The velocity at each point

$$v(t)=ds/dt=y'(t)-G'(t) \qquad (10)$$

equals the difference between the slopes of the trajectory $y(t)$ and the reference curve $G(t)$. The physical interpretation of this procedure follows now easily. $G(t)$ is the trajectory of a selected particle in rectangular coordinates. With (9) and (10), one in effect refers positions and velocities to that of the selected moving particle, thereby attaining straight lines for the newly defined trajectories $y(t)$.

One thus arrives at a simple graphical method for the analysis of transit time phenomena, see Fig. 1. First the reference curve $G(t)$ is plotted, as defined by (4) and (5). Next, the straight line trajectories are drawn starting from $G(t)$ at various points t_1, $G(t_1)$. The slope of the trajectory equals the sum of the slope of the curve $G(t)$ at point t_1 and the initial velocity v_0 at this point; if the particle starts at rest, a tangent results. The intersection of the trajectory with a curve parallel to $G(t)$ at a distance $s=d$ marks the arrival time t_a. The arrival velocity is given by the vertical distance of the trajectory from the tangent to the curve at the intersection, at distance one (unit of the abscissa) from this intersection. Other kinetic values can be obtained by simple additional constructions.

A review of the literature on pertinent graphical methods revealed that for the special case $f(t)=A\sin t$ the described transformation is identical with Kompfner's procedure,[1] which however arrives at parabolic trajectories for the more general case of (1), $f(t)=A\sin t+B$. Another special case is $f(t)=0$, $G(t)=0$ for field-free drift spaces which leads to Applegate's diagram.[2]

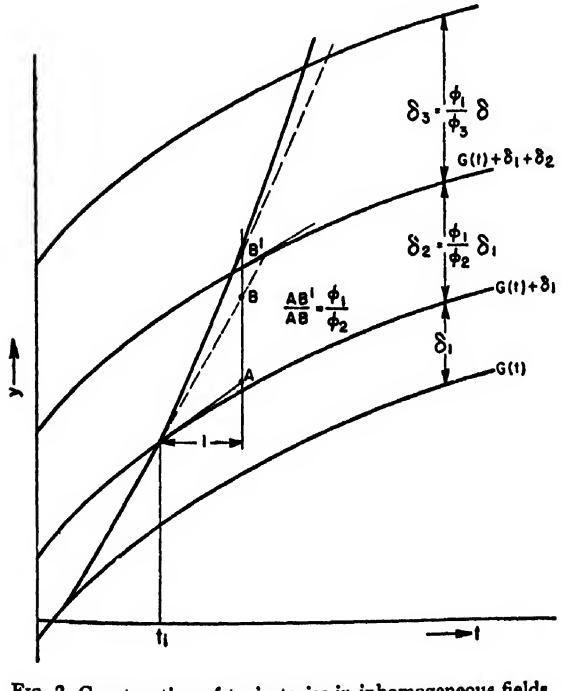

FIG. 2. Construction of trajectories in inhomogeneous fields.

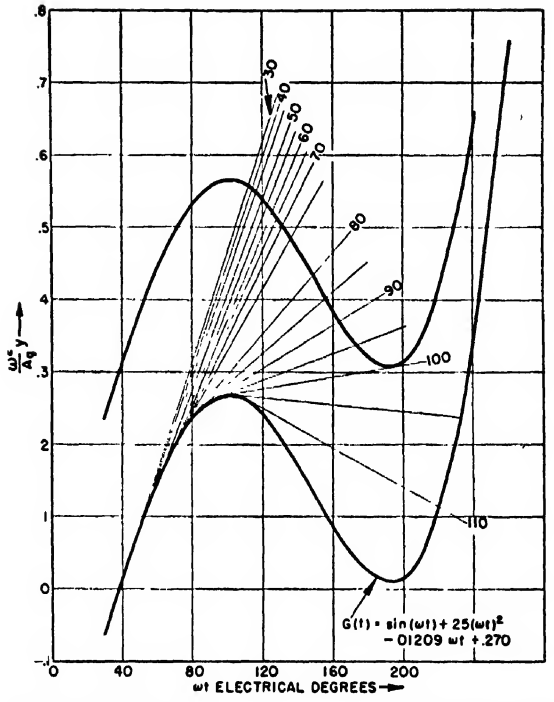

FIG. 3. Transformed electron trajectories for idealized conditions of cathode-grid cavities in dimensionless units. The chart results from the choice of $B_0/A_0=0.50$, $\delta_0=0.298$ (e.g., $d/\lambda=3.85\times10^{-3}$, $V_0=1$ Kv) and a p and q in (5) so as to increase the accuracy of the graph. The value for δ_0 corresponds to the limitation that the first emitted electron and the last not reflected electron leave at 30 and 100 electrical degrees, respectively.

III. EXTENSION OF THE METHOD TO INHOMOGENEOUS FIELDS

The method described above postulated forces which depended on time only. In inhomogeneous fields however the particle experiences forces which, in addition to being time variant, are also functions of position, i.e. one obtains for the acceleration instead of (4) the more general differential equation

$$d^2x/dt^2=\varphi(x)f(t). \qquad (11)$$

Here $\varphi(x)$ is, for one-dimensional motion, the static field distribution along the path of the particle. In simple geometries $\varphi(x)$ can be computed, while in other cases it has to be determined empirically, e.g. with the electrolytic tank method. One adopts now the following approximation method for the transformation of the particle trajectories, see Fig. 2.

The traversed distance $x=d$ is subdivided into a number n of intervals Δx_λ which are equal and small enough so that within them the variation of $\varphi(x)$ from

[1] See, e.g., *Klystron*, Sperry Gyroscope Company, 1944.

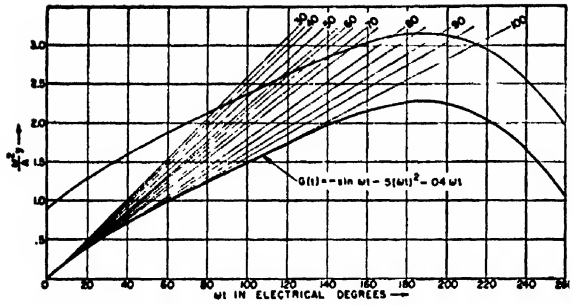

FIG. 4. Trajectories in the anode-grid cavity of a triode. Phase values marking the individual electron traces refer to the times of starting at the cathode in Fig. 3. Phase notation of the abscissa refers to the r-f voltage in the anode gap which adjusts itself to the bunched electron stream. $B/A=1$, $\delta=0.831$ (e.g., $d/\lambda=0.02$, $V=10$ Kv). A conversion efficiency of 62 percent is found by an evaluation of arrival velocities.

an average value φ_λ is sufficiently small. The condition that the forces are only time dependent is therefore approximately fulfilled within each segment.[3] The reference curves $G(t)$ and $G(t)+\delta_1$, are then plotted for the first interval Δx_1, $G(t)+\delta_1+\delta_2$ as the upper limit of the second interval Δx_2 etc. so that one plots altogether $n+1$ parallel traces of the same curve $G(t)$. The distances between the curves are inversely proportional to the fields in the intervals which they confine, i.e. $\delta_{\lambda+1}/\delta_\lambda=\varphi_\lambda/\varphi_{\lambda+1}$. The trajectories are straight lines within each interval, but at the crossing of a reference line the slope is changed. It can easily be verified that the slopes of two adjoining trajectory segments, when referred to the slope of the reference line at the intersection, are again inversely proportional to the field regions they traverse, i.e., referring to Fig. 2, $(y_{\lambda+1}'-G'(t_i))/(y_\lambda'-G'(t_i))=AB'/AB=\varphi_\lambda/\varphi_{\lambda+1}$, where $G'(t_i)$ is the slope of the reference curve at the intersection point. One obtains in this manner an approximation to the transformed trajectories in inhomogeneous fields.

[3] If the maximum variation of $\varphi(x)$ from φ_λ within Δx_λ is $d\varphi_\lambda$, the difference in the results obtained by using φ_λ and $\varphi_\lambda+d\varphi_\lambda$ is certainly larger than the actually occurring error. The difference of arrival times t_λ at the end of the interval is derived from (6) and (7) as $dt_\lambda=-d\varphi_\lambda(\Delta x_\lambda-v_{\lambda-1}(t_\lambda-t_{\lambda-1}))/v_\lambda\varphi_\lambda$. Hence the relative difference in transit time $dt_\lambda/(t_\lambda-t_{\lambda-1})\cong-bd\varphi_\lambda/\varphi_\lambda$, where $b=[\Delta x_\lambda-v_{\lambda-1}(t_\lambda-t_{\lambda-1})]/v_\lambda(t_\lambda-t_{\lambda-1})$ can be determined from the diagram. The relative difference in arrival velocity is then $dv_\lambda/v_\lambda-v_{\lambda-1})\cong d\varphi_\lambda(1-b)/\varphi_\lambda$. The actual errors will lie between zero and these upper limits.

IV. EXAMPLE: ELECTRON TRAJECTORIES IN CAVITY TYPE TRIODES

As a typical problem to which this method can be applied, the analysis of transit time phenomena in microwave triodes is briefly outlined in the following. The acceleration under negative bias conditions in the cathode-grid space is given by $f(t)=A_g\sin(\omega t)-B_g$. Using (5) and dividing by A_g/ω^2 to arrive at a dimensionless scale, one plots $G(t)$ (see Fig. 3) and a second parallel curve at a distance $\delta_g=\omega^2 d/A_g=2(2\pi d/\lambda\beta_g)^2$ wherein d/λ is the grid-cathode distance in fractional wave-lengths and β_g the fractional lightspeed of an electron corresponding to the peak r-f voltage $V_g=(m/e)A_g d$ across the gap. Since one usually chooses $B_g/A_g=0.5$ one such chart with varying parameter δ_g can describe most grid conditions which occur in the practical application of microwave tubes.

The velocities and times at which the electrons arrive at the grid are then applied as the initial conditions for the trajectories in the grid-anode space (Fig. 4). The square of the arrival velocities at the anode is proportional to the power loss, and one can in this manner, by averaging over all electrons, arrive at the total conversion efficiency.

The author wishes to express his appreciation for the many stimulating discussions with Dr. J. W. Coltman and Dr. W. Altar.

Some Observations on the Epitaxy of Sodium Chloride on Silver*

G. W. Johnson
Brookhaven National Laboratory, Upton, Long Island, New York
(Received May 22, 1950)

An experimental study was made of the orienting effects of silver on sodium chloride crystallized from solution. Pronounced epitaxy was observed in the following cases: (1) On oriented films of silver with (100) and also with (111) planes parallel to the surface; and (2) on polycrystalline high purity silver sheet.

INTRODUCTION

THE phenomenon of epitaxy, or oriented overgrowth of one crystal on another, has been known for over a century. The interpretation of the effect in general had to await the development of x-ray and electron diffraction techniques. Perhaps the most complete systematic study, after the x-ray lattice constants of the crystals were known, was that of Royer.[1] As a result of his work, he concluded that at least two of the following three conditions must be met before oriented growth** can occur:

(1) If crystal A is oriented by crystal B, then A must have a two-dimensional lattice which is commensurate within limits with the exposed two-dimensional lattice of B. The lattice spacings of atoms of A and B in the mutual plane of contact do not need to be the same; the lattice spacing of one crystal may be a small whole-number multiple of that of the other.

(2) The ions of A must take positions which corresponding ions of B of the same sign would have occupied had the lattice of B been extended.

(3) A and B must have the same type of binding, e.g. both ionic crystals or both metals.

Subsequently, notable exceptions were found to these conclusions. Beukers[2] discovered that galena, a semiconductor, oriented sodium chloride, an ionic crystal. Sloat and Menzies[3] looked for oriented growth of ionic salts on silver but obtained epitaxy only with NH_4Br and CsCl. It is now well established that some metals condensed in a vacuum on cleaved ionic crystals under proper conditions will assume preferred orientations.[4–6] Among these is the growth of silver parallel to the structure of rock salt. Since the cleavage surface of rock salt is the (100) plane, the condensation of silver yields a film with the (100) orientation. Films prepared in this way have a twinned structure but after heating to 500°C for a few minutes, they are converted into relatively perfect single crystals having the same orientation as the substrate.[7]

The study of the epitaxy of ionic crystals deposited from solution on metals has not been given much attention. Brück,[5] and Goche and Wilman,[7] after removing the silver film from rock salt by solution of the latter in water, observed interference points in the diffraction patterns which were attributed to the presence of sodium chloride on the surface, which had not been removed by their rinsing procedures. The indicated orientation was that the (100) plane of sodium chloride was parallel to that of silver, but that the [100] direction of the salt was along the [110] direction of silver. The films apparently were not examined under a microscope. In a recent general discussion of crystal growth by G. P. Thomson[8] and an excellent survey of the literature by van der Merwe,[9] no examples were given of epitaxy between ionic crystals and metals other than those referred to here.

This paper is a description of some observations of marked epitaxy of sodium chloride on oriented films and on polycrystalline sheets of silver. It was found that orientation resulted even when the difference in atomic spacings for the two planes in contact was large. It was concluded that the orienting influence was exerted in the embryonic stages of growth.

EXPERIMENTAL PROCEDURE

A few drops of sodium chloride solution were placed on the surface of a suitable silver specimen (the preparation of which is described below), and after evaporation of the solvent, the disposition of the sodium chloride crystals was examined with a microscope.

Two types of silver surfaces were employed: oriented thin films and polycrystalline sheet. The use of thin films provided a ready means of obtaining surfaces with known crystallographic planes exposed. It was essential to have such surfaces in order to relate the observed orientation of the deposited sodium chloride crystals with that of the silver. Polycrystalline sheet was used to find in a qualitative way how universal the orienting influences were, and to determine whether the grain boundaries exerted any specific effects.

The method of Brück and others[4–6] was applied to the

production of films with the desired orientations. Silver was vaporized in a vacuum from a tungsten filament and condensed (1) on cleaved rocksalt, and (2) on mica. To assure that properly oriented films are formed with this technique, it is necessary that the crystals be cleaved just prior to their introduction into the vacuum chamber. In addition, both the mica and the rocksalt must be held at a temperature above 150°C while the silver is being condensed. In our work the crystals were heated to 190°C during deposition. In this way, a silver film with the (100) plane exposed was produced on rock salt, and on mica the (111). Sufficient silver was evaporated to get a film thickness of ~1000A. The films were allowed to cool in a vacuum before removing them from the tube.

To reduce the possibility that the substrate might in some way influence the observations, the rock salt was dissolved in water. The film floated on the surface of the water and was readily picked up on a polished silver plate. The epitaxy experiments were made on the surface of the film that had not been in contact with the salt.

The film on mica was ready for testing for epitaxy as soon as it was taken from the vacuum chamber. It was unnecessary to remove the film from the substrate since it was shown by Royer[10] that mica does not orient sodium chloride The preparation of the polycrystalline silver sheet involved cleaning, heat-treatment, and in some cases etching. Square pieces ($\frac{1}{2}'' \times \frac{1}{2}''$) were cut from a 20-mil thick plate. These squares were washed carefully in detergent and rinsed successively in distilled water, benzene, and alcohol. The specimens were heated in a vacuum at 700°C for one hour and furnace cooled to removed the effects of the rolling of the sheet during its fabrication. Relatively large grains (~0.5 mm in diameter) resulted from this treatment. Each specimen then was electrolytically polished using published methods.[11,12] Although polishing was not essential to the production of epitaxy, a polished surface was easier to examine. To reveal the grain boundaries some specimens were etched in a mixture of equal parts of five percent solutions of potassium cyanide and ammonium persulfate.

The sodium chloride was crystallized from saturated solutions in mixtures of water and ethyl alcohol. By varying the amount of alcohol the rate of evaporation could be changed permitting the control of crystal size over wide limits. If large crystals were desired, an aqueous solution was necessary. On the other hand, if extremely small crystals were required, a strongly alcoholic solution was used.

To test for epitaxy, a few drops of the solution were placed on the surface. The surface was then dried under an electric hair-dryer. On a grease-free surface, the crystallization was spread uniformly over the surface except for variations from grain to grain due to orientation effects.

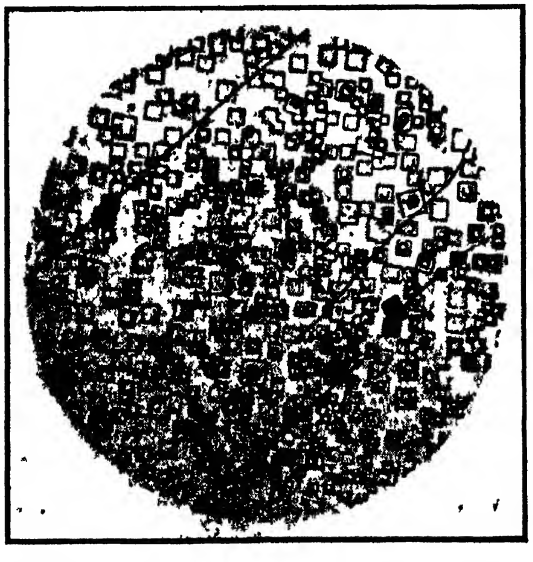

FIG 1 Epitaxy of sodium chloride on a silver film oriented by rock salt. The surface was a (100) plane The lines extending across the film were produced by cleavage steps on rock salt surface 300×

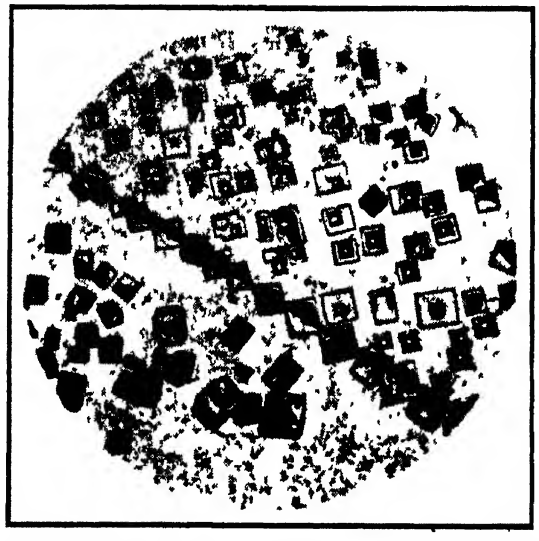

FIG 2 Sodium chloride crystals near edge of silver film oriented by rock salt Silver film supported by a polycrystalline silver plate. Note growth of crystals from edge of film 300×

Each specimen was then examined under a microscope to observe the presence or absence of preferred orientations. If the crystal size was unfavorable, the surface was cleaned by rinsing in distilled water. Another solution then was tried to get the desired crystal size. This procedure could be repeated many times, although usually after several rinses the surface would show evidence of contamination, as indicated by failure of the solution to wet the surface completely. arrangements were photographed using a Bausch and Lomb metallograph under bright field vertical illumination.

Material

The silver was of high purity (99.999 percent) supplied by Sigmund Cohen. The rock-salt crystals were cleaved from a synthetic single crystal from the Harshaw Chemical Company. The mica was ordinary muscovite.

RESULTS

Thin Films—On the films with the (100) plane exposed, almost complete orientation of the sodium chloride was achieved. Characteristic results are shown

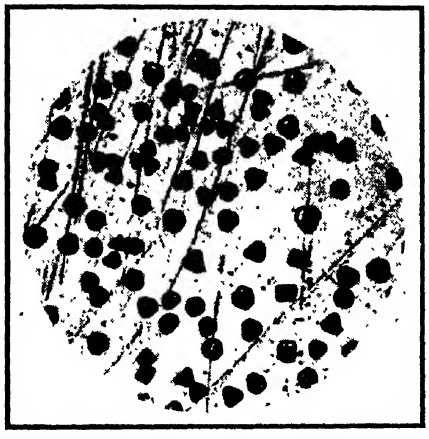

FIG. 3. Sodium chloride crystallized on silver film oriented by mica. 400×

in Fig. 1. The crystals formed rectangular pyramids whose bases were in contact with the silver surface. The straight edges forming the sides of the squares were [100] directions of sodium chloride and were directed along the [110] of the underlying silver. Thus the (100) planes of the salt and the silver were parallel, but the cube edge of the salt was aligned with the face diagonal of the silver.

Since the silver film was mounted on a polycrystalline silver plate, it was of interest to compare the areas of the film and the plate adjacent to the edge of the film to determine if the plate was affecting the results. Such an edge is shown in Fig. 2. On top of the film proper the sodium chloride crystals were oriented as illustrated in Fig. 1, whereas on the plate no general preferred alignment was noted. The edge of the film was the [100] direction of silver. The rotation of the salt crystals by 45° with respect to cube edge of the silver is plainly indicated. Of additional interest is the rather extended growth of crystals, which had nucleated at the edge of the film, over the support plate. In these cases, the crystal form was maintained even though the growth took place over a polycrystalline substrate. This means that the crystal form was determined in the embryonic

FIG. 4. Sodium chloride crystals on polycrystalline silver. Electropolished and etched. Note variation of density of crystallization from grain to grain and between twinned portions of grains. 150×

stage of development and subsequent growth was unaffected by the plate. This point will be amplified in the discussion.

On the silver film deposited on mica, the alignment was strict. The sodium chloride crystals assumed triangular pyramidal shapes. The results are presented in Fig. 3.

Striking effects were noted with polycrystalline silver. Practically complete epitaxy occurred for silver prepared in any of the following manners: electropolished and etched; electropolished but not etched; neither polished nor etched. In all cases, the surface was cleaned and heat-treated at 700°C for one hour prior to the application of the sodium chloride solution. The nature of the oriented overgrowth was the same for each of the three methods of surface preparation.

Characteristic results for a polished and etched specimen are shown in Fig. 4. The grain and twin boundaries may be seen in the field. The twinned regions are the generally banded areas within a grain. Each part of the grain which is twinned with the same orientation etches in the same way. Twinning is rather general over the whole area. Silver is well known to have a propensity for this behavior.

Those areas within a grain which etch in the same way are known to have the same orientation. Inspection of Fig. 4 reveals that the sodium chloride crystals had the same orientation over those parts of the grain which had the same appearance after being etched. In the dark areas of the large grain in the center of the figure, all the crystals had the same orientation. The white areas, which were devoid of crystals, were twinned regions of that grain.

The crystals on neighboring grains were oriented in various directions but on each grain one orientation was

preferred. On the twinned region of some of these grains no crystallization was observed. On others the crystals on the twins were all rotated through an angle with respect to those on the rest of the grain. Several examples of these effects may be seen in Fig. 4.

On polished but unetched silver similar behavior was noted. The crystals of sodium chloride clearly indicated the location and size of the grains. The similarity of the appearance of the sodium chloride crystals shown in the center of Fig. 5 and those in Fig. 1 suggest that the orientation of the substrate in the two cases was the same. Presumably the (100) plane of the grain in Fig. 5 lay in the surface of the plate.

It might have been anticipated that the discontinuities at the grain boundaries would provide places of ready nucleation. However, the grain boundaries, whether the silver was etched or not, were not preferred sites for crystallization. There was no evidence for such preference on any of the surfaces examined.

The density of crystallization varied from grain to grain. On some grains, in fact, no crystallization took place. The variation in density of crystallization was applied in one case to reveal the grain structure. A strongly alcoholic solution dried rapidly on a polished

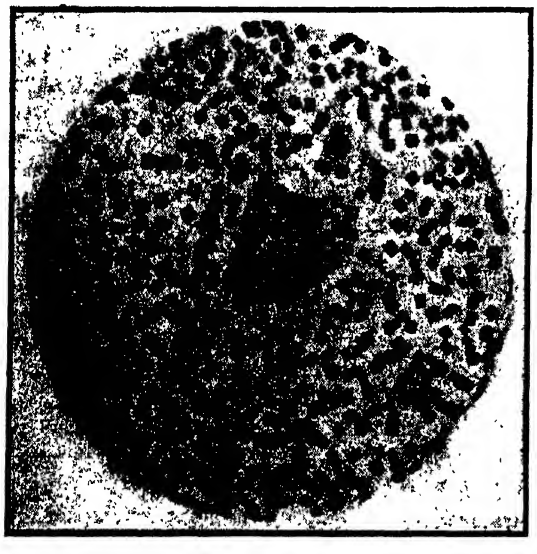

FIG. 5. Sodium chloride crystals on polycrystalline silver sheet. Electropolished and unetched. 150×

surface in a current of warm air was used to produce crystals ~1 micron in diameter. The variations in the density of crystallization produced sufficient contrast to outline the grains (Fig. 6). The same area was then rinsed and etched to delineate the grains in the usual manner. The result of this is shown in Fig. 7. The faithfulness of the reproduction by crystallization is apparent through a comparison of Figs. 6 and 7.

Another observation of interest was the growth of crystals across grain or twin boundaries without modification. From this it appeared that the form of the crystal was determined in the early stages of growth. Many examples of crystals which had nucleated on one side of a boundary and grown across may be found in Figs. 4 and 5. Additional illustrations were furnished when caesium chloride instead of sodium chloride was crystallized on the surface. The crystals grew farther into adjoining grains (Fig. 8) than did sodium chloride crystals. These results suggest that the influence of the substrate was exerted only in the embryonic stages of crystallization. Once the crystal had nucleated, subsequent growth was not affected by the nature of the

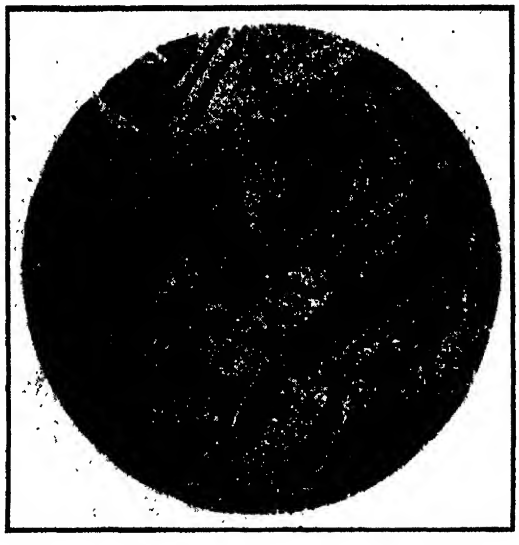

FIG. 6. Grain structure of polished polycrystalline silver revealed by variation of density of crystallization on the surface. 150×

underlying material. Further support to this view was given by the growth of crystals from the edge of the thin film shown in Fig. 2.

A silver surface, once it had been prepared so that it was capable of orienting sodium chloride, retained this capacity for months. There was no evidence of any aging effects.

DISCUSSION

There are four general features of the results which are of interest: (1) Pronounced epitaxy was found to exist between a metallic surface and an ionic crystal; (2) each area of the substrate of a given orientation was characterized by a particular orientation of the overgrowth; (3) the density of crystallization was dependent upon the orientation of the grain; (4) the crystals of sodium chloride often grew across grain and twin boundaries without modification. Each of these points is discussed in the following.

At the outset, it is clear that the third condition suggested by Royer,[1] requiring that the overgrowth and the substrate have the same type of binding, must be either modified or abandoned. Here we have strong evidence of epitaxy between a substrate with metallic binding and

an ionic crystal. The only question which might arise in interpretation is whether the salt was oriented directly by the substrate or by a compound on the surface. In particular the presence of an oxide layer would be suspected. Since each grain of silver in the polycrystalline specimens produced either a unique alignment or none, it follows that if an oxide layer were present it bore a definite crystallographic relationship to each grain of the substrate. While there are many such examples of oriented growth of oxides on metals, none have been reported for silver. Actually silver oxide is quite unstable

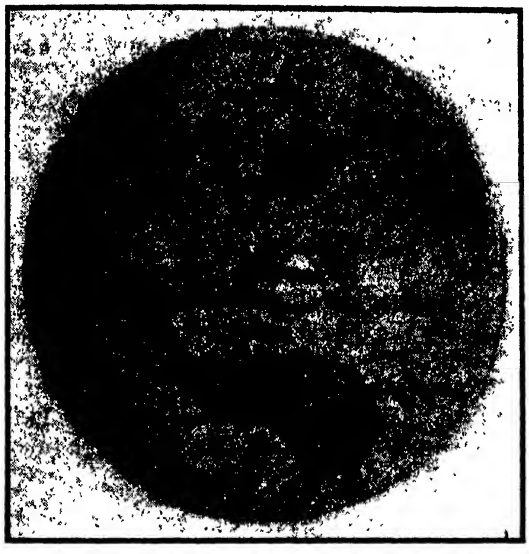

FIG. 7. Same area of polycrystalline silver sheet shown in Fig. 6 after etching. 150×

above 200°C and its rate of formation is exceedingly low at lower temperatures. As a result of an extensive investigation of the stability of silver oxide (Ag_2O) and the adsorption of oxygen on silver, Benton and Drake[13] concluded that silver acted upon by oxygen at room temperature becomes covered with a monomolecular layer. The rate of oxide formation would be negligibly small. From photoelectric work function measurements on silver, Brewer[14] found that an oxidized surface could be restored to a value characteristic of clean silver by heating at 600°C for several hours under vacuum. It will be recalled that the polycrystalline silver used in the present work was baked in a vacuum at 700°C for one hour and cooled in the furnace; and that the silver films were prepared by vacuum distillation. Consequently, while an adsorbed layer of oxygen probably existed on the surface, it is unlikely that an oxide film was present.

The results for polycrystalline metal and for oriented films indicated that the fit of the two lattices in contact need not be close for epitaxy to occur. On polycrystalline silver some form of alignment was produced on almost every grain. The universality of the effect in itself suggests that closeness of fit cannot be a strict requirement. Quantitative justification of this conclusion may be found in the results for oriented films.

When crystallized on a (100) plane of silver, the [100] direction of sodium chloride was directed along the [110] direction of the metal. The distance between adjacent atoms along the [100] axis of sodium chloride is 2.81A, and that between consecutive silver atoms along the [110] is 2.88A. Thus, with this arrangement the difference in atomic spacings 2.5 percent. As pointed out by G. P. Thomson[8] this relative orientation is the one of closest fit.

For (111) planes in contact, which was the situation for the film oriented by mica, the differences in atomic spacings of the sodium chloride and the silver lattice amounted to 73 percent. The existence of epitaxy between silver and sodium chloride, therefore, does not depend markedly on closeness of fit of the two lattices. Sloat and Menziers[3] obtained oriented growth on silver for only those salts whose lattice parameters differed from those of the metal by less than one percent; and, they concluded that the lattices must be commensurate

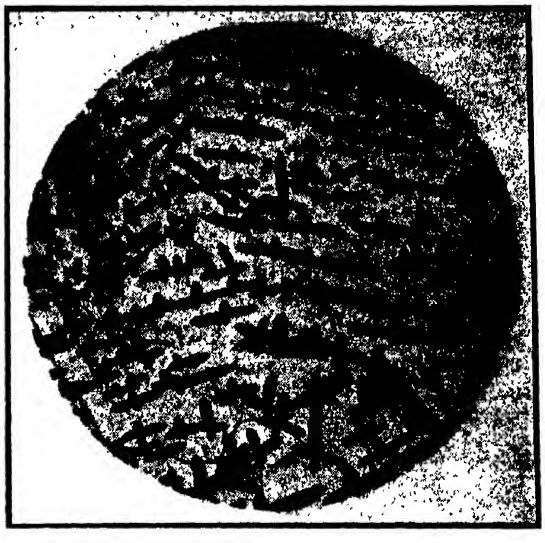

FIG. 8. Epitaxy of caesium chloride on polycrystalline silver. Note extensive growth of crystals across grain and twin boundaries without modification. 150×

within that tolerance. However, the present results show a much greater difference in lattice dimensions can be tolerated.

The observation that the density of crystallization depended upon the orientation of the substrate might have been anticipated. For electrodeposited metals, Finch and Sun[15] found that the adherence between the coat and the underlying surface was greatest when strong epitaxy existed between the two metals. Royer[1] noted that when a mixture of glass, mica, gypsum,

[13] A. F. Benton and L. C. Drake, J. Am. Chem. Soc. 56, 255 (1934).
[14] A. K. Brewer, J. Am. Chem. Soc. 56, 1909 (1934).
[15] G. I. Finch and C. H. Sun, Trans. Farady Soc. 32, 852 (1936).

calcite, talc, and orpiment were placed in a solution of ammonium iodide, the crystals always appeared first on the mica. The presence of epitaxy implies strong interatomic forces between the crystallizing atoms and those of the substrate. Therefore, a more rapid nucleation would be expected to take place on those surfaces favoring oriented growth. It is of interest to note that while contact of a crystal of a solute with a solution is the only means of completely preventing supersaturation, a surface which can show epitaxy with the solute may prevent a degree of supersaturation otherwise possible.[16]

For the silver film prepared on rock salt it was possible that nuclei were mechanically retained in the film after its removal from the salt. Such nuclei would serve as centers of crystallization when the film was tested for epitaxy. The growth, in this event, would have been parallel to the original rock salt lattice. Even after thorough rinsing a few crystals had this orientation, but practically all were rotated 45° with respect to this direction. Thus, the observed effects were undoubtedly characteristic of the silver film.

On the film with the (111) plane produced on mica, the observed results must be attributed to the silver, since Royer[10] showed that sodium chloride is not oriented directly by mica.

That the orientations of the crystals of the overgrowth were determined in the embryonic stages of crystallization was indicated by two observations: (1) the growth of crystals from the edges of an oriented film, and (2) the growth of crystals across grain or twin boundaries. Thus, the crystals often extended distances of ~0.01 mm, or several thousand atomic diameters, over areas of the substrate having an orientation different from that at the point of initial formation of the crystal. The fact that in many instances, a major portion of the crystal was resting on a surface which favored another orientation produced no modification of the overgrowth. More examples of this effect were found also with caesium chloride crystals on polycrystalline silver (Fig. 8). This situation could prevail only if the orientation of the crystal were determined on an area of much smaller dimensions than those of the final crystal. From the extent of growth across boundaries, a rough upper limit may be assigned to the size of the embryo. In many cases the crystallites were nearly centered on boundaries. Since the crystal diameters were about 0.01 mm, the embryo was certainly less than one-tenth of this value. Indeed, as pointed out by G. P. Thomson[8] and van der Merwe,[9] it is difficult to understand how the embryo could be larger than a few atomic diameters.

The epitaxy of sodium chloride provided a ready means of testing the degree of orientation of thin films without resorting to electron diffraction. Electron diffraction measurements are required to establish the crystallographic relationships of the overgrowth to the substrate, but once these are known, a rinse in sodium chloride solution suffices as a check. The rinsing procedure gives a representation of the orientation of the entire film, while the usual electron diffraction arrangement permits the examination of only a relatively small area. It must be emphasized however, that observations of epitaxy alone cannot be used to determine the orientation of the substrate, but can be used as a check after the expected orientation is known.

ACKNOWLEDGMENTS

Note on Stability of Electron Flow in the Presence of Positive Ions

J. R. PIERCE
Bell Telephone Laboratories, Murray Hill, New Jersey
July 17, 1950

THE writer once calculated what he believed to be the limiting stable current in parallel electron flow normal to parallel conducting bounding planes (as, grids).[1] The conditions assumed were the following: Two parallel grids are spaced L cm apart. A current i_0 amp./cm^2 of electrons with a velocity u_0 specified by the accelerating voltage V_0 is injected through one. In the space between the grids, a positive charge density of immobile ions is assumed, such that if the electrons retain their velocity of injection the net space charge between the grids will be zero. The question is, for how large a value of i_0 will the flow be stable? The answer was sought by considering a small sinusoidal perturbation of the flow of frequency ω. It was found that if

$$\frac{\omega_0 L}{u_0} = \pi + \alpha \tag{1}$$

where α is a positive quantity small compared with π, the boundary conditions are satisfied for a frequency

$$\begin{aligned} \omega &= -j\pi u_0 \alpha / 4L \\ j\omega &= \pi u_0 \alpha / 4L. \end{aligned} \tag{2}$$

Here ω_0 is the electron plasma frequency.

$$\omega_0^2 = \frac{(e/m)\rho_0}{\epsilon} \tag{3}$$

where e/m is the charge-to-mass ratio of the electron, ρ_0 is the electronic charge density and ϵ is the permittivity of space. Thus, for $\omega_0 L/u_0$ a little greater than π, perturbations in the flow grow exponentially with time; the flow is unstable.

The situation analyzed was a little unrealistic in that the ions were assumed not to move. Under these circumstances, one obtains an expression for the phase constants of the space-charge waves

$$\beta = \frac{\omega}{u_0} \pm \frac{\omega_0}{u_0}. \tag{4}$$

If we allow motion of the ions, we find[2]

$$\beta = \frac{\omega}{u_0} \pm \frac{\omega_0}{u_0}\left(1 - \left(\frac{\omega_i}{\omega}\right)^2\right)^{-\frac{1}{2}}. \tag{5}$$

Here ω_i is the ion plasma frequency

$$\omega_i^2 = \frac{(q/m)\rho_i}{\epsilon} \tag{6}$$

where q/m is the charge-to-mass ratio of the ions and ρ_i is the ion charge density (assumed to be equal and opposite to the electron charge density).

We can use all the relations developed in reference 1 if we there replace ω_0 by ω_1, where

$$\omega_1 = \omega_0[1 - (\omega_i/\omega)^2]^{-\frac{1}{2}}. \tag{7}$$

Suppose, for instance, that we let

$$\frac{\omega_1 L}{u_0} = \pi + \alpha. \tag{8}$$

We now assume that α is small compared with π, so that ω is given in terms of α by (2). Then, using (7) and (8), we obtain

$$\alpha^2\left(\frac{\omega_0 L}{u_0}\right)^2 = (\pi+\alpha)^2\left[\alpha^2 - \left(\frac{\omega_i L}{u_0}\right)^2\left(\frac{4}{\pi}\right)^2\right]. \tag{9}$$

We have already assumed that $\alpha \ll \pi$, so α will be neglected in comparison with π in the parentheses. This gives for α

$$\alpha = \pm \frac{4(\omega_i L/u_0)}{[(\omega_0 L/u_0)^2 - \pi^2]^{\frac{1}{2}}}. \tag{10}$$

We note that for

$$\frac{\omega_0 L}{u_0} < \pi \tag{11}$$

α will be imaginary, the frequency will be real and the flow will be stable. For

$$\frac{\omega_0 L}{u_0} > \pi, \tag{12}$$

α will be real and positive for one root and hence $j\omega$ will be a real positive quantity and the beam will be unstable.

This argument does not apply near

$$\frac{\omega_0 L}{u_0} = \pi \tag{13}$$

since α will be large in this vicinity. We note, however, that for equal electron and ion charge densities

$$\frac{(\omega_i L/u_0)}{(\omega_0 L/u_0)} = \left(\frac{\text{mass of electron}}{\text{mass of ion}}\right)^{\frac{1}{2}}. \tag{14}$$

Thus, for massive ions, α will still be small compared with π for $(\omega_0 L/u_0)$ fairly near to π.

The conclusion then seems to be that even when the positive charge consists of massive ions rather than a fixed charge, there is a change from a stable to an unstable condition near (13), which represents the value of the electron plasma frequency ω_0 for which the flow becomes unstable for a fixed positive charge. It is of course possible that some instability for a lower value of ω_0 has been overlooked.

This note is to be construed merely as an amplification and clarification of work published earlier. Experiments seem generally to indicate that electron flow becomes unstable for currents nearer to those calculated assuming no positive ions present than to the larger currents calculated for the presence of ions.

A Modification of the Radiofrequency Mass Spectrometer

A. F. HENSON
Imperial Chemical Industries Ltd., Butterwick Research Laboratories, The Frythe, Welwyn, Herts, England
April 26, 1950

THE resolution of a single stage of the radiofrequency mass spectrometer described by Bennett[1] is poor, and in order to obtain sufficient resolution a three-stage instrument is used. A possible method of obtaining the necessary resolution without the use of so many grids in the tube would be to apply a square wave form alternating potential to a single stage, the two halves of which were separated by constant potential "velocity selection" section. The tube would consist of the ion source as in Bennett's tube, four grids and a collector plate. For the analysis of positive ions, fixed potentials (negative with respect to the ion source) would be applied to the four grids. Grids 2 and 3 would be connected together and to them would also be applied the square wave form consisting of single complete cycles (positive half followed by negative) separated by intervals. The spaces between grids, the square-wave frequency and the intervals between cycles, would be arranged so that an ion of the selected mass passing through grid 1 at the start of a negative half-cycle passes through grid 2 at the end of the negative half-cycle. During the interval between cycles it travels in the field-free space between grids 2 and 3, emerges through grid 3 at the start of the next positive half-cycle, and through grid 4 at the end of this positive

half-cycle. It then passes on to the collector plate to which a blocking potential is applied in order to collect only the most energetic ions. It is thus accelerated by the square-wave field for the whole of the time it is between grids 1 and 2 and between grids 3 and 4.

A heavier ion than the selected one travels too slowly to gain maximum energy in either half-cycle. A lighter ion can gain maximum energy from either half-cycle but not from both. Thus ions of the selected mass gain more energy than any others. Different masses would be selected by varying the square-wave frequency and interval length, keeping the ratio of period of one cycle to interval constant.

A solution for the motion of the ions in the square-wave field shows that the discrimination between ions of the selected mass m (atomic weight units) and the next heavier ion $m+1$ is much larger than between m and $m-1$. The controlling consideration is then the discrimination between m and $m-1$. In the design of such an instrument there are many variables available. The values chosen will depend on the use to which the instrument is to be put and will be a compromise between conflicting requirements. Calculations have been made illustrating the use of the instrument for work in the low mass range up to about mass 50, such as might be used for stable isotope tracer work with carbon nitrogen and oxygen. The steady potential on the grids was -200 v and the amplitude of the square wave 60 v. It was considered that an energy discrimination between neighboring masses of at least 2 ev would be necessary and that, from consideration of ease of production of the square wave form, its period should not be less than 2 μsec. Under these conditions the tube length is about 80 cm and the energy discrimination between m and $m-1$ varies between 9.6 ev for $m=13$ and 2.4 ev for $m=50$. If it were convenient to produce the square wave form with greater amplitude or shorter period, or if a smaller energy discrimination were found to be sufficient, the tube could be considerably shortened.

Remark on an Aberration-Phenomenon in Electrostatic Lenses. "Kidney Effect"

E. Bas-taymaz
Swiss Federal Institute of Technology, Department of Applied Physics, Zürich, Switzerland
June 7, 1950

In a letter,[1] S. Harrison described an aberration phenomenon in electrostatic lenses, the so-called "Kidney Effect" and gave an explanation. We had observed the same phenomenon in a special electron gun structure a long time ago, not being able to give any explanation. We give here a short description of our observation.

The scheme of the electron gun is shown in Fig. 1. It consists of a tungsten-Bolzen-cathode[2] and a focusing system similar to the description given by R. R. Law. The surface of emission can be imaged sharply on a fluorescent screen. However, with this

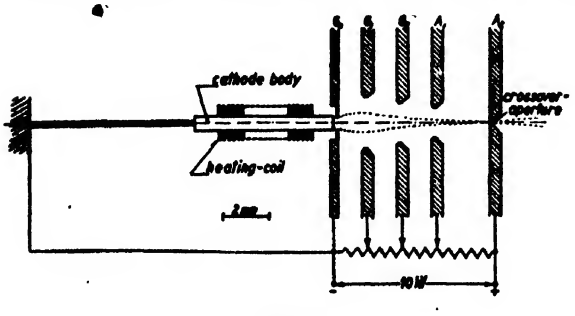

Fig. 1.

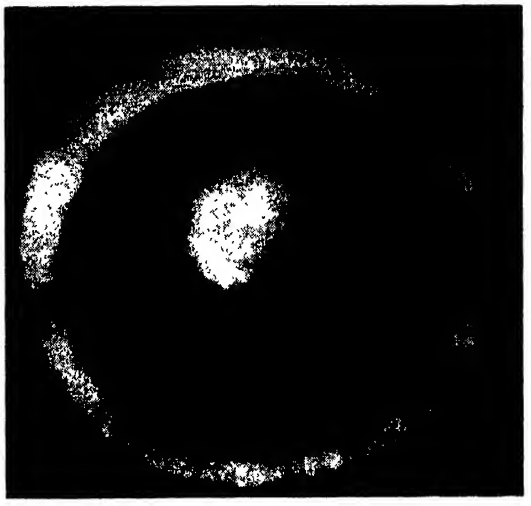

Fig. 2.

well-defined shape of the image produced by changing the strength of the lens by means of potentials of grids 1 and 2, a bright fluorescent spot occurred on the surroundings by further variation of the potentials, which grows to an illuminated circular area as shown in Fig. 2. The picture is the same as given by Harrison with only one difference that we have a greater symmetry resulting from the exact form of the electron gun. The picture, however, does not show exact symmetry and it shows how difficult it is to realize the condition of axial symmetry in electrostatic lenses.

The assumptions of Harrison make it possible to understand the phenomenon of the "Kidney Effect" in this special case, because we inserted *a priori* a little aperture in the focus (cross-over-aperture) which might cause the effect. Furthermore, we can see that this electron gun structure (Fig. 1) is showing a rather serious spherical aberration; a fact which is in accordance with our experience by which it has been ascertained that it is not possible to obtain the theoretical value of cross-over current density.

Dielectric Constants of Five Gases at 9400 Megacycles per Second*

James A. Murphy and Richard C. Raymond
Department of Physics, The Pennsylvania State College, State College, Pennsylvania
June 23, 1950

The dielectric constants of five gases have been measured at pressures up to one atmosphere by a resonant cavity method similar to that reported by Jen.[1] The cavity was a copper-walled cylinder with movable plunger and temperature control, and was operated in the TE01 circular mode. Measurements of the frequency shift and Q were taken from an oscillographic display of the effective resonance curve with the help of a coupled microwave circuit. Modulation power for measurement of frequency shifts was generated by a General Radio Type 1001A signal generator and could be varied in frequency from 5 kc/sec. to 50 Mc/sec. The minimum observable change in frequency was 0.25 Mc/sec.

The dielectric constants of the gases, as observed from the resonant frequency shift at a pressure of 730 mm mercury, are listed in Table I.

TABLE I. Dielectric constants of gases computed from observed resonant frequency shift at a pressure of 730 mm of mercury and wave-length 3.19 cm.

Gas	Dielectric constant $(\epsilon'-1)\times10^4$	Temperature
Acetone	17.1	75° C
Ammonia	6.8	26°
Carbon dioxide	1.6	26°
Carbon tetrachloride	3.9	85°
Water vapor	6.6	102°

Acetone and ammonia showed appreciable broadening of the resonance curves at the maximum pressures investigated. The loss factors were computed to be 2.7×10^{-4} and 4.7×10^{-4}, respectively, at the pressures and temperatures indicated in Table I.

The results are in general agreement with those reported by others[3-8] with the exception of CO_2. The CO_2 used here was prepared by sublimation of commercial dry ice, and may have included some water vapor.

* This paper is from a thesis by James A. Murphy submitted in partial fulfillment of the requirements for the degree of Master of Science at the Graduate School of The Pennsylvania State College.

A Simplified Air Flow Method for the Determination of the Surface Area of Powders

GERARD KRAUS AND JOHN R. THIEM
Applied Science Research Laboratory, University of Cincinnati, Cincinnati, Ohio

IN a recent paper appearing in this Journal, F. A. Schwertz[1] reported a series of surface area measurements on sintered Pyrex diaphragms by means of a gas flow method similar to those of Rigden[2] and Arnell.[3] A particularly useful modification of this method which is quite rapid and requires only the simplest kind of equipment has been used by the writers to measure the surface areas of powders ranging from relatively coarse granules to colloidal carbon blacks.

The specific flow rate in moles/sec. per unit pressure difference under combined Poiseuille and slip flow is, in the notation of Schwertz (reference 1, Eq. (15)):

$$G=\frac{\epsilon^3AP_m}{k_v(1-\epsilon)^2S^2\mu LRT}+\frac{\epsilon^2\pi A}{k_d(1-\epsilon)SL(2\pi MRT)^{\frac{1}{2}}}\cdot\left(\frac{2}{f}-1\right). \quad (1)$$

Now consider a partially evacuated reservoir connected to the atmosphere through a plug of packed powder whose surface is to be measured. If the atmospheric pressure is P_0, the pressure inside the reservoir is $(P_0-\Delta P)$ and its volume V, it can easily be shown that

$$\frac{d(\Delta P)}{dt}=\frac{A\epsilon^3}{10V\mu L(1-\epsilon)^2S^2}(\Delta P)^2-\left[\frac{A\epsilon^3P_0}{5V\mu L(1-\epsilon)^2S^2}+\frac{A\epsilon^2Z}{(1-\epsilon)VSL}\left(\frac{\pi RT}{2M}\right)^{\frac{1}{2}}\right]\Delta P \quad (2)$$
$$=\beta(\Delta P)^2-\alpha\Delta P$$

where k_v has been taken as 5.0 and $(1/k_d)(2/f-1)$ has been replaced by Z. Dividing through by ΔP it follows that

$$\frac{d[\ln(\Delta P)]}{dt}=\beta\Delta P-\alpha \quad (3)$$

so that as ΔP approaches zero the slope of a plot of $\ln(\Delta P)$ *versus* t will be α.

TABLE I. Comparison of modified air flow method with established methods of surface area measurement.

	Surface area m^2/g		
	Air flow	Check	Method of check
Microscopic glass spheres	0.136	0.139	Microscopic count
Carbon black (Thermax)	7.4	7.69	Nitrogen adsorption[a]

[a] P. H. Emmett and T. De Witt, Ind. Eng. Chem., Anal. Ed. 13, 28 (1941).

Integration and rearrangement of (2) gives

$$e^{\alpha t}-1=\frac{\alpha}{\beta}\left[\frac{e^{\alpha t}}{(\Delta P)_0}-\frac{1}{\Delta P}\right] \quad (4)$$

where $(\Delta P)_0$ is the initial pressure difference. A plot of $(e^{\alpha t}-1)$ against the quantity in brackets yields a straight line of slope α/β. By definition

$$\beta=\frac{A\epsilon^3}{10V\mu L(1-\epsilon)^2S^2}$$

and hence

$$S=\frac{\epsilon}{1-\epsilon}\left(\frac{A\epsilon}{10V\mu L\beta}\right)^{\frac{1}{2}}. \quad (5)$$

The use of Eq. (1) under varying pressure difference involves an approximation due to neglect of inertia forces; however, the error thus introduced is entirely negligible.

In practice it is most convenient to take two sets of pressure-time readings; one with P varying from 35 to 10 cm Hg and the other in the range of 2 to 0.5 cm Hg using an oil-filled manometer. The latter set of data is used for the $\log\Delta P$ *versus* time plot.

Table I gives two examples of results obtained by the above procedure. Both test plots gave excellent straight lines. The agreement of the surface areas with independent methods of measurement is seen to be entirely satisfactory. The glass microspheres were prepared in the laboratory. A count of 501 particles gave a normal distribution with a mean diameter of 14.21 microns and a standard deviation of 4.60 microns from which the value of S in Table I was calculated.

The Pursuit Course

RALPH HOYT BACON
The Perkin-Elmer Corporation, Elmhurst, New York
June 23, 1950

SOME properties of the path of a particle traveling along a curve whose tangent always passes through a point target moving with uniform speed along a straight line have been mentioned by Yuan.[1] Perhaps a fuller description of this curve, called the pursuit course, might be of interest.

Let the path of the target be the y axis, and let the x axis be tangent to the path of the seeker (or pursuer). Then, using Yuan's notation, let

$$\left.\begin{aligned} v_S&=Kv_T\\ dS&=Kdy_T\end{aligned}\right\}, \quad (1)$$

where dS is an element of arc of the pursuit course. For the slope of the tangent of course, at any point, we have

$$\tan\theta=dy_S/dx_S=(y_S-y_T)/x_S.$$

Therefore,

$$\frac{d^2y_S}{dx_S^2}=-\frac{1}{x_S}\frac{dy_T}{dx_S}=-\frac{1}{Kx_S}\frac{dS}{dx_S}=\frac{[1+(dy_S/dx_S)^2]^{\frac{1}{2}}}{Kx_S}.$$

Transposing,

$$\frac{d(dy_S/dx_S)}{[1+(dy_S/dx_S)^2]^{\frac{1}{2}}}=\frac{dx_S}{Kx_S}.$$

Integrating,

$$2\frac{dy_S}{dx_S}=\left(\frac{x_S}{x_0}\right)^{1/K}-\left(\frac{x_S}{x_0}\right)^{-1/K}, \tag{2}$$

where x_0, the constant of integration, is the abscissa of the point of contact of the pursuit curve with the x axis.

Integrating again,

$$\left.\begin{aligned} y_S&=\frac{Kx_S}{2}\left[\frac{1}{1+K}\left(\frac{x_S}{x_0}\right)^{1/K}-\frac{1}{K-1}\left(\frac{x_S}{x_0}\right)^{-1/K}\right]+\frac{Kx_0}{K^2-1} \quad (K\neq 1)\\ y_S&=\frac{x_S^2-x_0^2[1+2\log(x_S/x_0)]}{4x_0} \quad (K=1)\end{aligned}\right\}. \tag{3}$$

For the length of path traveled by the seeker,

$$dS=-\left[1+\left(\frac{dy_S}{dx_0}\right)^2\right]^{\frac{1}{2}}dx_S=-\frac{1}{2}\left[\left(\frac{x_S}{x_0}\right)^{1/K}+\left(\frac{x_S}{x_0}\right)^{-1/K}\right]dx_S.$$

Therefore,

$$\left.\begin{aligned} S&=\frac{K^2x_0}{K^2-1}-\frac{Kx_S}{2}\left[\frac{1}{K+1}\left(\frac{x_S}{x_0}\right)^{1/K}+\frac{1}{K-1}\left(\frac{x_S}{x_0}\right)^{-1/K}\right] \quad (K\neq 1)\\ S&=\frac{x_0^2[1-2\log(x_S/x_0)]-x_S^2}{4x_0} \quad (K=1)\end{aligned}\right\}, \tag{4}$$

where S is measured, plus or minus, from the point of tangency, the point at which $x_S=x_0$.

Combining Eqs. (3) and (4):

$$\left.\begin{aligned} S-y_S&=\frac{K}{K+1}\left[x_0-x_S\left(\frac{x_S}{x_0}\right)^{1/K}\right]\\ &=(x_0^2-x_S^2)/2x_0 \text{ when } K=1\end{aligned}\right\}. \tag{5}$$

Let the distance between the seeker and the target be denoted by P. Then

$$P^2=x_S^2+(y_S-y_T)^2=x_S^2\left[1+\left(\frac{y_S-y_T}{x_S}\right)^2\right]$$

$$=x_S^2\left[1+\left(\frac{dy_S}{dx_S}\right)^2\right]=\frac{x_S^2}{4}\left[\left(\frac{x_S}{x_0}\right)^{1/K}+\left(\frac{x_S}{x_0}\right)^{-1/K}\right]^2.$$

Therefore,

$$P=\frac{x_S}{2}\left[\left(\frac{x_S}{x_0}\right)^{1/K}+\left(\frac{x_S}{x_0}\right)^{-1/K}\right]. \tag{6}$$

Finally, for the radius of curvature of the course,

$$R=\frac{[1+(dy_S/dx_S)^2]^{\frac{1}{2}}}{d^2y_S/dx_S^2}=\frac{Kx_S}{4}\left[\left(\frac{x_S}{x_0}\right)^{1/K}+\left(\frac{x_S}{x_0}\right)^{-1/K}\right]^2. \tag{7}$$

Now, as x_S approaches zero,

$$y_S\to\frac{Kx_0}{K^2-1}-\frac{Kx_0^{1/K}}{2(K-1)}x_S^{(K-1)/K}, \text{ when } K\neq 1;$$

$$\to\frac{Kx_0}{K^2-1} \text{ when } K>1;$$

$$\to\infty \text{ when } K=1 \text{ or when } K<1.$$

$$S\to\frac{K^2x_0}{K^2-1} \text{ when } K>1;$$

$$\to\infty \text{ when } K=1 \text{ or when } K<1.$$

$$S-y_S\to\frac{Kx_0}{K+1}.$$

$$P\to 0 \text{ when } K>1;$$

$$P\to\frac{x_0}{2} \text{ when } K=1;$$

$$P\to\infty \text{ when } K<1.$$

$$R\to 0 \text{ when } K>2;$$

$$\to\frac{x_0}{2} \text{ when } K=2;$$

$$\to\infty \text{ when } K<2.$$

The fact that R approaches zero if K be greater than 2 is well know to every student of the subject.

All of this is an interesting exercise in mathematics; the limitations of its usefulness as a tactical maneuver are pointed by Yuan,[1] who suggests an alternative course.

Some Observations on the Back Heating of Magnetron Cathodes

R. T. Young, Jr., L. W. Holmboe, and W. E. Waters, Jr.
National Bureau of Standards, Washington, D. C.
May 24, 1950

In the course of work on *CW K*-band magnetrons, we have observed some cathode back heating effects which we consider to be of sufficient interest to be worth recording. The magnetrons were of the interdigital type.[1] The pertinent dimensions of a typical tube are: anode radius—0.16 cm, cathode radius—0.11 cm, active cathode length—0.12 cm, number of teeth—20. The fundamental, first-, second-, and third-order cavity modes for this tube were at 2.9, 1.8, 1.2, and 0.9 cm, respectively. The tubes were designed to operate at 2000–3000 volts, 4000–5000 gauss and 30 ma, some in the second-order mode and some in the first-order mode. A catephoretically deposited thoria on molybdenum cathode was employed.

The experimental results on all tubes were of the same general nature, namely: (a) The tube operated very inefficiently in the desired cavity modes. This type of operation was possible only at low currents, and only under very critical conditions of voltage, magnetic field, and particularly cathode temperature. (b) When either the cathode temperature or the anode voltage was raised, the tube would break discontinuously into an undesired state of oscillation characterized by large back bombardment of the cathode, a marked increase in anode current, and a low power broad-band noise output. The back bombardment power was estimated to be at least 10 watts since it was enough to keep the cathode operating without heater power.

The observed noise output was centered at 1.8 and 1.2 cm, the wave-lengths of the first- and second-order cavity modes, with the stronger signal at 1.8 cm. The frequency separation between the half-power points corresponded roughly to the Q of the cavity. These observations were made on a spectrum analyzer; the power was too small to detect with a thermistor bridge sensitive to 25 microwatts. A signal in the fundamental cavity mode would not be detected because the wave guide was beyond cut-off for the wave-length of that mode. To avoid the frequency limitation of the wave-guide output, a special tube was constructed with a coaxial probe electrostatically coupled to the tooth structure and oriented so as to couple to any degenerate modes. No significant differences in the output could be detected. Our interpretation of these observations is that the cavity acted as a filter for noise generated in the interaction space.

To corroborate the fact that the cavity was not supporting this undesired oscillation, a smooth anode magnetron with identical end space and pole piece configuration, but with a solid cylindrical anode replacing the tooth structure, was tested. The same back bombardment phenomena were observed. A careful search was made for radiation coming out of the cathode leads using a horn feeding X-band wave guide, but none could be detected.

Plots of anode voltage *vs.* anode current for the above oscillations were made at magnetic fields from 1200 to 6200 gauss for both the interdigital and smooth anode tubes. They were all similar to the *V-I* curves of a normal cavity magnetron. The curves of voltage *vs.* magnetic field also were similar to the *V-B* curves of a normal cavity magnetron. That is, they were straight lines, approximately tangent to the cut-off parabola. These results held for tubes with a variety of end space configurations, magnetic field distributions, and ratios of anode-cathode radii.

It would appear that a state of oscillation is involved which is primarily a function of the space charge conditions in the interaction space. Since we have not identified any frequency associated with the oscillation, it is difficult to draw any conclusions as to its nature. One supposition is that there is a generation of noise alone. However, one cannot rule out the possibility that the observed signals are noise side bands of a coherent signal. From the linearity between V and B, one concludes that the condition for the oscillation depends upon the angular velocity of the electrons.

The phenomenon of back heating in smooth anode magnetrons has been noted by several authors[2-4] and has generally been attributed to some type of oscillation. There is no completely satisfying explanation available. Using a rising sun design, Columbia Radiation Laboratory[5] has obtained up to 30 watts from K-band magnetrons under roughly the same operating conditions as ours. Their reports briefly mention some back heating effects which probably are due to the same type of oscillation as reported here, but these effects do not prevent normal oscillation in their tubes.

It appears that in the magnetrons we worked with this undesired oscillation is sufficiently pronounced to prevent normal operation of the tube. An understanding of this type of oscillation may be of fundamental importance in the design of low voltage, short wave-length magnetrons.

Some Magneto-Acoustic Effects in Nickel*

T. F. Rogers
Air Force Cambridge Research Laboratories, Cambridge, Massachusetts
AND
S. J. Johnson
Crystal Research Laboratories, Inc., Hartford, Connecticut
June 1, 1950

An investigation has been made of effects produced by a magnetic field upon the ultrasonic propagation properties of certain ferromagnetic substances, of which nickel is reported upon here. A rod of commercially pure—99.4 percent—"A" nickel 45.8 cm long and 1.25 cm in diameter employing a.c.-cut quartz crystal transmitting and receiving transducers, exhibits an "electrical length" of some 170 μsec. when acting as a propagation medium for a short-pulsed, 1-Mc sonic carrier frequency, with the transmitting crystal generating a transverse (shear) wave within the rod. After having been heated to approximately 1600°F, a red heat assuring demagnetization, and allowed to cool slowly to room temperature, 70°F, the rod was subjected to a longitudinal magnetic field throughout its entire length; changes in its physical length were measured directly, while transmission (delay) time and relative attenuation were measured by means of an oscilloscope reproduction of the received pulse, both as functions of the applied field strength.

Figure 1 indicates the change—a decrease—in transverse wave propagation time delay (electrical length) ΔT, relative to the original time delay T, as a function of the field intensity in oersteds. The observed changes in delay of approximately 10^3 times that expected from the magnetostrictive (Joule) effect in nickel can, apparently, only be explained as signifying a marked increase in the acoustic velocity of propagation within the rod while it is under the magnetic field stress.

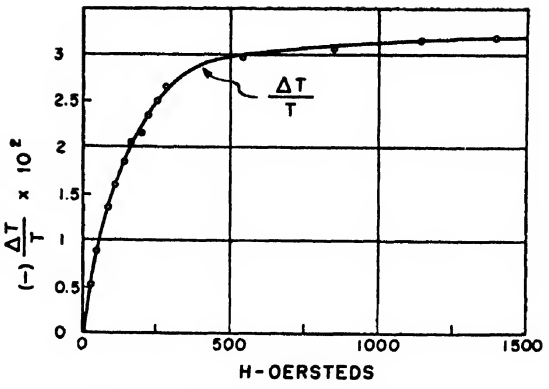

FIG. 1. Some magneto-acoustic effects in nickel.

The velocity of propagation of a transverse vibration is given as:[1]

$$V_t=\left[\frac{\mu}{\rho}\right]^{\frac{1}{2}}=\left[\frac{E}{2\rho(1+\sigma)}\right]^{\frac{1}{2}},$$

where μ is the modulus of rigidity, E is Young's modulus, ρ is the density, σ is Poisson's ratio, and $E=2\mu(1+\sigma)$. With the applied field, the change in density is considered negligible as a factor contributing to the velocity change, since it amounts to a factor of less than 10^{-4}, and, therefore, the increase in velocity must be attributed to a change in the value of the modulus of rigidity; the work of various groups[2] on the variation of E with magnetization (the so-called ΔE effect) would also appear to warrant this conclusion.

A large decrease in attenuation was also noted upon application of the field, with the received pulse increasing in amplitude some 10^2 times its normal value. Figure 2 presents a representative

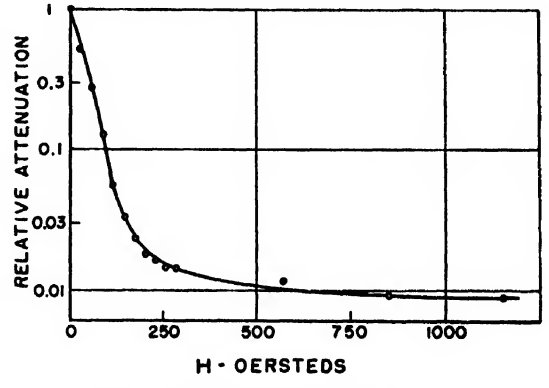

FIG. 2. Some magneto-acoustic effects in nickel.

change in attenuation throughout the transmission system as a function of H with the output pulse taken as unity height for $H=0$. It has been found that, for certain metallurgical conditions of the sample, irregularities are noted in the attenuation *vs.* H curve, with treatment of the rod immediately previous to test influencing the general march of values to a considerable extent. While possibly connected with a reorientation of the nickel crystalline structure, at this time, especially in view of the fact that ultrasonic attenuation effects in solid media are not altogether understood,[3] no adequate explanation of this decrease in attenuation presents itself.

It is planned that work on nickel, as well as other magnetic materials, will be continued and extended. These initial results are presented at this time for reasons of the natural interest in

such originally noted phenomena and in the expectation that this investigative technique will lend itself to a study of acoustic propagation in magnetic media and the structure of the media themselves.

Electron-Microradiography of Electrodeposited Metals

ROLF WEIL AND HAROLD J. READ
Division of Metallurgy, Pennsylvania State College, State College, Pennsylvania
August 2, 1950

IN the course of research on the structure of electrodeposited metals, a new method of examining specimens directly in the electron microscope, without the aid of replicas, was developed. This method is most valuable in the study of the initiation of plating, revealing some features not seen when conventional techniques are employed. As annealed electroplated metals are essentially the same as annealed metals prepared from the melt, the method described here should also be a useful tool in the study of other metallurgical phenomena.

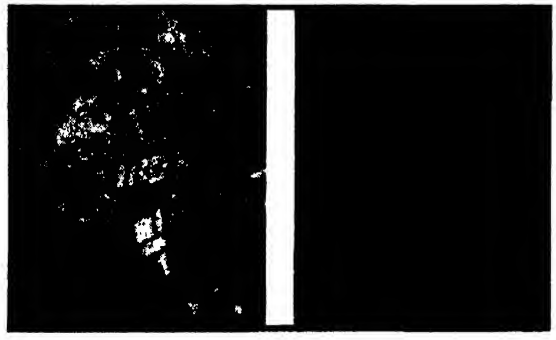

FIG. 1. (Upper left.) Electron-microradiography of electrodeposited nickel on copper. 5000 X.

FIG. 2. (Upper right.) Electron-micrograph from collodion replica of specimen shown in Fig. 1. 5000 X.

FIG. 3. (Lower left.) Electron-microradiograph of electrodeposited nickel on zinc. 5000 X.

FIG. 4. (Lower right.) Electron-micrograph from collodion replica of specimen shown in Fig. 3. 5000 X.

To date, nickel films plated on copper and zinc have been examined. The method of preparing the samples was as follows: The starting cathode was cleaned by the usual procedures for electroplating, and a deposit approximately 5×10^{-4} cm thick laid down. A piece the size of an electron-microscope screen was cut from the plated cathode, and placed in a suitable solvent to dissolve the basis-metal. For nickel-plated copper, a solution of 500 g/l CrO_3 and 50 g/l H_2SO_4 dissolved the copper, leaving the nickel. A solution of five percent by volume of concentrated HCl in water served for dissolving zinc basis-metals. When the original cathode was dissolved, the nickel film was washed and placed on a screen, ready for examination.

The accompanying photographs (Figs. 1–4) show the structures of nickel films deposited on copper and zinc respectively as seen by electron-microradiography and by the collodion replica techniques. The films were deposited under the same plating conditions, thus illustrating the effect of the basis-metal. The direct method resolved the structure far more distinctly than collodion replicas.

For convenience in referring to pictures made by the above technique, we should like to suggest the term "electron-microradiography" so as to distinguish conveniently such pictures from those obtained by the replica technique.

The Limiting Hydrostatic Tension of Water Near 0°C

J. C. FISHER
General Electric Research Laboratory, Schenectady, New York
August 3, 1950

RECENTLY L. J. Briggs has determined the limiting negative pressure in water as a function of temperature.[1] Above 5°C his values are in the neighborhood of 270 negative bars, about 20 percent of the theoretical value calculated from nucleation theory.[2] Below 5°C the limiting tension was observed to drop rapidly with decreasing temperature to a value near zero just above 0°C.

The rapid decrease of limiting tension can be explained in terms of the nucleation of ice under reduced pressure. Assume that ice nuclei form readily and grow when the solid phase is stable, and that ice nucleates the vapor phase. The assumption that ice nucleates water vapor is consistent with the lower solubility of gasses in ice and the tendency of gas bubbles to form at the surface of a growing crystal. Then near 0°C the limiting tension that water will withstand is that required to raise the freezing point to the testing temperature.

A negative pressure of 300 bars raises the freezing point of water 2.7°C, in fair agreement with Briggs' observations. A possible check of the ice nucleation hypothesis would be to determine the supercooling limit of the water at atmospheric pressure. If appreciable supercooling is observed, it is unlikely that ice nuclei form as readily as would be required to account for the decrease in limiting tension.

Local Order in Solid Cu_3Au

R. A. ORIANI
Research Laboratory, General Electric Company, Schenectady, New York
June 5, 1950

RECENT x-ray data by Cowley[1] on Cu_3Au at temperatures above the critical temperature of superlattice formation enable the degree of local order computed from x-ray measurements to be compared with that calculated from thermodynamic

activity coefficients measured by Weibke and Quadt.[3] Such a comparison is of great interest, for this is the first system, to the writer's knowledge, for which two independent sets of data at overlapping temperatures have been obtained from which local order may be computed by two different methods of analysis. This note briefly summarizes calculations of local order at the composition Cu_3Au at 500°C, over 100° higher than the critical temperature of superlattice formation.

1. *X-ray data.*—Cowley's short-range order parameters for the first coordination shell at 405, 460, and 550°C were employed to interpolate the value of $\alpha = -0.142$ at 500°C, since the e.m.f. data for 500°C were used. In Cowley's terminology,

$$\alpha = 1 - (P_{l,m,n}/m_{Cu}), \tag{1}$$

where $P_{l,m,n}$ = probability that the atom with coordinates l, m, n with respect to an Au atom should be a Cu atom; m_{Cu} = proportion of Cu atoms = 0.75 for Cu_3Au. For complete randomness, $\alpha = 0$ so that $P = m_{Cu}$. For perfect order, $\alpha = 1$ for even-numbered shells, and $\alpha = -\frac{1}{3}$ for odd-numbered shells. The experimental value of α, and hence the degree of local order, depends only on the precision of the experimental measurements and on the adequacy of the three-dimensional Fourier analysis of the diffuse background scattering of x-rays. From $\alpha = -0.142$, one easily computes that (a) for Cu at the origin, the average number of Cu atoms in the first coordination shell is 8.55, and of Au atoms, 3.45; (b) for Au at the origin, the average number of Cu atoms in the first coordination shell is 10.3, and of Au atoms, 1.7. Hence, x = the ratio of the number of Au–Au bonds to the total number of bonds = 0.0354, whereas for random distribution $x = 0.0625$. Hence, there are more bonds between dissimilar atoms than the number expected from a random distribution of atoms; the percent reduction of Au–Au bonds from that characteristic of a fully disordered structure is 43.4 percent.

2. *Activity data:* A. *First method.*—From Weibke and Quadt's 500°C e.m.f. data, a smoothed curve of $\ln\gamma_{Cu}$ *vs.* mole fraction of Cu was constructed; the activity coefficients, γ, are referred to pure copper as the standard state. From this curve $\gamma_{Cu} = 0.79$ at 0.75 mole fraction of Cu was obtained. The activity coefficient for gold was calculated as 0.143 by graphical integration of the Duhem-Margules equation.

Takagi[3] has developed a relation between x, the fraction of Au–Au bonds, and ΔF°, the free energy change for the bond reaction

$$\text{Au–Au} + \text{Cu–Cu} \rightarrow 2(\text{Au–Cu}). \tag{2}$$

Birchenall[4,5] independently derived the special case applicable to Cu_3Au, i.e.,

$$\frac{(1-4x)^3}{2x(1+2x)} = 4e^{-\Delta F^\circ/RT}. \tag{3}$$

In order to compute ΔF°, we make use of regular solution theory,[6] relating the activity coefficient of A to the difference between the partial molar internal energy of vaporization of an ideal solution of A in B and that of the pure metal. Following Birchenall,[4] we neglect the volume change in going from ideal to regular solution, and assume as a first approximation that the atoms in the solution are distributed randomly in order to compute the partial molar internal energy of vaporization of the solution. Then,

$$\Delta F^\circ = \Delta\bar{F}_{Cu} + \Delta\bar{F}_{Au} \cong \Delta\bar{E}_{Cu} + \Delta\bar{E}_{Au} = RT(\ln\gamma_{Cu} + \ln\gamma_{Au}),$$

and by use of (3), a value of x is obtained. The whole calculation may be repeated, correcting for the randomness assumed by using this value of x; the second approximation yields ΔF° for reaction (2) = −820 cal./mole of bonds, and x = fraction of Au–Au bonds = 0.0453, representing a 27.5 percent reduction in the number of Au–Au bonds from the number characteristic of randomness. In order to evaluate the kind of variation introduced by an error in the experimental data, the first part of this calculation was repeated using a γ_{Cu} some 3 percent lower than the 0.79 employed above, since this is about the scatter of the data. The value of x thus computed is less than 2 percent larger than that obtained above.

B. *Second method.*—Lo-Ching Chang,[7] using Takagi's development has shown that if there is no volume change on mixing, and if the pairwise energies of the atoms are independent of composition, the heat of solution,

$$\Delta H = (x_{11} - m_1)(v_{11} + v_{22} - 2v_{12}), \tag{4}$$

where x_{11} = fraction of 1–1 bonds, m_1 = mole fraction of component 1, and v = energy of a pair of atoms. Transcribing this into our nomenclature, we have

$$\Delta H = (1/2)Z\Delta F^\circ(0.25 - x), \tag{5}$$

where Z = coordination number = 12. This method of treatment is very similar to that of part (A), since Eq. (5) also makes use of the regular solution approximation. If we use the value of $\Delta H = -1000$ cal./mole obtained from Weibke and Quadt's activity data, and solve (3) and (5) simultaneously, we obtain

$\Delta F^\circ = -816$ cal./mole for reaction (2)
$x = 0.0455$
27.2 percent reduction in the number of Au–Au bonds.

In view of the difficulties of the measurements and the approximations involved in the thermodynamic treatment, the agreement among the three methods is quite satisfactory, and lends confidence to the use of activity coefficients in this manner. A similar satisfactory comparison between x-ray and thermodynamic measurements of local order on the Ag–Au system, though at two different temperatures, has been made by B. L. Averbach reported by C. E. Birchenall.[8]

Formation of Annealing Twins during Grain Growth

R. L. FULLMAN
Research Laboratory, General Electric Company, Schenectady, New York

June 5, 1950

A DOMINANT feature of the microstructures of most annealed metals and alloys with a face-centered cubic crystal structure is the presence of many straight-sided crystals that have a twinned orientation relative to the grains in which they appear. Mathewson[1] proposed that these "annealing twins" form during recrystallization, by lateral growth of "twin faults" produced by the slip process. Carpenter and Tamura[2] found that annealing twins may form under conditions where it appears doubtful that slip could be of importance. They suggested that annealing twins form by accidents of growth when grain growth occurs. Burke[3] found that, during grain growth, annealing twins appear, one boundary at a time, in the corners of growing grains. During continued grain growth the distance between twin boundaries was not observed to change.

The interfacial free energy of the boundary between adjacent grains is a function of the orientation relationship between the grains.[4] During grain growth, changes occur in the identity of a grain's neighbors, and the interfacial free energies of the grain boundaries also change. It is suggested that an annealing twin forms in the corner of a growing grain when the orientation relationships between the twin and the grain's neighbors lead to a smaller total interfacial free energy than do the orientation rela-

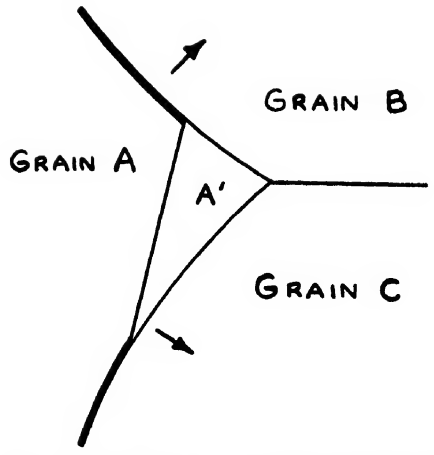

FIG. 1. Schematic representation of the changes in grain boundary free energy associated with the formation of a twin, A', in an infinitesimal region in the corner of a growing grain, A. Grain boundaries with high interfacial free energies are represented by wide lines.

tionships between the grain itself and its neighbors.* A twin boundary then forms in a corner of the grain, and the grain continues to grow as a twin of the original crystal. This could occur at various times during the growth of a grain, when the identity of one or more of the neighboring grains changes. The conditions required for a decrease in free energy may be clarified by reference to Fig. 1, which represents schematically a small region where atoms are being added to the corner of a growing grain, A, and removed from grains B and C. The small arrows indicate the directions of grain boundary migration, and the wide lines indicate boundaries with relatively high interfacial free energy. The free energy will be decreased by formation of a twin, A', in the corner of grain A, if

$$l_{A'B}\sigma_{A'B}+l_{A'C}\sigma_{A'C}+l_{AA'}\sigma_{AA'}<l_{A'B}\sigma_{AB}+l_{A'C}\sigma_{AC}, \quad (1)$$

where l and σ represent the areas and interfacial free energies, respectively, of the boundaries indicated by the subscripts. Annealing twins would form in grain corners during grain growth when the geometry and orientation relationships are such that inequality l is satisfied.

During grain growth the identity of a grain's neighbors may change by several mechanisms. Such changes may lead to the formation of new twins or the removal of existing twins. Details of the mechanism of formation and disappearance of annealing twins, and experimental evidence supporting the theory, will be given in forthcoming papers. Experiments designed to detect the difference in the interfacial free energies of grain boundary segments on opposite sides of twin boundaries newly formed in grain corners indicate that the free energy actually is smaller toward the grain corners. The dependence of the abundance of annealing twins in copper on the preferred orientation and grain size was found to be in agreement with predictions made on the basis of the proposed theory of twin formation and disappearance. The ratio of the interfacial free energy of twin boundaries to that of grain boundaries has been measured in copper and in aluminum. The values found were 0.036 ± 0.006 and 0.21 ± 0.05, respectively. Annealing twins rarely are observed in aluminum. The difference observed in the abundance of annealing twins in copper and aluminum is in accordance with the proposed theory and the difference found in the twin boundary to grain boundary interfacial free energy ratios.

This letter is an abstract of a dissertation presented to the Yale School of Engineering in partial fulfillment of the requirements for the degree of Doctor of Engineering. The investigation was supported by the United States AEC under Contract No. W-31-109-ENG-52.

On Crazing of Linear High Polymers*

C. C. Hsiao and J. A. Sauer
The Pennsylvania State College, State College, Pennsylvania
(Received April 21, 1950)

The effect of various variables, such as type of stress, stress magnitude, duration of stressing, and environment on the initiation and development of crazing in linear polymers is discussed. The basic nature of crazing is investigated in some detail for polystyrene specimens by means of the light microscope, the electron microscope and the x-ray spectrometer. The results of these observations and their bearing on the fundamental group structure of polystyrene molecules is presented.

The relationship between crazing and orientation is discussed, as well as the effect of both of these factors on the mechanical properties. The experimental results are compared, wherever possible, with the previously reported data of other investigators. A short discussion is then given of a theory of crazing from the point of view of the molecular structure of the material.

INTRODUCTION

THE phenomenon of crazing of thermoplastic materials, especially polystyrene, has been under intensive investigation recently by many scientists.[1-5] One of the aims of this research is to discover the cause of crazing and to find methods of eliminating it, if possible. The inception and subsequent growth of crazing are undesirable features that tend to destroy optical transparency and influence the mechanical behavior. Although considerable information is now available on the macroscopic effects of crazing and their relation with other variables such as birefringence, tensile stress, temperature, etc., the basic nature of crazing from the viewpoint of the molecular structure of the material is still not very well understood. It seems advisable, therefore, not only to investigate and record the various external manifestations of this general phenomenon but to examine critically the fundamental nature of crazing from the microscopic and submicroscopic viewpoint. This is the intent of the present investigation which reports the results of observations made with the light microscope, the electron microscope and the x-ray spectrometer. It is hoped that the results of this investigation will aid in providing a better understanding of the crazing of linear high polymers in general.

DEFINITION OF CRAZING AND GENERAL OBSERVATIONS

By "crazing" of thermoplastic materials is meant the development of a state in which the normal optical transparency of the material is reduced. For such thermoplastics as polystyrene or polymethyl methacrylate, crazing may be described in terms of the development of mechanical cracks visible to the naked eye[1] or as a blushing of the material produced by the scattering and reflection of light.[5] Several different patterns of crazing have been observed. Russell[1] has classified them as stress crazing, solvent crazing and combinations of the two. Maxwell and Rahm[4] have likewise reported observations of crazing produced both by application of stress and by solvent action. Sauer, Marin and Hsiao[5] have shown pictures of stress crazing occurring on the fracture surfaces of tension and bending

* This invited paper was presented at the meeting of the Division of High Polymer Physics of the American Physical Society in New York City, February 4, 1950.

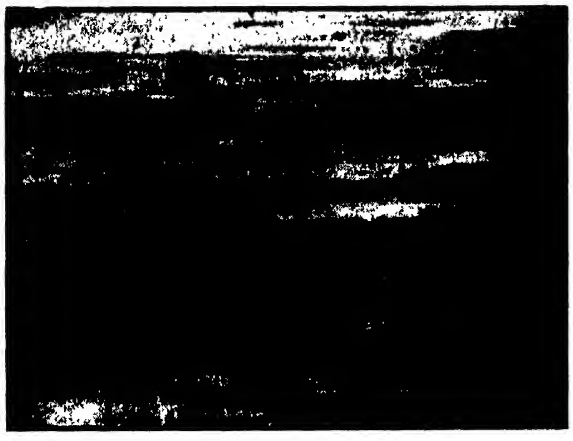

FIG. 1. Crazing cracks in polystyrene.

creep specimens of polystyrene subject to different stresses and different durations of load application. The latter authors have also summarized[5] their observations of the phenomena of stress crazing and interpreted the phenomena observed in terms of changes of molecular structure. It was their feeling that crazing is not merely a mechanical crack phenomenon, although it may be and frequently is closely associated with visible mechanical cracks.

In order to differentiate between these somewhat different descriptions of essentially the same phenomenon, we will consider "crazing cracks" to be the visible cracks produced only after "crazing," in the form of real but submicroscopic discontinuities, has previously come into existence. Crazing may then refer to or be observed in the form of a blushing or haze of a previously transparent material. In other words, crazing is not necessarily actual cracks, but may be some sort of infinitesimal openings which are either still within the field of molecular attraction or are physically prevented by other neighboring molecules from developing into cracks.

The most basic fact about the development of crazing in specimens of linear high polymers subject to load is that the observed crazing cracks are always found to be at right angles to the direction of maximum tensile stress. A microphotograph indicating this behavior for polystyrene is shown in Fig. 1. If, however, the specimen is subject to pure compression rather than tension, no crazing will occur.

Both of the above facts are simultaneously observable when a rectangular specimen is subject to pure bending, as under this type of stress condition one-half of the specimen is subject to tension and the other half to compression. Figure 2 shows two views of a polystyrene specimen which had been continuously subject to a constant bending moment until fracture occurred. The left view clearly shows the absence of crazing on the compression side of the specimen and its strong presence on the tension side. The right view showing the fracture surface reveals on close examination two distinct types of cracks; one type is the fracture cracks which spread radially outward from a more or less point source usually coincident with a flaw, and the second type is the crazing cracks which are seen as normal openings or planes starting from the surfaces of the specimen.

Increase of crazing of polystyrene specimens with increase of time of load application is shown by the six specimens of Fig. 3, each of which was subject to a constant tensile stress varying from 3250 p.s.i. for the specimen on the left to 5500 p.s.i. for the specimen on the right as indicated. The specimens were allowed to remain under these stresses until fracture occurred; for the 5000-p.s.i. specimen the duration of test was very short (minutes), while for the 3250-p.s.i. specimen hundreds of hours elapsed before the specimen failed.

The size, density and depth of penetration of crazing openings depends not only on stress and time but also on the particular material under investigation. For example, it is found that for comparable stress and time conditions, the crazing cracks on the surface of polymethyl methacrylate specimens are usually larger and less dense than those in polystyrene specimens, but at the same time, do not extend inward from the surface as deeply. This latter fact may be due to the

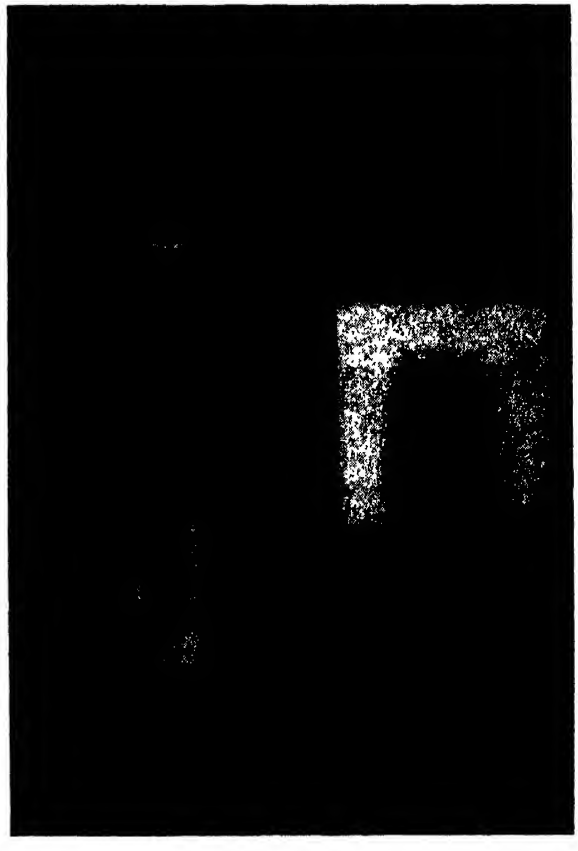

FIG. 2. Bending creep specimen of polystyrene showing crazing along length and on cross section of tension side of specimen.

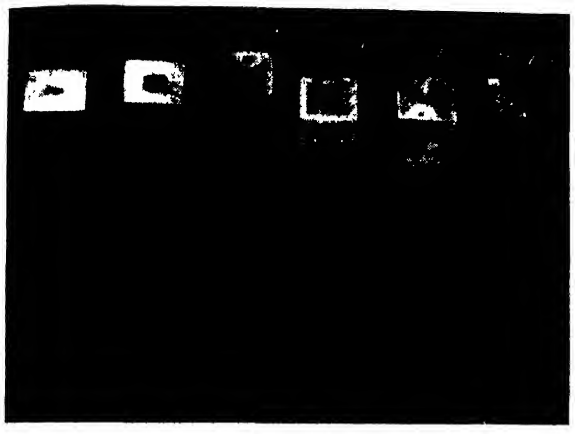

FIG. 3. Fracture surfaces of crazed tension creep specimens of polystyrene subject to different stresses and different durations of load application.

inability of the relatively "brittle" polystyrene specimens to relieve themselves of high local stress concentrations as readily as the more ductile methacrylate specimens.

Another rather interesting observation is that crazing may extend throughout the entire cross-sectional area and yet the specimen can continue to carry load even though reduced in value. This is well shown by the stress-strain curve in Fig. 4 along with that of a standard amorphous polystyrene specimen. While the stress-strain curve of the crazed specimen indicates that it is considerably weaker than the original specimen, it is clear that even the entirely crazed regions of a specimen can carry considerable stress despite the existence of the numerous crazing openings or cracks. The stress-strain curve suggests that the material has been locally oriented due to stretching as the modulus of elasticity of the earlier part of the curve appears to be slightly higher than that of the amorphous material. Above 1500 p.s.i., the crazing openings grow rather rapidly into visible cracks and fracture of the specimen occurs at usual strain values but at lower stress values.

In order to determine whether any similar damage had been done to the apparently non-crazed central portions of a tension creep specimen, the crazed outer portion of the polystyrene specimen was machined off and the remaining central core then subject to tension. The stress-strain curve is shown in Fig. 4 and, on comparison with that of the original amorphous specimen, the change, if any, is seen to be very slight. The modulus of elasticity is slightly higher suggesting that some short-range orientation of the polymer chains might have occurred. Also, a slightly lower ultimate strength might be partly due to the existence of submicroscopic crazing cracks too small to be seen. Both of these effects are, however, small enough to be caused by unavoidable differences between specimens.

In order to find whether compression would be beneficial in eliminating crazing previously produced by tension, a piece of a crazed polystyrene specimen was compressed and released three different times and then tested in tension. Although all the crazing cracks had seemingly disappeared after the third compression, they reopened after tension was applied. The four stress-strain curves are shown in Fig. 5 and the tension stress-strain curve is shown to a larger scale in Fig. 4. While it is clear that the material does not regain completely its original strength, it may be noted that its tensile strength is slightly higher than that of the fully crazed specimen, perhaps indicating that some of the submicroscopic crazing openings have been partially restored thereby providing some additional resistance to loading.

The most noticeable effects of the compressions were the gradual reduction and apparent elimination of the crazing planes and the large increase in ductility.

The effect of the environment on the initiation and development of crazing has been studied by running tensile creep tests on specimens of polystyrene subject

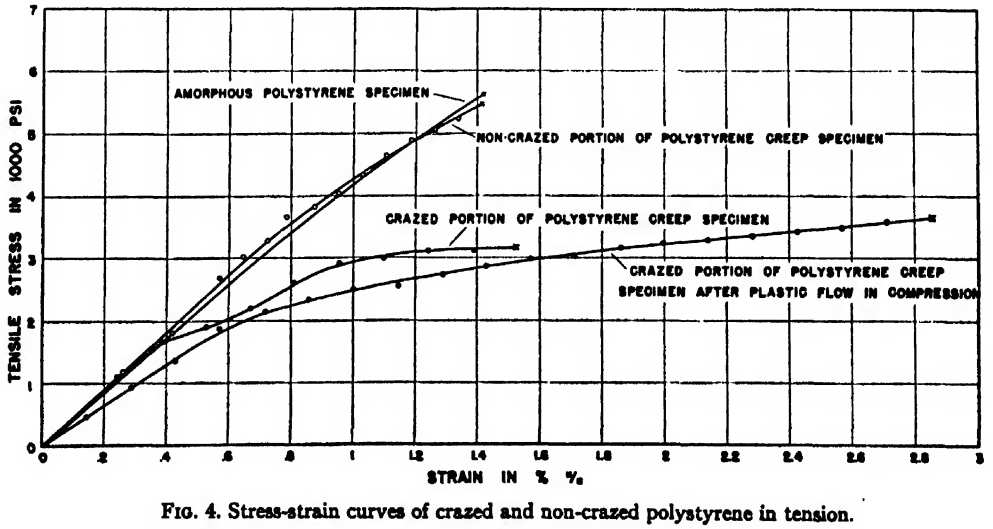

FIG. 4. Stress-strain curves of crazed and non-crazed polystyrene in tension.

to various atmospheric conditions. It was observed that in dry nitrogen, a specimen crazed rather easily and crazing seemed to penetrate deeper than in specimens subjected to the same stress in the ordinary atmosphere (50 percent R.H.). Less crazing was observed for a specimen tested in wet nitrogen. These results seem to indicate that water vapor has a healing effect on cracks that would otherwise open up under the prevalent stress system. This conclusion was subject to additional verification by running one creep test on a polystyrene specimen completely immersed in water. As expected, there was much less penetration of the crazing cracks into the specimen. It was also observed that crazing could be reduced considerably by coating the exterior surfaces of the polystyrene specimen before test. The results were somewhat spotty due probably to the fact that it was rather difficult to get a continuous uniform adherent coating on the square specimen. Nevertheless, the particular coating used, a compound of styrene monomer recommended for attachment of strain gauges to polystyrene specimens, was helpful in reducing crazing.

Crazing can also be produced by action of ultraviolet or x-ray radiation. The effect of the radiation is to cause depolymerization of the material. After the radiation is removed, the material will tend to repolymerize although a fairly long period of time may be required if the temperature is low. On repolymerization, the material will shrink, thereby inducing tensile stresses which in turn will cause crazing cracks to open up at right angles to the stress direction. Since repolymerization is at random, crazing patterns produced by ultraviolet radiation show randomly directed crazing openings or planes and hence are somewhat similar to crazing patterns produced by solvent action.

Although the external manifestations of crazing are now fairly well established for a wide variety of external conditions, little is known about their relation to internal structural changes of the material itself. If crazing could be directly related to elastic or plastic extension of the chain linkages or to tensile or shear deformation between individual chains or to other rearrangements of the polymer chain structure, a major step in general understanding of the phenomena would have been made and would unquestionably lead to fruitful suggestions concerning its elimination.

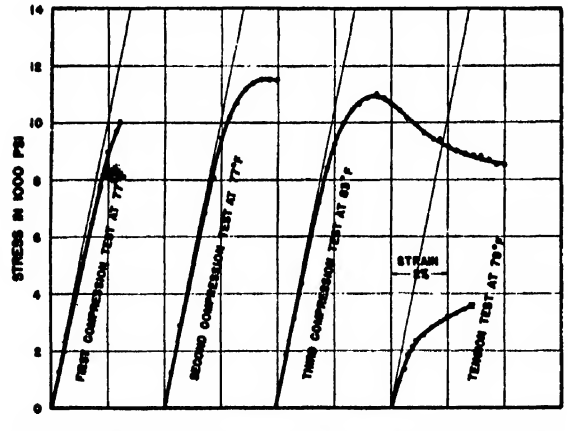

FIG. 5. Effect of compression on the stress-strain curve of crazed polystyrene specimen in tension.

To accomplish the above, the first step would appear to be a careful detailed examination of the crazed and non-crazed surfaces by the best means at our disposal so that whatever changes were present could be detected. This examination is made first visually, then by the light microscope and finally by the electron microscope. In addition, a study has also been made of the crazed and non-crazed portions of the specimen using x-ray diffraction methods. The results of this general examination are now presented.

DETAILED DESCRIPTION OF A PARTIALLY CRAZED POLYSTYRENE SPECIMEN

Lustrex of an average molecular weight between 67,600 and 68,700 was used in this investigation. The stress-strain properties of this material have been described previously by the authors.[5]

The fracture surfaces of tension creep specimens of polystyrene (Fig. 3) subject to different stresses and different durations of load application reveal the dependence of crazing and its growth on the tensile stress magnitude and its duration. The fracture surface is seen to consist of a crazed and a non-crazed portion, the relative amounts of each depending on the magnitude and duration of stress to which each specimen was subjected. The amount of crazing is greater for the specimens subjected to the lower stress levels because the time of load application for these specimens was much greater. The relation between tensile stress and time to fracture appears to be a linear one on a semi-log plot (see Fig. 6).

The specimen at the extreme right of Fig. 3 was loaded at a stress approximately equal to the ultimate strength of polystyrene in tension (~5500 p.s.i.) and hence fractured shortly after application of the load. There is no apparent crazing and no crazing cracks are visible on the fractured surface. The second specimen from the right was stressed at 5000 p.s.i. and hence lasted for some time longer before it failed. The growth of crazing from the edges normally inward toward the center of the specimen is very evident. It may also be noted that the crazing regions are uniformly distributed throughout the total gauge length of the specimen. (This is especially evident when cross-sectional planes other than the fractured surface are examined.) In general, as we go from right to left in Fig. 3, penetration of crazing increases. Meanwhile, the duration of load application also increases in the manner of Fig. 6.

In order to clearly show the difference between crazed and non-crazed material, the fracture surface of a partially crazed specimen of polystyrene was photographed as shown in Fig. 7. This photograph was taken

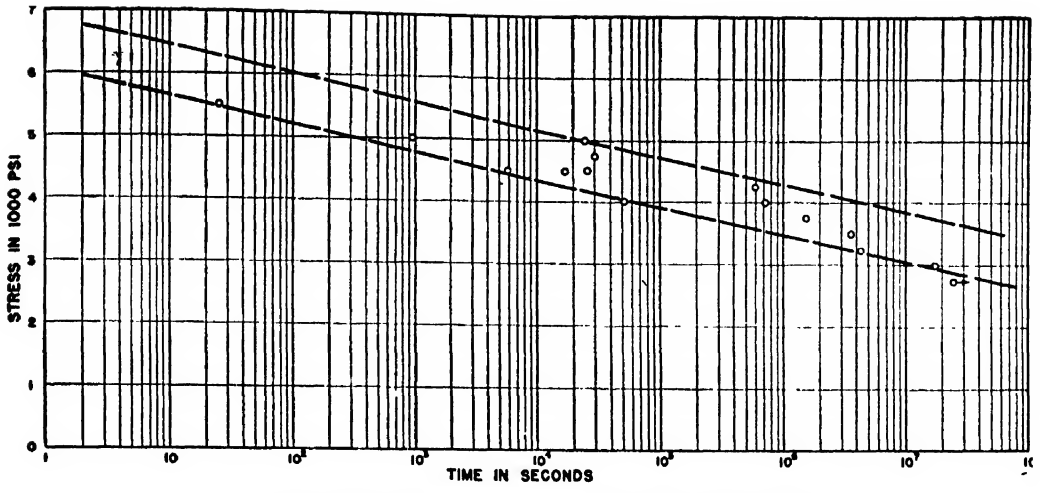

FIG. 6. Effect of tensile stress on fracture time of polystyrene.

by placing the polystyrene specimen against a black background so that the only reflected light would be that coming from the fracture surface. The crazed material along the edges of the specimen is easily differentiated from the centrally located non-crazed material by the smoother, mirror-like appearance.

It should be emphasized that when fracture does occur, the fracture cracks of the material are not the same as crazing cracks and that the source of fracture is usually some flaw in the material and not one of the crazing openings. In Fig. 7, this flaw is located at the center of the smooth circular region. After initiation, the fracture cracks proceed (probably initially at a constant rate) in directions at right angles to the principal stress direction. In Fig. 7, they are seen to extend more or less radially outward from the region in which the fracture first started whereas the crazing cracks are seen to extend normally inward from all edges of the $\frac{1}{2}$ in.$\times\frac{1}{2}$ in. specimen. During the propagation of the crazing and fracture cracks, the effective cross-sectional area of the specimen reduces and hence the tensile stress increases. Accordingly, the molecular rupturing stress is reached at an increasing rate near the neighborhood of the fracture surface. Possibly, the velocity of propagation of the rupture is also increased. Two clear concentric rings just outside the smooth circle indicate that this type of propagation at a varying rate has taken place. Similar phenomena on the fracture of glass have been studied and reported by Smekal.[6]

LIGHT MICROSCOPIC EXAMINATION OF CRAZED POLYSTYRENE

When the fracture surface of a polystyrene tension creep specimen is examined under higher magnifications, there are additional interesting features. Rochow and Rowe[7] have previously reported the characteristic structures of both fractured polystyrene and polymethyl methacrylate surfaces, but did not report on the nature of the crazing regions and surfaces. Under microscopic examination, the blushed or crazed region of Fig. 7 is seen to be entirely different from the amorphous, non-crazed central region. The crazing surfaces are found to be smooth parallel flat surfaces even when examined at a magnification as high as 500×. The flatness of these crazing surfaces as well as their parallel existence throughout the length of the specimens are largely responsible for the high reflectivity of these regions to white light.

Under a magnification of 50×, the fracture surface of a tension creep specimen of polystyrene shows many interesting patterns. Figure 8a is the upper inset of

FIG. 7. Fracture surface of tension creep specimen of polystyrene showing crazed and non-crazed areas and a starting circle from which the cracks are radiated throughout the entire cross-sectional area.

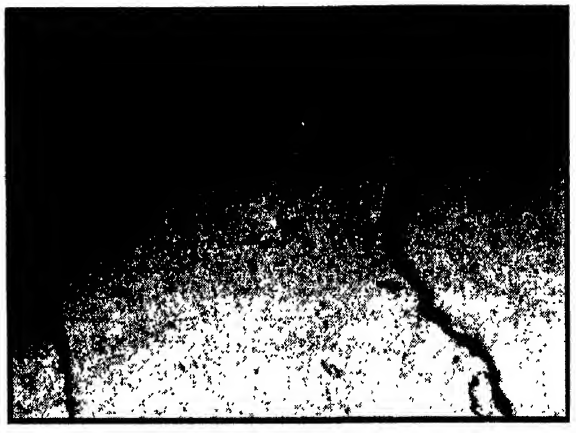

FIG. 9a. Fracture surface of tension creep specimen of polystyrene showing crazed areas and inner structure (upper inset of Fig. 8a).

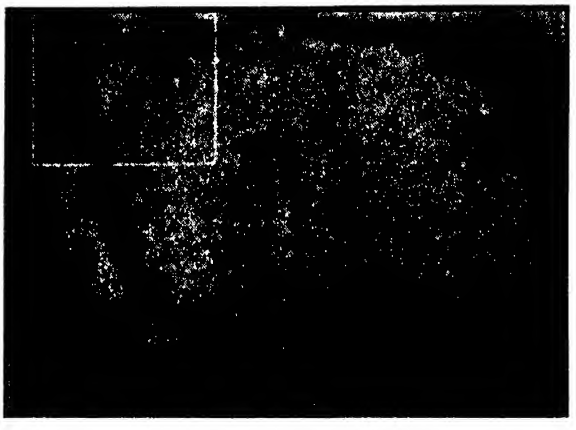

FIG. 9b. Fracture surface of tension creep specimen of polystyrene showing different elevations of crazed areas (lower inset of Fig. 8a).

Fig. 7 which illustrates principally many regions of crazing cracks. These surfaces are quite smooth and reflect white light, if not completely, at least, to a large degree. Both Russell[1] and Maxwell and Rahm[2,4] have made investigations of crazed high polymers with reflected light as the means of determination of the amount of crazing or crazing cracks. It is evident that practically the entire crazed section of a crazed polystyrene specimen can reflect light. The black lines in Fig. 8a are the boundaries of the crazing planes. These planes do not necessarily lie at one elevation as will be seen under higher magnifications later.

The termination of the crazed regions and their juncture with the non-crazed central portion of the specimen is shown in Fig. 8b. The upper white regions are the flat crazing areas separated from one another only by fracture or crazing cracks. The central rupture surface is no longer smooth. As a matter of fact, it is so much different in its elevations that a micrograph at 500× magnification will not show the details of even a very small portion of the texture. Figure 8b shows also,

FIG. 10a. Fracture surface of tension creep specimen of polystyrene showing the connection of edge of the starting circle and the first ring of propagation (left inset of Fig. 8b).

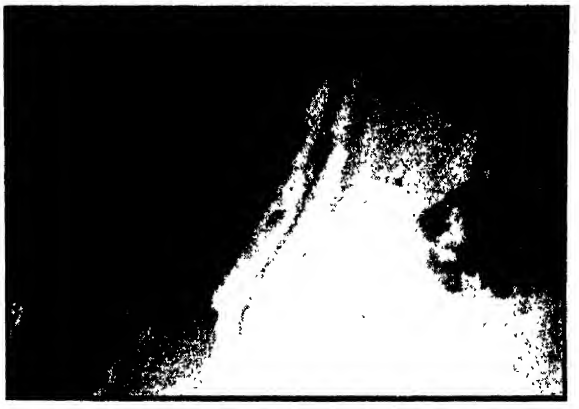

FIG. 10b. Fracture surface of tension creep specimen of polystyrene showing the wavy colored bands occurring inside the starting circle (middle inset of Fig. 8b).

on the right half, part of the smooth starting circle which surrounds the flaw from which the fracture crack propagated. To the naked eye, this circular area is somewhat similar to the crazing area. However, it possesses an entirely different texture. It is a region having needle-like structure with no preferred orientation. Also, to be seen near this region are wavy and continuous lines or contours, indicating the presence of cavities. The clear arc in the middle of this figure is a part of the boundary of the starting circle. Successive rings of propagation are clearly shown in Fig. 8c. As was mentioned before, this is probably indicative of a changing rate of propagation of the crack that continues until failure of the total cross section of the specimen takes place.

The previous pictures have indicated that the surface of the crazing crack is different from that of the rupture crack originating from a flaw. This difference is even more strikingly illustrated by the higher magnification pictures of Figs. 9 and 10. Figures 9a and 9b two are pictures of the surfaces of the crazing areas. In these crazing planes, rather fine structure of the crazing surfaces shows that the smooth mirror-like surface is not a flat plane. Figure 10a shows the fracture surfaces in the region mostly bounded by the first ring of propagation. Figure 10b shows the enlarged cavity and the fine structure in the bottom of the cavity. In Fig. 10c the needle-like structure of the inside region of the starting circle is shown. This structure is somewhat similar to crazing patterns that are induced either by absorption of solvent vapor or by radiation depolymerization. Such patterns likewise show random orientation of the crazing openings. It should be noted that these cylindrical needles or openings are distributed at different elevations, whereas the fine structures on the surface of stress crazing cracks such as those shown in Figs. 9a and 9b are essentially located on one single plane. This latter fine structure is more clearly revealed by still higher magnifications such as Fig. 11 showing the inset of Fig. 9b.

ELECTRON MICROSCOPE EXAMINATION OF CRAZED POLYSTYRENE

In order to show the fine structure of crazed material still more clearly, electron micrographs were prepared. The results of both silica shadowed and beryllium shadowed crazed surfaces of polystyrene show similar structure. Here, only the electron micrograph of a beryllium shadowed crazed fracture surface is illustrated as shown in Fig. 12. This picture apparently correlates very well with Fig. 11. The double lines probably indicate the difference in elevations between two crazing planes. The order of the elevation in this particular picture is about two-tenths of a micron. The smoothness of the crazing surface is estimated to be less than one-tenth of a micron.

It is difficult to obtain a definite interpretation of this picture in terms of the polystyrene molecular structure. Are the small circles, for example, the end views of a group of parallel polymer chains? Under the same conditions of preparation, occasionally figures of the

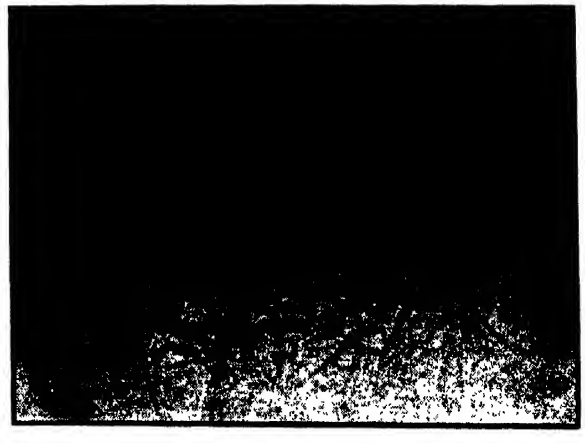

FIG. 10c. Fracture surface of tension creep specimen of polystyrene showing the needle-like structure occurring inside the starting circle (right inset of Fig. 8b).

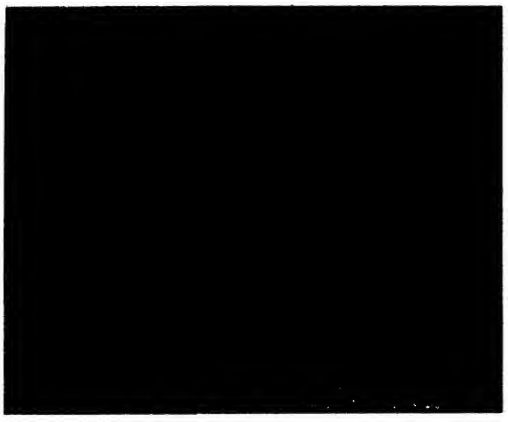

FIG. 11. Fracture surface of tension creep specimens of polystyrene showing the fine structure of crazed area at different elevations (inset of Fig. 9b).

type of Fig. 13 are obtained. Are these pictures of the inverse surface of Fig. 12 or do they indicate the existence of local regions or domains bounded by networks? In contrast to Fig. 12, showing a crazed surface of polystyrene, a molded surface of the same material was also recorded as shown in Fig. 14. This molded surface is perpendicular to the crazing surface. Many fine scratches are shown and the central breakage of the beryllium film may possibly indicate one of the actual large crazing cracks.

In addition to the electron-microscope pictures of the molded and fractured surfaces of solid polystyrene specimens, several additional electron-microscope pictures were taken of oriented polystyrene film. This was done both because the crazing properties of polystyrene are believed to be closely associated with orientation and also to provide some knowledge of the physical behavior of long-chain molecules under their natural configurations. The film was obtained by first dissolving the resin in a solvent and then allowing a drop of the solution to fall into water. As the drop comes back

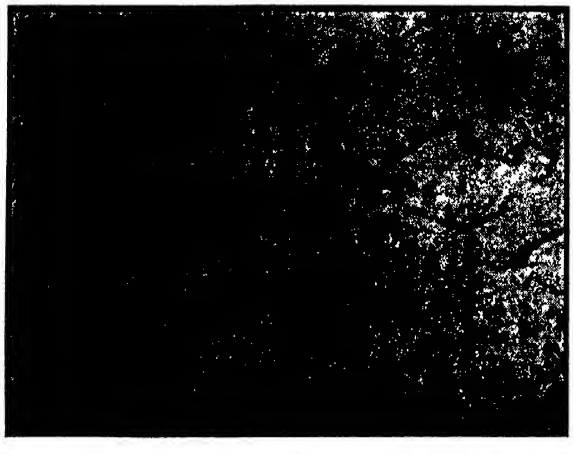

FIG. 12. Electron micrograph of beryllium shadowed crazed polystyrene showing crazing surface at various planes.

FIG. 13. Electron micrograph of beryllium shadowed crazed polystyrene showing crazing surface with various regions of domain structure.

to the water surface, it spreads out radially, the solvent evaporates and the plastic film is left behind on the surface of the water.

Figure 15 is an interesting picture of polystyrene film obtained by dropping polystyrene ethyl bromide solution on a cold water surface. This picture does seem to show the possible existence of domains bounded by networks and hence this type of structure may be the proper interpretation of Fig. 13. Since the formation of domains of polystyrene molecules is probably a very temperature dependent phenomenon, somewhat more striking results might be expected if the ethyl bromide polystyrene solution is dropped in hot water rather than cold. Such indeed is the case. Fig. 16 shows the electron micrograph of polystyrene film when prepared in this manner. This interesting picture reveals the

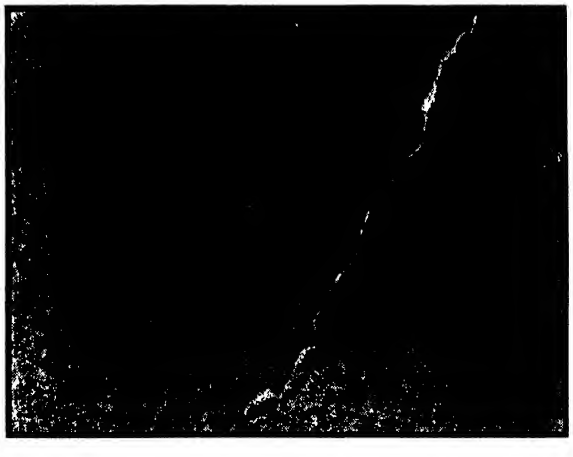

FIG. 14. Electron micrograph of beryllium shadowed polystyrene surface (perpendicular to crazed surface) showing various scratches on the molded surface.

tendency of the material to agglomerate in the form of rods or long slender domains. The picture shows two layers of rodlets both of which are oriented in one general direction. The proper interpretation of this picture is not yet well established but the cylindrical rods are quite possibly more or less parallel pencils of long chain molecules.

The technique employed in the preparation of an oriented film of polystyrene molecules under their natural configurations is briefly described as follows. A drop of dilute polystyrene ethyl bromide solution was dropped in hot water from a position a few inches above the water level. The solution droplet went into the hot water and was heated up before it came back to the water surface. As soon as the solution droplet came out of the water surface, it spread out radially and the polystyrene molecules formed a thin film on the water surface while the ethyl bromide evaporated away. The concentration of the polystyrene ethyl bromide solution varies depending upon the rate of evaporation of this solution. An approximate figure is a few percent of polystyrene by volume in ethyl bromide. The temperature of the hot water is not critical either. For polystyrene, around 80 degrees C, which is the second-order transition temperature of polystyrene, is desirable.

Under this kind of technical treatment, both uniform film and film as shown in Fig. 16 can be obtained. On the basis of this figure and the previous discussion, several generalizations concerning structure may now be attempted:

(a) Under certain conditions, polystyrene molecules can be grouped together as slender domains, (b) It is possible to orient these domains in one general direction, (c) Macroscopic fine structure of polystyrene domains may be observed.

However, there are still many interesting phases which are not understood and need further study. For instance, what is the relationship between the volumetric energy and the surface energy of each domain? Would these domains of polystyrene be present if mercury or other substance was used instead of water, as water molecules are of strong polar groups?

Now, let us consider the size of these rodlets or domains and how they compare with the length of the polymer chains. Figure 16 shows a section of the film magnified some 19,000 times so that a distance of 2 cm would correspond to about 10^{-4} cm or 1 micron. Most of the rods appear to be of the order of 1 micron in length and perhaps one-tenth of a micron in thickness. Now, in polystyrene the primary bonds are C—C bonds having a distance l between them of 1.54A and an angle α between the valence bonds of 109°. The maximum length of an extended chain is then given by[8]

$$L_{\max} = Nnl \sin(\alpha/2),$$

where N is the number of monomer units and n is the number of bonds per unit. For polystyrene, the extended

[8] E. Guth and H. M. James, Ind. Eng. Chem. 33, 624 (1941).

FIG. 15. Electron micrograph of polystyrene film formed by dropping polystyrene ethyl bromide solution on top of cold water surface showing large domain structure.

length of the polymer chain is of the order of 1.6×10^{3}A, or roughly $\frac{1}{6}$ of a micron. Thus, the length of the rodlets is approximately four to six times the length of the polymer chains. The width of the domains is, on the other hand, some 100 times larger than the approximate distance across adjacent chains (10A) and hence if the domain is interpreted as a large conglomeration of more or less parallel chains, it should contain several thousand or more depending on how closely they are packed.

In the polymerized solid state rather than in film form it may well be that the individual long-chain molecules of polystyrene are not arranged in this fashion although this type of structure has been suggested and the polymer chains treated as long rods.[9,10] Regardless

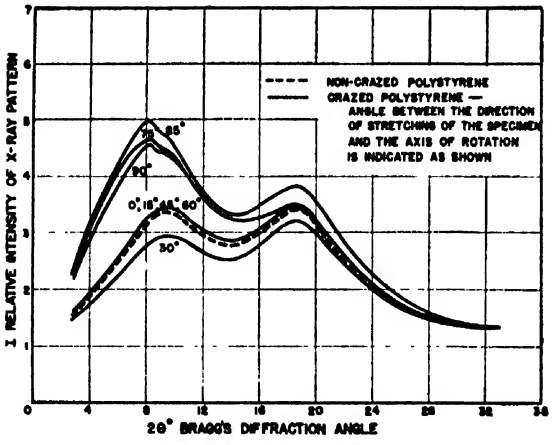

FIG. 17. X-ray photometer curves of crazed polystyrene.

of this situation, Fig. 16 reveals that the natural configuration of polystyrene molecules, at least under certain environments, is one of more or less oriented, intertwined cylindrical domains. Before additional generalizations concerning structure are attempted, results of x-ray investigations of the structure of crazed and non-crazed material will be discussed.

X-RAY INVESTIGATION OF CRAZED AND NON-CRAZED POLYSTYRENE

Both crazed and non-crazed polystyrene samples have been subject to x-ray and electron diffraction examination. The diffraction picture[6] reveals that polystyrene is amorphous in structure. Very little information can be obtained from this picture except to note that the existence of the two somewhat diffuse rings is indicative of the existence of two spacings in some fairly definite regular pattern. Since only one of these rings (the outer one) appears in x-ray pictures of the monomer the other is characteristic of the polymer and may represent either chain to chain spacing or else link to link spacing.

If, however, the x-ray spectrometer is used to obtain intensity measurements, the results indicate a variation of the intensity of the diffracted rings and a shift of the peak of the inner ring or polymerization ring (see Fig. 17). If the peaks indicate some characteristic spacings of the C—C chains, the variation of these spacings with angle is shown in Fig. 18. This shift of the peaks and the variation of the intensity of the diffracted ring for different directions of the axis of rotation relative to the direction of stretching indicate the existence of orientation and "crystallization" of the material.[5,11,12] It should also be noted that no such indications of orientation are found if the non-crazed portions of a specimen are examined by means of the x-ray diffraction.[5]

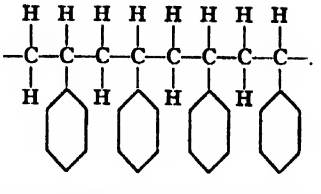
CRAZING AND MOLECULAR STRUCTURE

In the preceding sections, the results of light microscope, electron microscope and x-ray examinations of crazed and non-crazed polystyrene material, as well as of some naturally oriented polymeric film, have been presented. The studies were made on polystyrene or polymethyl methacrylate specimens which had been permitted to craze under the action of stress and time. The crazed material is found to consist of very fine, very smooth more or less parallel openings lying in planes at right angles to the principal tensile stress direction. For a given magnitude and time duration of stressing, the size of the openings and their density varies with the particular polymer under consideration. The openings are finer and much more dense for polystyrene than for methyl methacrylate. Crazing as such is not confined to these two materials, but probably occurs in all linear polymers. It is visible, however, only in transparent materials.

The studies also show that there are differences in orientation between the crazed and non-crazed portions of a linear polymer, although these differences are slight when the crazing is produced by long-time loading at room temperature conditions. There seems also to be some evidence supporting the view previously presented[5] based on observations of behavior of linear polymers under various types of mechanical testing, that polystyrene molecules, at least under certain environments, may group together in more or less cylindrical domain form, with the various long-chain molecules essentially parallel to one another within the domain. The molecular forces across these groups of chains are probably not very large and the precise configuration will depend on which structure gives the minimum free energy. The polymer chains are held together by secondary van der Waals forces and possibly by some side group interlocking.

EFFECT OF DOMAIN STRUCTURE ON CRAZING

Many of the facts pertaining to the inception, growth, and location of crazing and crazing cracks in polystyrene seem to be explainable in terms of orientation and the separation of domains of polystyrene molecules under the action of tensile stress. Consider first the accepted chemical structure of the polystyrene molecule. It is a series of styrene monomers arranged regularly in the following manner



Because of the presence of the large benzene rings around the main C—C chains, it is difficult for these chains to slide in the longitudinal direction of the chains.

However, it should be relatively easy to separate parallel chains by pulling them in their perpendicular directions. It may also be possible under the action of stress for one domain to separate and form several shorter domains if the original domain is many lengths longer than the average length of the long-chain molecules.

The styrene polymer presumably possesses no unused valence bonds except possibly at chain ends. Thus, there are essentially no primary bond linkages across polymer chains and hence the only forces across chains should be relatively weak non-valence or van der Waals London type forces.[13] These forces may be sufficiently large to maintain a rod-like structure when no external forces are acting but under applied transverse tensile stress the polymer chains within the rods would tend to separate from one another. Other evidence that the polymer of styrene is of a thread-like structure arises from consideration of its Raman spectra.[14]

When material having a randomly directed domain type of structure is placed under tensile stress, the various domains tend to orient themselves according to the state of stress applied. Those which are perpendicular to the direction of applied stress will theoretically not be able to orient and in virtue of their weak transverse holding power will open under the action of applied stress. Along the external surfaces of the material these openings will grow more easily than those in the inside, both because of stress concentrations arising from the existence of surface flaws and also because the restrictive force fields of neighboring domains of molecules will probably be somewhat less for domains located on the open surface. When these openings become sufficiently large (many times the dimension of the wave-length of light), they are seen as macrocracks by the naked eye. However, long before the openings become large enough to be individually seen, and when still in the form of microcracks or submicroscopic openings, they may still have the ability to reflect light.[15] In other words, these openings may be sufficiently numerous and sufficiently regular in their general orientation pattern to cause a large proportion of the light striking them to be reflected. Crazing is then evident in the form of surface blushing rather than visible cracks.

When a rigid linear polymer is subjected to tensile stress at room temperature, the tendency of the original randomly directed domains to orient is greatly restricted by the internal molecular interactions of other groups and chains. If, however, the applied stress is high and is maintained for some time, the domains originally

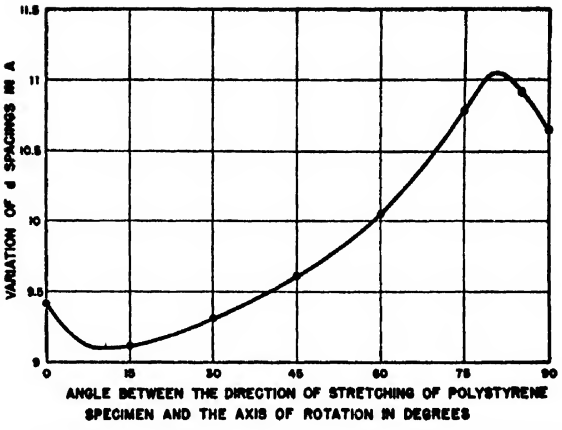


FIG. 18. Variation of polymerization ring of crazed polystyrene.

directed at right angles to the direction of stressing will open up and will initiate the phenomenon of crazing. It is usually possible for many crazing cracks to occur before fracture because the micro-openings soon run up against other domains or groups of molecules not so favorably oriented for separation and then they are automatically halted. A somewhat similar view of the development and growth of crazing cracks has been presented by Maxwell and Rahm.[4]

The mechanism of crazing is now becoming more apparent. Domains or groups of molecules which are at right angles to the applied stress open up first but do not immediately produce failure or a fracture crack as we might expect from prior knowledge of the behavior of brittle materials because they soon run into domains of regions not so oriented. On the submicroscopic or even microscopic scale, the material is by no means homogeneous and the crazing planes are stopped by irregularities in the orientation pattern very much like slip lines in metals are stopped by crystal boundaries lying between differently oriented crystallites. The flatness of the crazing surface (see Fig. 9a) suggests a slow propagation of crazing caused mainly by the joining together of the many microscopic openings induced by separation of the properly oriented domains of the material in their longitudinal directions. The difference in elevation of crazing planes, noted to be about one-fifth of a micron in Fig. 12, is of the same order of magnitude as the extended length of a polymer chain and serves as an indication of the distance the microcrack can extend without running into differently oriented domains.

EFFECT OF ORIENTATION ON CRAZING AND STRENGTH

The effects of orientation on crazing and strength are intimately tied in with the effects of molecular structure. When groups of molecules tend to join together to form domains, it is the opening up of those groups oriented more or less at right angles to the direction of stressing that initiates the development of microcracks or crazing.

[13] A. E. Van Arkel, *Molecules and Crystals* (translated by J. C. Swallow) (Butterworths Scientific Publications, London, and Interscience Publishers, Inc., New York, 1949), Chapter IX.
[14] H. Mark and R. Raff, "High Polymer Reactions, Their Theory and Practice," *High Polymers* (Interscience Publishers, Inc., New York, 1941), Vol. III, p. 73.
[15] S. W. Hawkins and R. B. Richards, J. Polymer Sci. IV, No. 4, 515 (1949).

Also, since the domains can carry considerable stress in their longitudinal direction but only very little stress in the transverse direction, it is clear that the orientation of the domains will greatly affect the strength properties of the polymer.

In general, two kinds of orientation concern us, differing greatly in degree. One is orientation produced by hot stretching and the other by cold stretching. Hot stretching is usually carried out above the second-order transition temperature and only a very small force is required to stretch the material to thousandths of percent of its original length. Evidently, above the second-order transition temperature, thermal agitation energy is great enough to overcome the secondary attractive forces which hold the various polymer chains in more or less tight formation. These chains are then free to slide past one another as well as to orient in the direction of the applied tensile stress. It is thus to be expected that exceedingly large percentages of orientation (in terms of original length) can be produced when the stretching is done at these high temperatures. If the previous picture of the development of crazing is correct, it is also to be expected that when tensile stress is applied in the direction of orientation to specimens previously oriented to some great degree (~1000 percent), crazing, as such, should be absent. This is so because the specimen will no longer contain domains oriented at right angles to the tensile direction and hence no separation of domains is to be expected. Fracture, when it occurs, should be of the fiber type.**

For cold stretching at ordinary room temperature, only little orientation occurs prior to fracture. In polystyrene specimens, failure occurs at a strain of approximately 1.45 percent in./in. and hence only local short range orientation can be accomplished. Somewhat greater orientation might be expected from relatively slow creep tests but even here in terms of percent increase over original length about 1.5 percent seems to be the maximum obtained.

Evidently, the restrictive force fields of neighboring molecules are too great at room temperatures to allow much orientation. That which does occur is also not homogeneous over the entire cross-sectional area of the specimen. On the outside regions of the specimen where surface flaws and the growth of microcrazing cracks affect the stress distribution, x-ray evidence indicates that more orientation takes place than in the central non-crazed portions of the specimen.

The effect of orientation of groups of molecules on strength is a problem which should be susceptible to statistical treatment. It might also be used to check the concept that the polymer molecules are usually grouped together in the form of cylindrical domains bonded together by long-range intermolecular forces with the

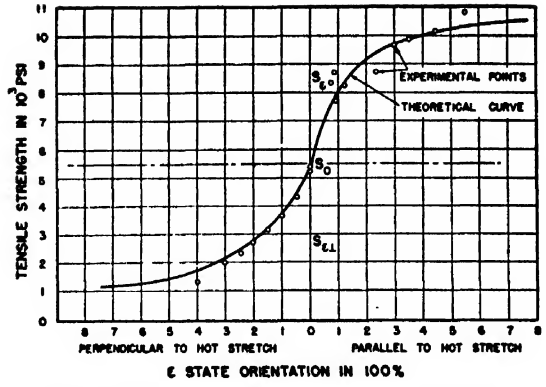

FIG. 19. Effect of uniaxial orientation on ultimate strength of polystyrene.

long chain molecules more or less parallel in each individual domain. For an amorphous polystyrene specimen, these domains of the polymer molecules are randomly oriented. The ultimate strength of this material tested at 77°F±2°F, 50 percent R.H. with the rate of straining 20×10^{-6} sec.$^{-1}$, has been determined experimentally to be approximately 5400 p.s.i. The ultimate strength of oriented material can be shown mathematically to be[16]

$$S_\epsilon = 2\frac{(1+\epsilon)^{\frac{1}{2}}}{1+(1+\epsilon)^{\frac{1}{2}}}S_0, \tag{1}$$

where S_0 is the strength of this material without any preferred orientation, ϵ is the measure of the unit strain in the direction of orientation, and S_ϵ is the ultimate strength of this material oriented at a unit strain change of ϵ in the direction of orientation. When $\epsilon\to0$, S_ϵ is seen to approach S_0 as $(1+\epsilon)^{\frac{1}{2}}/[1+(1+\epsilon)^{\frac{1}{2}}]$ approaches $\frac{1}{2}$. It can also be shown that for the material with perfect orientation in one direction, i.e. $\epsilon=\infty$, S_ϵ approaches $2S_0$ since the expression

$$\left[\frac{(1+\epsilon)^{\frac{1}{2}}}{1+(1+\epsilon)^{\frac{1}{2}}}\right]_{\epsilon\to\infty} = 1.$$

This condition as well as Eq. (1) in general seems to be in satisfactory agreement with experimental studies of oriented polystyrene made by Bailey[17] and hence seems to lend further support to the domain concept of molecular structure.

If oriented material is tested in tension in the direction perpendicular to the direction of orientation, the statistical treatment is somewhat more complicated. The expression found for the ultimate strength is[16]

$$S_{\epsilon\perp} = 2\frac{(1+\epsilon)^{\frac{1}{2}}}{(1+\epsilon)^{\frac{1}{2}}-1}\cdot\frac{2}{\pi}[K-E]S_0, \tag{2}$$

** These observations are in accord with the work of Bailey (see reference 17). Dr. Dietz informs us that similar observations have been experimentally noted in tests on highly oriented polystyrene specimens made at the M.I.T. Plastics Laboratory.

[16] C. C. Hsiao, "Effect of Uniaxial Orientation on Strength and Crazing of Some Linear High Polymers." (It is hoped to submit this paper for publication elsewhere in the near future.)

[17] J. Bailey, India Rubber World 118, 225 (1948).

where K and E are the values of Legendre's complete integrals of the first and second kind respectively. The value $S_{\epsilon\perp}$ varies from S_0 to 0 as ϵ varies from 0 to ∞.

Both Eqs. (1) and (2) for the strength parallel and perpendicular to the stretching direction are plotted in Fig. 19 for various values of percent stretch. It is seen that the predicted results and the experimental results previously reported by Bailey[17] are in good agreement. Small discrepancies that exist between the theoretical and experimental results may be due to differences in rates of straining applied to the specimen.[18]

The general principle employed in the development of the mathematical theory of the effect of orientation on the strength properties of polystyrene is that a domain can contribute its full strength in essentially only one direction, i.e., the direction of its length. Thus, the strength of a linear high polymer is not uniformly distributed from the microscopic point of view. The strength of the material depends upon the orientation of the domains. When stress is applied, some of the unfavorable oriented domains will open up while the more favorably oriented domains will carry the load. The micro-openings gradually grow and join together particularly if the stress is applied for a long period of time. For reasons mentioned previously, they usually start first on the surface and then propagate from the surface of the material toward the center. When they become sufficiently large and numerous enough to noticeably reflect visible light, crazing is said to have occurred.

CONCLUSIONS

A considerable amount of evidence is now available to draw the general conclusion that crazing is an actual mechanical separation of polymer chains or groups of chains under the action of tensile stress. The stress system need not be external as crazing can be produced by internal stresses caused by shrinkage, absorption, radiation, or combinations thereof. Even when the proper stress conditions are present, however, the separations may be too small to be seen either by the naked eye or by a high powered light microscope. The phenomenon of crazing is probably common to many solids other than transparent linear high polymers but, if the material is not transparent, crazing is not observed.

Crazing usually starts on the surface in a region where the polymer chains are oriented at right angles to the direction of applied tensile stress and then gradually penetrates inward. Crazing will not occur if the material is fully oriented in the direction of stretching and it can be reduced for randomly oriented materials by means of suitable surface coatings. Crazing, or even visible crazing cracks, will not necessarily produce fracture but will reduce the total load the specimen can carry. Compression tends to close existing crazing openings and to partially heal them but cannot restore the material to its former state.

For polystyrene, many of the facts pertaining to crazing are explicable in terms of orientation of molecular domains containing many polymer chains held together in more or less parallel fashion by secondary forces. The same type of structure seems to provide a satisfactory model for calculating the effect of orientation on the strength properties of the material.

End-Cooling of Power Tube Filaments*

JOHN W. CLARK** AND RALPH E. NEUBERT†
Research Division, Collins Radio Company, Cedar Rapids, Iowa
(Received February 24, 1950)

The differential equation defining the relation between temperature and distance in that portion of a vacuum tube filament which is cooled by both conduction and radiation is formulated. This equation has been solved by numerical integration; the results are presented as a set of universal curves in a form convenient for use in vacuum tube design. The calculations agree well with some experimental measurements which were made to verify the theory.

INTRODUCTION

IN conventional power tube design the end cooling of the filaments by their supports is not particularly important and is usually treated by simple approximate methods.[1] This is due to the fact that the filaments in such tubes are very long compared to their diameter, so the power lost by conduction is much smaller than that radiated. Power tubes intended for use at very high frequency must have their filaments not too long as compared with the shortest wave-length at which they will be operated; accordingly as the radio industry continues to demand more power at high frequency the tube designer is forced to use correspondingly short filaments in which conduction cooling cannot be neglected.

This paper presents a method for designing the end portion of a filament so that the temperature distribution in that portion of the filament affected by conduction can be readily determined. The solutions are presented as a family of universal curves for convenience in design work. While this method is intended primarily for use in connection with the design of short filaments, it may be used for filaments of any length.

FORMULATION OF THE PROBLEM

In order to fix the ideas, let us first consider the simple case of a filament of cross section area A, perimeter P, and resistivity ρ which is cooled by radiation only. Then in any incremental length of filament the power lost by radiation must equal the Joule heat developed in that same increment of length by the current passing through it. That is

$$I^2R=I^2(\rho dx/A)=P\gamma dx, \tag{1}$$

where I is the current passing through the filament and γ is the radiation coefficient, i.e. the number of watts per square centimeter radiated by the filament. The equation is set up in terms of P, the perimeter, so it will apply regardless of the shape of the wire. It is convenient to write this equation in terms of the current density $J\equiv I/A$, and of a shape factor $F\equiv P/A$. In terms of these new variables,

$$J^2\rho=F\gamma. \tag{2}$$

This simple equation determines the operating temperature of a radiation-limited filament. Ordinarily it is required to determine the current to produce a given temperature in a wire of given cross section. Since both ρ and γ are known as functions of temperature for any material which might be used to construct a filament, it is a straightforward matter to solve the problem.

Let us now consider that portion of the wire which is so close to the support that it is not at uniform temperature. This portion of the wire will lose heat both by radiation and by conduction. Figure 1 defines the geometry of the problem. The heat carried across a boundary at x must be the difference between the Joule heat generated and the heat lost by radiation between x and 0. The point $x=0$ is defined as the value of x where $dT/dx=0$. Beyond this point, radiation alone suffices to carry away the I^2R heat, as formulated in Eq. (2). This energy balance can be formulated in the following equation, letting K be the coefficient of thermal conductivity:

$$\int_0^x \frac{I^2\rho(T)}{A}dx-\int_0^x P\gamma(T)dx=AK(T)\frac{dT}{dx}. \tag{3}$$

Rewriting (3) in terms of current density and shape factor, we have the fundamental integro-differential equation of temperature distribution in a filament cooled by both conduction and radiation:

$$\int_0^x J^2\rho(T)dx=\int_0^x F\gamma(T)dx+K(T)\frac{dT}{dx}. \tag{4}$$

Now $\rho(T)$, $\gamma(T)$, and $K(T)$ are all known functions of temperature. Accordingly we can differentiate (4) to get it in the form of a second order differential equation:

$$J^2\rho(T)=F\gamma(T)+K(T)\frac{d^2T}{dx^2}+\frac{dK(T)}{dx}\frac{dT}{dx}. \tag{5}$$

The remainder of this paper is concerned with obtaining solutions of Eq. (5).

[1] L. R. Koller, *The Physics of Electron Tubes* (McGraw-Hill, Book Company, Inc., New York, 1937), pp. 89–91.

SOLUTION OF THE TEMPERATURE EQUATION

The formal solution of Eq. (5) is

$$x(T)=\int_T^{T_H}\frac{K\,dT}{\left(\int_T^{T_H}2K(J^2\rho-F\gamma)dT\right)^{\frac{1}{2}}}. \qquad (6)$$

The solution of Eq. (5) is outlined in Appendix A.

Since ρ, γ, and K are all known functions of temperature, it is in principle possible to evaluate the integrals in (6) for any case of interest. This is a very laborious process and hence it is useful to calculate a set of generalized curves which can readily be used in any particular case.

The only metal for which detailed data are available for values of electrical resistivity, thermal conductivity, and specific radiation over the temperature range of interest is tungsten. Fortunately this is the metal most likely to be used for a power tube filament.

Equation (6) has been solved by numerical integration using the known values of the physical properties of tungsten. The numerical integration was performed by the Computations Group of the RAND Corporation, Santa Monica, California. This assistance is gratefully acknowledged.

The method used in the numerical integration is given in Appendix B. The results were computed with the aid of an auxiliary function K^* defined by the following equation:

$$x(t)=(10^4/J)K^*(t, t_H, \alpha), \qquad (7)$$

where t is temperature measured in kilo-degrees centigrade and the parameter α is the shape factor F divided by the square of the current density in amperes per square centimeter. That is

$$\alpha\equiv 10^6F/J^2. \qquad (8)$$

These calculations enable one to predict the temperature distribution in a tungsten filament in the range of interest in typical power tubes. Typical curves are shown in Fig. 2 for one specific case. The agreement between calculation and experiment is quite gratifying.

One is frequently interested in the distance from the cold filament support to the point where radiation cooling becomes controlling, rather than in the detailed variation of temperature up to this point. This point has previously been identified as the point where $T=T_H$; it is here that dT/dx vanishes and the useful part of the filament (as far as electron emission is concerned) starts. Let us denote the value of x corresponding to $T=T_H$ by l. Then l is the length of that part of the filament in which conduction cooling causes a variation in temperature.

It frequently happens that l is fixed by other design considerations. Since l is an implicit function of t_H, F, and J, it is possible to use the calculated values to determine values of F and J consistent with the given

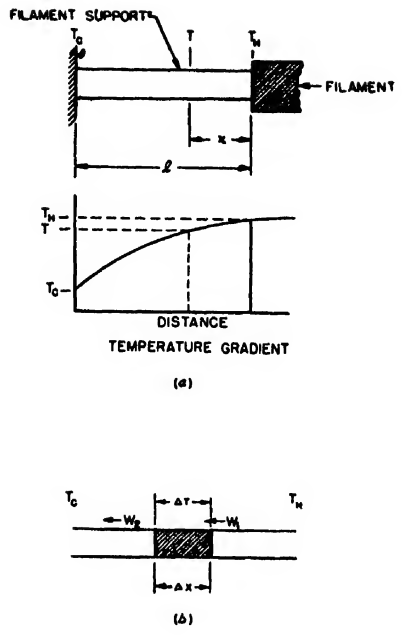

FIG. 1. The geometry of the problem.

values of t_H and l. To facilitate this process, the curves of Fig. 3 were prepared. An inspection of Eq. (7) shows why this single family of curves can give all the required information. Remembering that $l\equiv x(t_H)$, we obtain from (7):

$$l=(10^4/J)K^*(t_H, \alpha). \qquad (9)$$

Thus it is possible to plot one family of curves with lJ as ordinate, with α as abscissa, and with T_H as a parameter. It is convenient to use $(lJ)^{-1}$ as ordinate rather than lJ; this has been done in Fig. 3. On this plot the heavy lines are fixed values of T_H, the temperature of the emitting portion of the filament. The abscissa is $\alpha\equiv 10^6F/J^2=10^6PA/I^2$. The ordinate is $10^4(Jl)^{-1}=10^4A/Il$. The light lines are lines of constant $100Pl/I$.

One can enter the plot with given values of any four of the five quantities T_H, P, A, I and l and obtain the corresponding value of the fifth. Usually other considerations fix T_H, I, and l; and if the shape of the wire is fixed, P and A are of course not independent. This means that it may be necessary to make either the shape or the area of that portion of the filament where temperature variations exist different from that of the filament proper. This can be regarded as a procedure for controlling the position of the beginning of the emitting region; the curves of Fig. 3 give one all the information necessary to do this.

DETERMINATION OF PHYSICAL CONSTANTS

The method outlined above can also be used to determine the three physical constants ρ, K, and γ of metals at elevated temperatures. The writers have not done this, but feel that a brief outline of the procedure would be appropriate. In view of the paucity of data concerning the physical properties of metals at high

temperatures, it would be very desirable for someone to undertake these measurements.

A test piece (of circular cross section) at least ten diameters long would be mounted between electrodes of accurately controlled temperature and of accurately known spacing. Data would be obtained of brightness temperature and current as a function of applied voltage. A new sample of the same wire would then be mounted in the same way, with the electrodes moved so that the sample is now only about four diameters long; it must still have a short radiation-limited area at its center at the highest operating temperature. The same data as before are taken. It is now easy to obtain resistance *vs.* temperature curves for each sample, and by subtraction to obtain resistance *vs.* temperature for the mid-portion of the filament which was cooled by radiation only. Thus we can calculate ρ as a function of temperature, and by the use of Eq. (2) we can calculate the specific radiance γ.

If we are dealing with a metal for which the relation between brightness temperature and blackbody temperature is not known, this will have to be determined in a separate experiment.

The determination of K, the thermal conductivity, can be accomplished with the same set-up. We now use a still shorter wire, so that radiation limiting does not occur. We then measure the mid-temperature, and the distance Δx from the midpoint of the wire to a point where the temperature is ΔT degrees less than the mid-temperature. Writing Eq. (4) as a difference equation, and solving for K, we find

$$K=(J^2\rho-F\gamma)(\Delta x)^2/2\Delta T. \tag{10}$$

The factor 2 in the denominator occurs because we are averaging K over the interval in question.

APPENDIX A

To solve the second-order non-linear differential equation

$$J^2\rho(T)=F\gamma(T)+K(T)\frac{d^2T}{dx^2}+\frac{dK(T)}{dx}\frac{dT}{dx}, \tag{5}$$

where $\rho(T)$, $\gamma(T)$, and $K(T)$ are known tabulated functions.

Rearranging,

$$\frac{d^2T}{dx^2}+\frac{K'(T)}{K(T)}\left(\frac{dT}{dx}\right)^2=\frac{J^2\rho(T)-F\gamma(T)}{K(T)}. \tag{11}$$

We have written K' for dK/dT and have made use of the fact that $dK/dx=dK/dT\cdot dT/dx$. Now let $dT/dx=u$; then $d^2T/dx^2=udu/dt$, and our equation becomes

$$u\frac{du}{dT}+\frac{K'(T)}{K(T)}u^2=\frac{J^2\rho(T)-F\gamma(T)}{K(T)}. \tag{12}$$

Let $m=u^2$; then $udu/dt=\frac{1}{2}dm/dt$, and

$$\frac{dm}{dt}+2\frac{K'(T)}{K(T)}m=2\frac{J^2\rho(T)-F\gamma(T)}{K(T)}. \tag{13}$$

This is a linear differential equation of the first order. The solution is:[2]

$$m[K(T)]^2=2\int_T^{T_H}k(T)[J^2\rho(T)-F\gamma(T)]dT. \tag{14}$$

Returning to our original variables,

$$\left(\frac{dT}{dx}\right)^2=\frac{2}{[K(T)]^2}\int_T^{T_H}K(T)[J^2\rho(T)-F\gamma(T)]dT. \tag{15}$$

Equation (15) can be formally solved for x, giving the integral

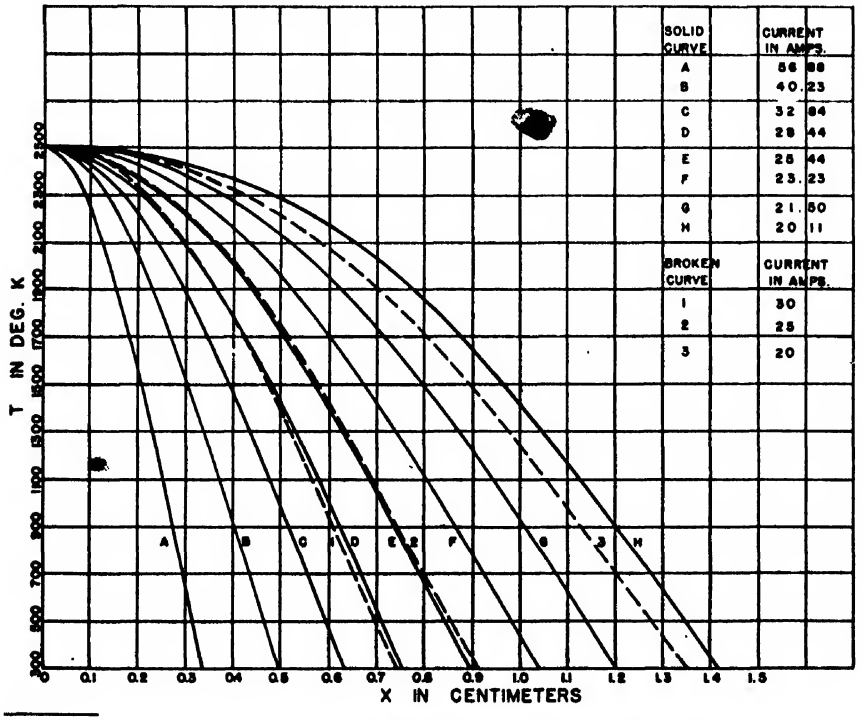

FIG. 2. Comparison between measured and calculated values of temperature distribution in a tungsten filament 0.020 in. diameter. The solid curves are calculated, while the dashed curves are measured values.

[2] F. S. Woods, *Advanced Calculus* (Ginn and Company, Boston, 1932), p. 220.

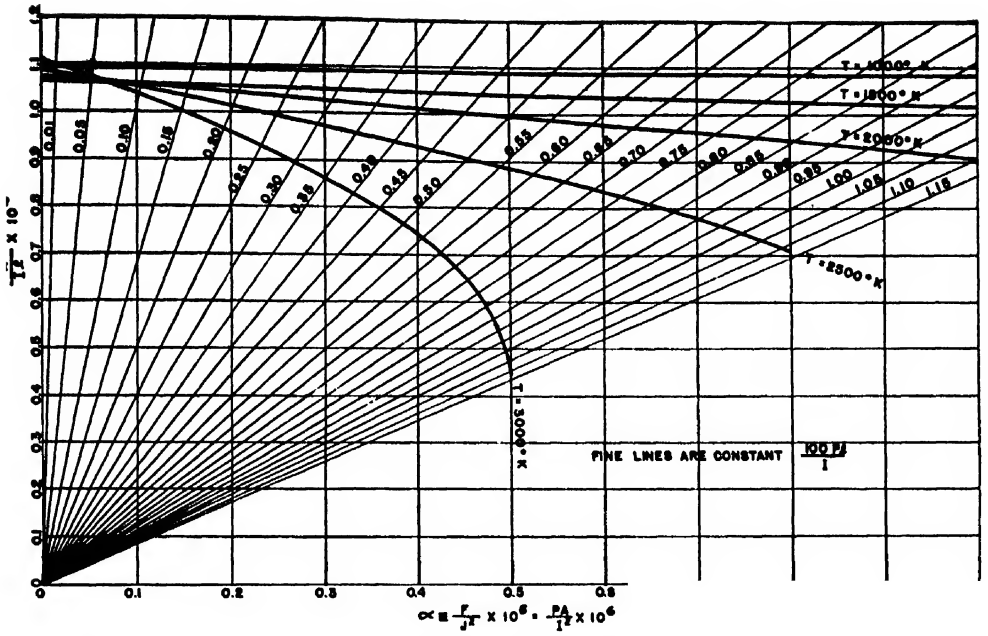

FIG. 3. Universal curves for determining the length of the conduction cooled portion of a tungsten filament.

solution

$$x(T)=\int_T^{T_H}\frac{K(T)dT}{\left(\int_T^{T_H}2K(T)[J^2\rho(T)-F\gamma(T)]dT\right)^{\frac{1}{2}}}. \tag{6}$$

APPENDIX B

The numerical integration of Eq. (6) was carried out as follows:

The physical constants of tungsten as functions of temperature can be approximated by the following equations:

$$K(T)=1.346-1.6\times10^{-4}T, \tag{16}$$

$$\gamma(T)=1.818\times10^{-19}(\log T)^{38.8}, \tag{17}$$

$$\rho(T)=1.51\times10^{-6}\left(\frac{T}{100}\right)^{1.21}. \tag{18}$$

The data from which these empirical equations were derived was obtained from Jones and Langmuir[3] for electrical conductivity and radiation constants, and from Coolidge[4] and Osborn[5] for thermal conductivity.

The analytic functions are introduced into the integrand of (6) and the integration performed by machine. In order to present the results compactly, two new variables are introduced:

$$t=T/1000, \tag{19}$$

$$\alpha=10^6F/J^2. \tag{20}$$

It is apparent from the form of (6) that it can be written

$$x(t)=(10^4/J)K^*(t,t_H,\alpha); \tag{7}$$

Eqs. (6) and (7) together constitute the definition of the function K^*. This function was computed with the aid of the approximate analytical formulations given in (16), (17) and (18) for $T_H=1000°K$, $1500°K$, $2000°K$, $2500°K$, and $3000°K$, for appropriate fixed values of α. The results were used in plotting the design curves given in Fig. 3.

[5] R. H. Osborn, J. Opt. Soc. Am. 31, 428–431 (June, 1941). There appears to be a genuine discrepancy between the room temperature value of K and that at elevated temperatures. The empirical Eq. (16) fits Osborne's data and does not pass through the point given at room temperature. Further work is needed to resolve this discrepancy.

Space-Charge Effects in Electron Beams and Their Reduction by Positive Ion Trapping*

E. G. Linder and K. G. Hernqvist**
RCA Laboratories Division, Radio Corporation of America, Princeton, New Jersey
(Received April 19, 1950)

The spread of electron beams caused by space-charge forces is discussed. Under certain conditions ions formed from the residual gas may be trapped in the beam. An equilibrium condition may be established in which the electron and ion densities are equal, and then space-charge forces will be neutralized. Under these conditions high current densities may be produced at low voltages. A theory of ion trapping is discussed, and the equilibrium condition is formulated.

Experimental data are presented which were obtained by the application of microsecond pulses to the beam. This technique is described, and its advantages and possibilities are mentioned. Data are given on beam spread as a function of current, voltage and pressure. Data on the improvement due to ion trapping are included. An increase of current density by a factor of 30 was observed with the structures tested. Results are included on ion build-up time as a function of pressure, and on beam noise and stability in the presence of trapped ions.

I. INTRODUCTION

SPACE charge is the chief limiting factor in the production of high current-density electron beams. On account of space charge, repulsive forces exist so that beams parallel at their origin, become divergent, or beams originally convergent fail to converge. This effect appears to have been studied first by E. E. Watson[1] who, in 1927, derived the expression for the divergence of an initially parallel beam. Numerous other workers[2–8] have further developed Watson's results, and some have devised methods of controlling the spread. In 1940 Thompson and Headrick[9] extended the theory to the case of convergent beams. Field, Spangenberg, and Helm[10] showed in 1947 that a universal curve could be drawn giving beam spread in terms of certain general parameters.

This article covers the following topics: (a) Theory of space-charge spread, (b) Ion trapping and space-charge neutralization, (c) Pulse technique and apparatus, (d) Experimental data, (e) Beam stability.

M.k.s. units are used throughout, except when otherwise specified. The abbreviation SCN will be used throughout for "space charge neutralized," or "space charge neutralization."

II. THEORY OF SPACE-CHARGE SPREAD

Thompson and Headrick[9] have derived an expression for the spread of a convergent beam giving the shape, or profile, for systems of circular transverse symmetry. They found that the radius of the beam at any point is

$$r = R_0 \epsilon^{-\pi\epsilon_0 \frac{m}{e} \frac{v}{I}(v_{ro}^2 - v_r^2)},$$
$$= R_0 \epsilon^{-S(V_{ro} - V_r)/V}, \quad (1)$$

where R_0 = initial beam radius, I = beam current, ϵ = natural logarithmic base, ϵ_0 = permittivity of free space, m = electron mass, e = electron charge, v = beam velocity, v_r = radial velocity, v_{ro} = initial radial velocity, V = beam voltage, V_r = radial velocity in equivalent volts, V_{ro} = initial radial velocity in equivalent volts, and $S = (8\pi^2\epsilon_0^2 e/m)^{\frac{1}{2}} V^{\frac{1}{2}}/I$. The minimum radius is obtained by putting $V_r = 0$, that is,

$$r_m = R_0 \epsilon^{-SV_{ro}/V}. \quad (2)$$

The longitudinal (axial) position of any surface electron is found to be

$$z = 2S^{\frac{1}{2}} R_0 \epsilon^{-SV_{ro}/V} \int_{(SV_r/V)^{\frac{1}{2}}}^{(SV_{ro}/V)^{\frac{1}{2}}} \epsilon^{x^2} dx, \quad (3)$$

and the axial position of the point of minimum radius is

$$z_m = 2S^{\frac{1}{2}} R_0 \epsilon^{-SV_{ro}/V} \int_0^{(SV_{ro}/V)^{\frac{1}{2}}} \epsilon^{x^2} dx. \quad (4)$$

A typical set of curves computed from Eqs. (1) and (3) is given in Fig. 1. Profiles b are plotted for a series of beam currents from 0 to 60 ma. The beam voltage is 300, the source radius $R_0 = 0.3$ cm, and the focal distance with no spreading is $z_0 = 0.8$ cm. The curve cc is the locus of the points of minimum radius.

In the same figure, a partition A is shown which contains a circular aperture a, concentric with the beam. By use of the beam profiles it is evident that the amount of current passing through this aperture may be computed. Thus it is seen that for currents up to about 9.0 ma, the total amount traverses the aperture, whereas at 20 ma less than 25 percent passes through, and at 60 ma only about 3.5 percent.

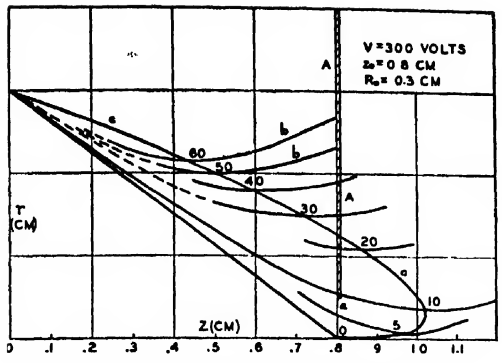

FIG. 1. Typical computed beam profiles.

If I_a is the current traversing the aperture, and I is the total beam current, the beam efficiency may be defined as I_a/I. This is determined by the ratio of the aperture area to the beam cross-sectional area, i.e.,

$$\mathcal{E}=I_a/I=r_a^2/r_1^2,$$

where r_a is the aperture radius and r_1 is the beam radius at the aperture.

A set of curves showing beam efficiency, thus computed, is given in Fig. 2, for beam voltages of 200, 300, and 400 volts. These curves, as well as those of Fig. 1, are idealized in that they are based on the original Thompson and Headrick assumptions, and furthermore no account has been taken of any aberrations, or effects of initial velocities.

By inspection of Eqs. (2) and (4) it is seen that r_m and z_m may be written as functions of the quantity $V^{\frac{1}{2}}/I$, since, by assumption, V_{ro} is proportional to V. It is not evident by inspection that Eqs. (1) and (3) also may be written as functions of this same parameter. However it has been shown by Field, Spangenberg, and Helm[10] that universal beam profiles may be drawn in terms of this parameter. Hence curves such as those of Fig. 1, may be considered universal, in so far as one may be drawn for each value of $V^{\frac{1}{2}}/I$, for any given geometry.

Thus, the curves of Fig. 2, also may be combined into a single universal curve by plotting $I/V^{\frac{1}{2}}$ along the horizontal axis instead of I. Such a curve is shown in

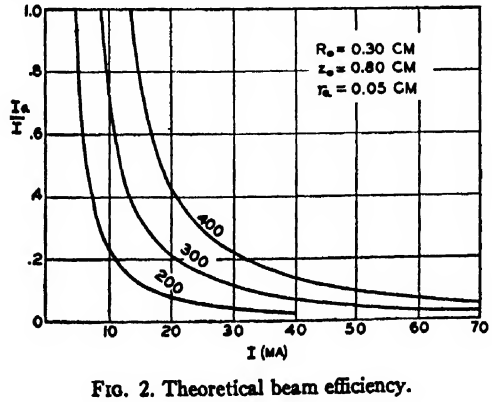

FIG. 2. Theoretical beam efficiency.

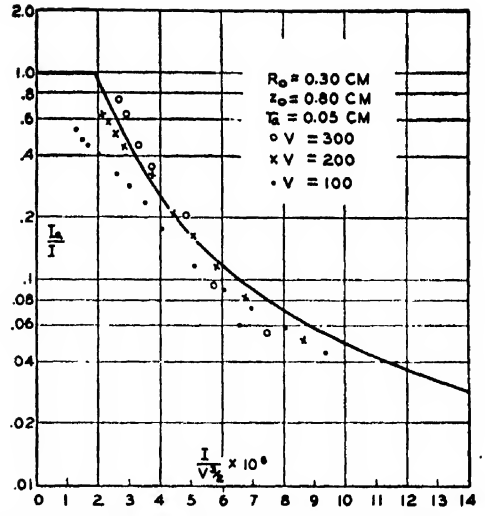

FIG. 3. Universal beam efficiency curve with experimental points at three different voltages.

Fig. 3. The experimental data shown in this figure will be discussed later.

III. ION TRAPPING AND SPACE CHARGE NEUTRALIZATION

In this section the prevention of space charge spread will be discussed. The method used here is based on the neutralization of electron space charge by positive ions. The first similar application of positive ions appears to have been made by J. B. Johnson[11] in 1922 in connection with a cathode-ray oscillograph tube in which beam spread was reduced by admitting gas into the tube. However, the conditions differed widely from those under discussion in this article, and did not involve the trapping of ions as described hereinafter.

A more recent application by O. Heil[12] has been described but many details are not available. The most detailed study was made by Field, Spangenberg, and Helm.[13] Here ions formed by collisions between beam electrons and residual gas molecules were trapped in long, high voltage beams. It was also shown that the number of residual gas molecules at pressures used in ordinary high vacuum tubes was sufficient to supply ions for beams of high current density. However, again, conditions and methods differed considerably from those of the present work.

An understanding of the ion-trapping process may be had with the aid of Fig. 4, which shows the potential variation across the tube diameter. At the top, a cross section of a cylindrical tube and beam is illustrated, where D is the cylindrical wall, and b is the beam, see

[11] J. B. Johnson, J. Opt. Soc. Am. 6, 701 (1922).

[13] See reference 10. This same work was printed privately in 1942. See report on "The Production and Control of Electron Beams," Electrical Engineering Dept., Stanford University.

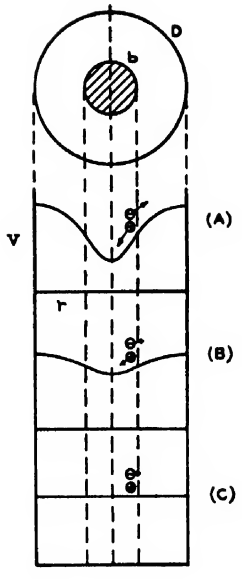

FIG. 4. Potential distribution across beam with various degrees of SCN.

Fig. 6. Below at (A) is shown a typical potential variation for an unneutralized beam. In the case of a cylindrical, parallel beam the variation is approximately parabolic within the beam, and logarithmic between the beam and the wall, (see Smith and Hartman[7]). Thus there is a potential minimum at the beam center.

This depression extends along the longitudinal axis, but decreases as the grid or aperture are approached, and becomes negligibly small at these electrodes. Thus there is formed a potential valley surrounded by higher regions on all sides.

Such a potential valley acts as an ion trap, as shown in Fig. 4(A). Positive ions, formed by collisions between beam electrons and residual gas molecules, move toward the beam center, and are trapped. On the other hand, low velocity electrons, formed by the ionization process, are forced away from the center of the beam.

The resulting accumulation of ions in the beam causes a progressive neutralization of electron charge, and consequently, the potential rises and the depression decreases, as shown at (B). If, eventually, the positive ion density equals the electron density, the potential becomes uniform, as at (C), then ion-trapping obviously ceases, and an equilibrium condition is established. Actually, under most circumstances, there will remain a slight potential depression of the order of a few tenths of a volt just sufficient to overcome the thermal energies of the ions. This will be discussed in detail below. Furthermore, electrons formed by ionization will continue to be lost from the beam, even with no potential depression, since they will encounter no resisting forces.

When the electron space charge is thus neutralized, the electron paths become straight and radial. The total current then passes through the aperture, except insofar as there are limitations due to unconsidered factors, such as structural aberrations and initial velocities.

The rate of formation of ions in an electron beam is given by

$$(dN_2/dt)_1 = \pi r^2 p P(V) n_1 v_1, \tag{5}$$

where p is the gas pressure, P is the number of electrons (or ions) formed per unit length, per electron, at unit pressure, n_1 is the electron density, N_2 is the number of ions per unit beam length, and v_1 is the electron velocity.

The rate of loss of ions will be computed by assuming that the trapped ions form an ion gas. This seems plausible in view of the long lifetime of the ions in the trap and the consequent possibility of the attainment of an equilibrium state. The rate of loss will then depend upon the ion gas density at the wall and the average normal velocity component there. The density will be controlled by the Boltzmann law and at the wall it will be

$$n_2 = n_2' \epsilon^{\Delta V e/kT_2},$$

where n_2' is the ion density at the beam center, T_2 is the gas temperature, and ΔV is the potential difference between the beam center and surrounding cylindrical wall. In the case of an electron beam, the potential is depressed, and ΔV is such as to make $\Delta Ve/kT_2$ negative for positive ions. The average normal velocity at the wall is, from kinetic theory,

$$v_2 = \left(\frac{V_{02}e}{2\pi M}\right)^{\frac{1}{2}}.$$

Thus the rate of ion loss may be written

$$\left(\frac{dN_2}{dt}\right)_2 = 2\pi R n_2' \epsilon^{\Delta V/V_{02}} \left(\frac{V_{02}e}{2\pi M}\right)^{\frac{1}{2}}. \tag{6}$$

The net rate of change of number of ions may therefore be written

$$\frac{dN_2}{dt} = \left(\frac{dN_2}{dt}\right)_1 - \left(\frac{dN_2}{dt}\right)_2 = \pi r^2 p P n_1 v_1 - 2\pi R n_2' \epsilon^{\Delta V/V_{02}} \left(\frac{V_{02}e}{2\pi M}\right)^{\frac{1}{2}}. \tag{7}$$

Throughout the trapping period the first term remains constant, however, at the beginning of the process, n_2' is small, also $|\Delta V| \gg V_{02}$, hence the second term is small. As the trapped ion density n_2' increases, $|\Delta V|$ also decreases, and the second term increases. At equilibrium the two terms must be equal, then $dN_2/dt = 0$, and Eq. (7) becomes,

$$\pi r^2 p P n_1 \left(\frac{2Ve}{m}\right)^{\frac{1}{2}} = 2\pi R n_2' \epsilon^{\Delta V/V_{02}} \left(\frac{V_{02}e}{2\pi M}\right)^{\frac{1}{2}}.$$

Cancelling terms, and solving for p, gives

$$p = \frac{R n_2'}{\pi^{\frac{1}{2}} r^2 P n_1} \left(\frac{m}{M}\frac{V_{02}}{V}\right)^{\frac{1}{2}} \epsilon^{\Delta V/V_{02}}. \tag{8}$$

This represents the equilibrium condition for a potential depression in the beam. It is evident that ΔV is a function of pressure, and that at a certain pressure, $\Delta V=0$. Under this condition also $n_2'=n_1$, and then

$$p_{(\Delta V=0)}=\frac{R}{\pi^{\frac{1}{2}}r^2P}\left(\frac{m}{M}\frac{V_{02}}{V}\right)^{\frac{1}{2}}. \tag{9}$$

Only at this pressure is there accurate space charge neutralization; at other pressures n_2' is not exactly equal to n_1. However, under practical conditions, such as are of interest here, ΔV is usually less than a volt, and then $n_2'\approx n_1$ for beam currents of several milliamperes or more. This arises from the fact that the potential depression is caused by the unneutralized charge n_1-n_2', and since these are both large numbers, n_1-n_2' may be large even though n_1/n_2' is nearly unity.

When the pressure exceeds the value given by Eq. (9), ΔV changes sign and the potential depression becomes a potential increase. This is due to the formation of ions at a rate greater than that at which they can escape without an assisting electric field.

In this case ions are no longer trapped, but electrons are, and thus it is now possible to set up equations for electrons, similar to Eqs. (5) and (6), representing the rates of electron formation and loss.

The rate of flow of electrons to the wall will be given by

$$\left(\frac{dN_1}{dt}\right)_1=2\pi Rn_1'\epsilon^{-\Delta V/V_{01}}\left(\frac{V_{01}e}{2\pi m}\right)^{\frac{1}{2}}. \tag{10}$$

The rate of formation of electrons in the beam will be

$$\left(\frac{dN_1}{dt}\right)_2=\pi r^2pPn_1\left(\frac{2Ve}{m}\right)^{\frac{1}{2}}. \tag{11}$$

Here n_1' is the density of the electron gas at the beam center, that is, the density of the trapped electrons. This does not include the beam electrons, which are not trapped, do not form a gas, and do not obey the Boltzmann law. Also V_{01} is the electron gas temperature in equivalent volts.

Equating Eqs. (10) and (11) and solving for p yields,

$$p=\frac{Rn_1'}{\pi^{\frac{1}{2}}r^2Pn_1}\left(\frac{V_{01}}{V}\right)^{\frac{1}{2}}\epsilon^{-\Delta V/V_{01}}. \tag{12}$$

This equation is valid only for potential rises in the beam, whereas Eq. (8) is valid only for potential depressions. For $\Delta V=0$ they should both be valid. Equating them, and putting $\Delta V=0$, yields,

$$\frac{n_1'}{n_2'}=\left(\frac{m}{M}\frac{V_{02}}{V_{01}}\right)^{\frac{1}{2}}. \tag{13}$$

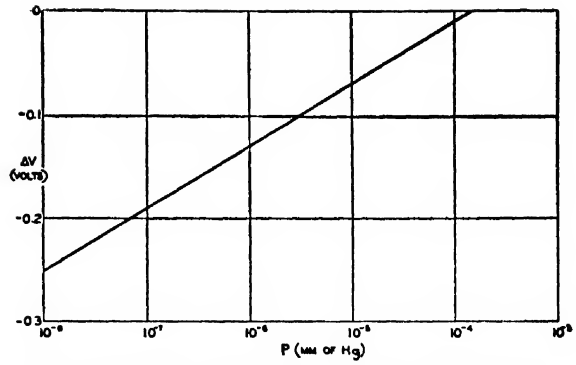

FIG. 5. Variation of potential depression with pressure.

If this is written

$$n_1'\left(\frac{V_{01}}{m}\right)^{\frac{1}{2}}=n_2'\left(\frac{V_{02}}{M}\right)^{\frac{1}{2}},$$

it is seen that this means that the electron and ion currents escaping from the beam, due solely to thermal motion, are equal, when $\Delta V=0$.

Equation (12) can not now be evaluated for other values of ΔV since n_1' is an unknown function of ΔV. Further work must be done to determine this function.

However, Eq. (8) for the potential depression case, can be evaluated, assuming $n_1=n_2'$. This is plotted in Fig. 5, for the following conditions: $R=0.5$ cm, $r=0.1$ cm, $P=7.7$, $M/m=52{,}000$, $V=300$ volts, and $V_{02}=0.026$ volt. These values correspond approximately to a set of experimental conditions to be discussed later. The values of R and r are averaged for a conical beam. P and M/m are taken for nitrogen. The ion gas temperature is assumed to be 300°K. These data give

$$p=1.5\times10^{-4}\epsilon^{\Delta V/0.026}.$$

It is seen from this that as the vacuum improves, the equilibrium potential depression increases in order to decrease the rate of ion escape from the trap. However for all practical vacuums the depression is very small compared to the beam voltage.

The build-up time of the ion density and the aperture current I_a may be computed from Eq. (7). However, this computation is complicated by the fact that the variation of ΔV during build-up is not known. Fortunately the term which contains ΔV does not become important until the final stages of build-up, when ions begin to escape from the trap. It is then responsible for the tail of the curves, as shown in Figs. 9 and 11. An approximation may be made by neglecting this term and using only the first term of Eq. (7). The values thus obtained will be too small, but will be sufficiently accurate for many purposes. If this is done, there results,

$$dn_2/dt=pPn_1v_1$$

since

$$N_2=\pi r^2n_2.$$

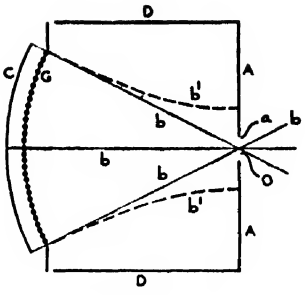

FIG. 6. Schematic diagram of ion-trapping gun.

The ion build-up time τ is the interval required for n_2 to equal n_1, i.e.,

$$\tau=\int_0^{\tau} dt=\int_0^{n_1}\frac{dn_2}{pP(V)n_1v_1}.$$

But $v_1=(2Ve/m)^{\frac{1}{2}}$, and also, if the number of ionized gas molecules is small compared to the total number of residual gas molecules in the beam-region, so that p can be considered constant during the ionization build-up period, it follows that

$$\tau=\frac{(m/2e)^{\frac{1}{2}}}{pP(V)n_1V^{\frac{1}{2}}}\int_0^{n_1}dn_2,$$

or

$$\tau=\frac{(m/2e)^{\frac{1}{2}}}{pP(V)V^{\frac{1}{2}}}.$$

If τ is measured in microseconds, p in mm of mercury, and $P(V)$ in number of ions formed per cm, per electron, at a pressure of 1 mm of mercury, this becomes

$$\tau=\frac{0.0169}{pP(V)V^{\frac{1}{2}}}. \qquad (14)$$

Thus τ varies inversely as the pressure, is independent of current, and is a function of voltage which can be specified only when $P(V)$ is known.

In the above treatment it is assumed that the number of residual molecules in the beam region is large compared to the number of ions required, that is, to the number of electrons in the beam. This condition is usually easily consistent with electron beam tube operating conditions.

IV. PULSE TECHNIQUE AND APPARATUS

The construction of the tubes used in the tests is shown schematically in Fig. 6. The cathode C comprises a segment of a spherical surface with its center of curvature at 0. Immediately in front of the cathode is the grid G, which also is a spherical segment having its center of curvature at 0. The aperture a, through which it is desired to pass current, is placed at 0. The disk A, cylinder D, and grid G form a shielded enclosure, which is field-free when G, A, and D are at the same potential. Under this condition, and in the absence of space charge, electrons will follow radial trajectories, as shown by lines b. But in the presence of space charge, divergence will occur, as illustrated by dashed lines b'.

A scale drawing of an actual tube is shown in Fig. 7. Parts are lettered to correspond to similar parts of Fig. 6. In addition there is shown here the focusing electrodes B, and the Faraday cage F to collect the aperture current I_a. The tests were made with a tube of demountable design in which the position of the electron gun and the Faraday cage could be adjusted by external knobs, working through metal bellows. This adjustment could be either lateral or longitudinal.

The greater part of the data obtained in this study was obtained by use of a pulse technique. It is believed that this is the first application of pulse methods to the investigation of electron beams. It has proved to be very superior to d.c. methods, eliminating several sources of error and yielding additional information. These advantages will be discussed below.

The circuit used is illustrated schematically in Fig. 8. The tube elements are cathode C, grid G, aperture disk A, and Faraday cage F. The pulser produced a square pulse of width T_2 variable from $\frac{1}{2}$ to 5 microseconds, and of spacing T_1 variable from 50 to 5000 microseconds. The pulse amplitude was adjustable up to 400 volts.

A typical oscillogram is sketched in Fig. 9, where grid voltage (above) and aperture current (below) are plotted against time. From a to b all electrodes have the same potential with respect to the cathode, and the current is constant. At b, a pulse is applied to the grid of sufficient amplitude to bring its potential down to zero. This stops the cathode emission current, and it also applies an ion-sweeping field between the grid and

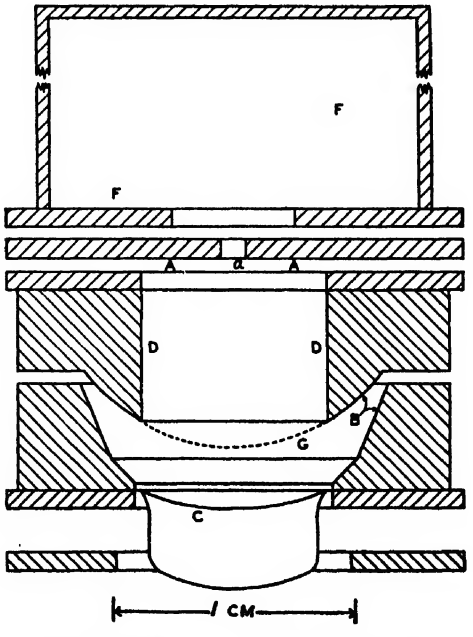

FIG. 7. Scale drawing of ion-trapping gun.

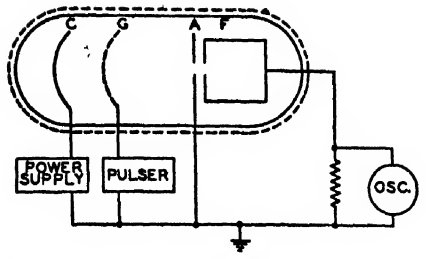

FIG. 8. Schematic diagram of tube and circuit.

the aperture for the duration of the pulse from c to d. At d the pulse is terminated and the grid-potential and the cathode emission current return to their initial values. The aperture current however rises only to e, which is less than the initial value. The reason for this is that the positive ions were swept out of the beam region during the application of the pulse, consequently at its termination, and the reformation of the beam, there is no space-charge neutralization. The current at e represents that passing through the aperture with the beam in a diverged state due to space charge. However, at point e ions again begin to be formed and trapped, hence there is an increase in current during the time interval from e to f. At the latter point the current has attained its original value, which represents that obtained with complete space-charge neutralization.

This method has several advantages over a dc method in which ions are swept out by applying a steady sweeping voltage on the grid. (1) Electrons maintain constant velocity between grid and aperture, as is required for comparison with existing theories. (2) There is no defocusing, or other distortion of the beam, by nonuniform fields in the beam region. (3) There are no complications caused by secondary electron currents. (4) An ion-sweeping field as large as desired may be used. (5) Data on ion build-up time are obtainable.

V. EXPERIMENTAL DATA

1. Space Charge Spread

The decrease in aperture current due to space charge spread may be obtained directly from oscillograms such as that of Fig. 9. The ratio of the current without SCN to that with, is the ratio of lengths ed/bc. The numerical value of the current at point b may be measured with a meter while the pulser is switched off. All other desired currents may likewise be metered except the current corresponding to point e. This is obtained from the ratio of ed/bc.

Measurements of this sort were made to determine the beam efficiency, $\delta = I_a/I$, as a function of beam current I, gas pressure p, and beam voltage V. Typical oscillograms are shown in Figs. 10–12.

The variation of I_a/I with beam current shows directly the effect of space charge in causing beam spread. Oscillograms for a series of beam currents are shown in Fig. 10. Here the beam voltage and pressure are substantially constant. As the current is varied, point e (see Fig. 9) changes, moving upward with decreasing current. This shows that the space charge spread is smaller for smaller currents. Data taken from such oscillograms are plotted in Fig. 13, where beam efficiency, I_a/I is plotted against beam current for three different beam voltages. The rapid drop in efficiency due to beam spread is apparent.

As pointed out above, these data may be presented in the form of a universal curve by plotting against $I/V^{\frac{1}{2}}$, instead of against I alone. This has been done in Fig. 3. The solid line has been computed from the Thompson-Headrick theory; the points have been obtained from ed/bc ratios on oscillograms such as those of Fig. 10. These data at different voltages show a systematic drop in efficiency as the voltage decreases. This will be shown later to be due to the effect of initial thermal velocities. Both voltage and pressure effects will be discussed later.

2. Space-Charge Neutralization

In Fig. 13 are shown also the values of I_a/I for space charge neutralized beams. These are substantially horizontal lines, except for a small upward rise for small currents. This indicates that there is little or no beam spread as the current increases in this case. Over the range of the measurements there appears to be no limitation of current due to space-charge spread. The tests were not usually extended beyond $I=55$ ma at $V=300$, because of excessive heating of the grid, and danger of destroying it. However, for a period of a few seconds, an aperture current $I_a=68$ ma was obtained at 400 volts with a beam efficiency $E=86.8$ percent. The lower voltage tests terminate at values of current which represent the space charge limited values of current between cathode and grid. This is not a fundamental or serious limitation since it can be varied by changing the cathode-grid spacing. (There is no SCN effect in the cathode-grid region since it is not field-free and ion trapping does not occur.) It is seen from these data that the maximum gain obtained in these tests from SCN corresponds to an increase in I_a of about 30 times at $I=55$.

It also is evident from Fig. 11 that the gain due to

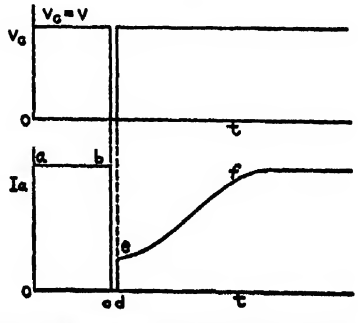

FIG. 9. Typical pulse shape showing applied grid voltage (above), and resulting aperture current (below).

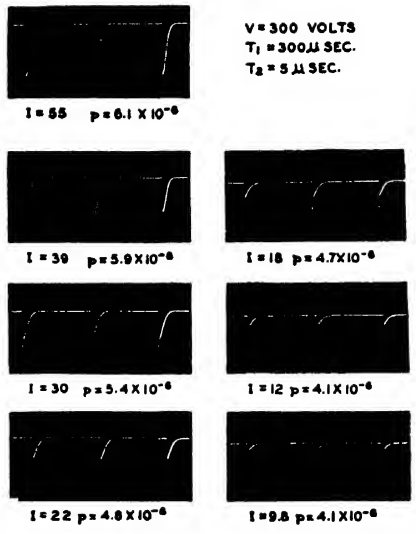

FIG. 10. Effect of current variation.

SCN is independent of pressure, since the ratio bc/ed does not vary with pressure. This is in agreement with the above theory.

3. Ion Build-Up Time and Pressure

The ion build-up time τ may be determined from oscillograms such as those of Fig. 9 by measuring the time difference between the points e and f. However, by using this method good agreement could not be expected when comparing the results with the simple theory used in deriving Eq. (14), because of some serious sources of error that cannot be overcome, namely: (1) The point f is very hard to localize on the scope picture because of the smooth transition to the equilibrium condition. (2) The tendency for the ions to escape from the beam region increases as the potential

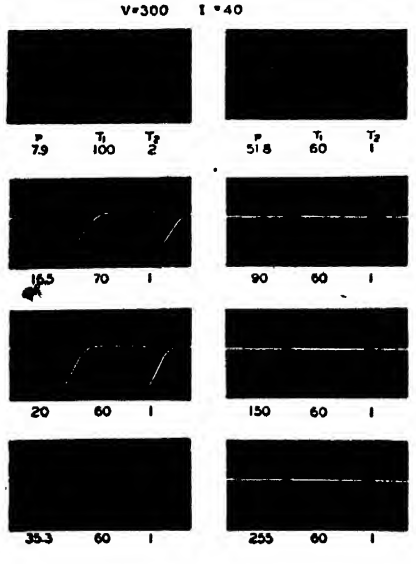

FIG. 11. Effect of pressure variation.

across the beam approaches the equilibrium state thus giving a longer ion build-up time than predicted by Eq. (14). These factors can be overcome by using another method, in which the build-up time is determined from the rate of formation of ions at the point e and from the knowledge of the number of ions required for full neutralization. The values thus obtained of course may differ somewhat from the practical ones, such as the time from e to f in Fig. 9, but they are consistent with the assumptions of Eq. (14) and are valid for comparison therewith. This method of obtaining τ has been used for all values given in this paper.

It is seen that, theoretically, according to Eq. (14), the build-up time varies inversely as pressure, inversely as $P(V)\ V$ and is independent of current. This latter independence can be seen to be substantially verified by the data of Fig. 10. No attempt at a more exact verification has been made.

The variation with pressure has been more completely checked. Pulse characteristics are shown in Fig. 11 for a range of pressures from 7.9×10^{-6} to 255×10^{-6} mm of mercury. These apply to a 40-milliampere, 300-volt beam. The decrease in build-up time is of an easily apparent magnitude in the photographs.

Values of τ obtained from such oscillograms are plotted against pressure in Fig. 14, on log-log paper. The solid lines are drawn with the theoretical slope of -1. The agreement lies within the experimental error. The 200-volt plot lies above the 300-volt one since the quantity $P(V)\ V$ of Eq. (14) is smaller in the former case. The values of $P(V)$ were taken for air.[14]

4. Variation of Beam Voltage

The build-up time is seen, from Eq. (14), to vary with beam voltage inversely as $P(V)\ V$. The function $P(V)$ in general has a value which rises to a maximum near a hundred volts and then drops slowly as V increases.[14] Multiplying by V shifts the maximum to a higher value. This function is inverted in the expression for τ, and results in a curve such as shown in Fig. 15, by the solid line. The experimental values, plotted as crosses, were obtained from oscillograms such as those of Fig. 12, by the method described in the preceding Section 3. Although the agreement is not quantitatively good, it is satisfactory in view of the assumptions involved. It is evident from known $P\ (V)$ functions that 300 volts represents an optimum voltage region, but that at higher voltages the build-up time would probably not be seriously larger.

At low beam voltages (below about 100 volts) it has been observed that the efficiency (I_a/I) drops very rapidly. This is illustrated in Fig. 16. It can be shown that this is caused by beam spread due to initial thermal velocities which become of importance when the beam velocity is small. To estimate this effect consider a

[14] See Engel and Steenbeck, *Elektrische Gasentladungen* (Berlin, 1932), p. 35.

small current, or an SCN case, so that space charge can be neglected. Assume a system such as shown in Fig. 17, where R_0 is the emitter radius, and r_2 the radius at the aperture, i.e., at the focal spot, due to initial velocities. Neglecting initial velocities, the focal spot would be a point, and the beam angle would be α, as shown.

For the system of Fig. 17, E. Ruska[15] has derived the expression

$$\frac{r_2}{R_0}=\frac{2\sin\beta}{\sin 2\alpha}\left(\frac{kT}{Ve}\right)^{\frac{1}{2}}.$$

To obtain the total spread put $\beta=\pi/2$. Also substitute the approximation,

$$\sin 2\alpha = 2R_0/z_0,$$

then

$$\frac{r_2}{R_0}=\frac{z_0}{R_0}\left(\frac{kT}{Ve}\right)^{\frac{1}{2}}, \quad \text{or} \quad \frac{r_2}{z_0}=\left(\frac{kT}{Ve}\right)^{\frac{1}{2}}. \tag{15}$$

Since the total current remains constant $\pi R_0^2 J_0 = \pi r_2^2 J$, or

$$J/J_0 = R_0^2/r_2^2, \tag{16}$$

where J_0 is the initial current density, and J the density at the focus.

From Eqs. (15) and (16),

$$J/J_0 = R_0^2/z_0^2(Ve/kT) = (Ve/kT)\tan^2\alpha.$$

For small α, $\tan\alpha \approx \sin\alpha$, so that this is in agreement with the expression of D. B. Langmuir.[16]

The fraction of current passing through an aperture of radius r_a is r_a^2/r_2^2, or from Eq. (15),

$$I_a/I = r_a^2/r_2^2 = r_a^2/z_0^2(Ve/kT). \tag{17}$$

This expression is valid, of course, only for $r_a \leq r_2$. Under this condition, and for a given geometry, the beam efficiency varies directly as V, the beam voltage.

This theoretical expression is plotted in Fig. 16 as a straight line through the origin. According to this simple theory the ratio I_a/I should rise linearly until it attains unity ($r_2=r_a$) after which it should remain constant. The departure of the experimental curve from the simple theory may be due in part to the neglect of the Maxwell-Boltzmann distribution in the theory. This distribution would cause a rounding off, instead of a sharp break, at $I_a/I=1$. Also there is spreading of the beam due to other factors, such as grid irregularities, which prevent the experimental value of I_a/I from reaching unity.

The slope of the line in the figure is drawn to equal that of the experimental curve at the origin and corresponds to a temperature of 1370°K. This is a little high, but the actual cathode temperature was not determined, and this value is close enough to indicate

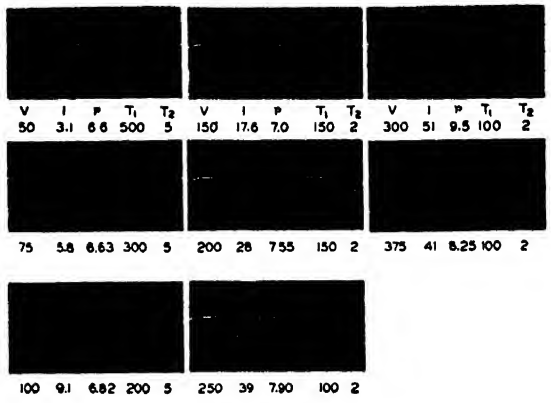

FIG. 12. Effect of voltage variation.

definitely that the drop in I_a/I is due to thermal velocities.

If the beam voltage is reduced below the ionization potential it is clear that the formation of ions will be affected and the neutralization of electron space charge may not be possible. Data taken in this region showed that as V increases from 9 to 10 volts there is an abrupt increase in I_a, corresponding, very likely, to the onset of ionization. However, as V is decreased from 10, the current drops smoothly until it reaches the original value at about 7 volts. Thus there is a hysteresis effect. This phenomenon is shown in the oscillogram of Fig. 18 wherein the horizontal scale was scanned by a 60 c.p.s. voltage, while the vertical represents I_a.

5. Comparative Results

Comparisons of SCN electron guns with several other types are given in Table I. The other types represent various previous attempts to obtain high current density, except, the 2K25 which is a widely-used commercial type, but not designed for particularly high density. The comparison is made on the basis of six quantities. As listed in order in the columns, they are: (1) total aperture current, (2) current density at the emitter, (3) current density at the aperture, (4) perve-

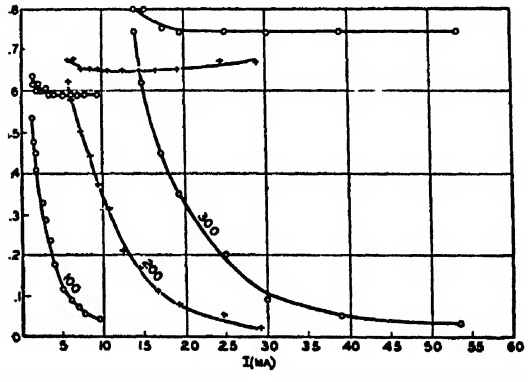

FIG. 13. Experimental beam efficiency curves with (above), and without ion trapping (below).

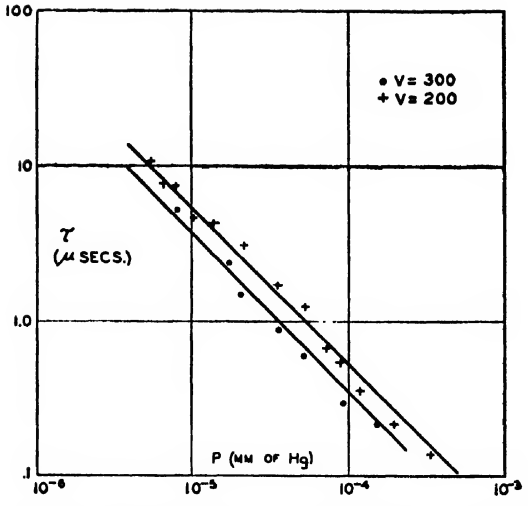

FIG. 14. Variation of ion build-up time with pressure.

ance$\times 10^6$, (5) concentration factor, or the ratio J/J_E, and (6) a figure of merit, F.

The figure of merit represents an attempt to indicate, in a manner independent of voltage and electrode size, the comparative ability of various guns to pass current through an aperture. To do this the Child-Langmuir law for parallel beams has been modified by introducing the factor F, i.e.,

$$I_a = 2.334\times 10^{-6}(V^{\frac{1}{2}}/x^2)a\cdot F,$$

where I_a is the current in amp./cm², V is the beam voltage, x is the distance from emitter to aperture in cm a is the aperture area in cm², and F is the figure of merit. For a parallel beam, $F=1$, and the greater the value of F the greater the aperture current compared to a parallel beam. Thus

$$F=\frac{I_a x^2 10^6}{2.334V^{\frac{1}{2}}a}. \tag{18}$$

For space charge limited beams this is independent of

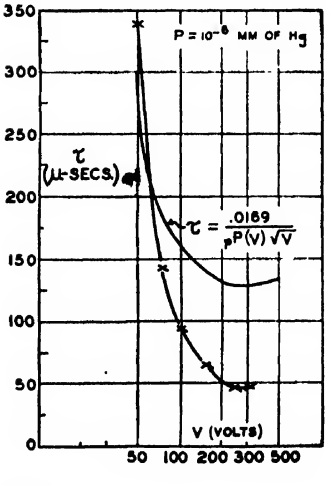

FIG. 15. Variation of ion build-up time with voltage, theoretical and experimental (X).

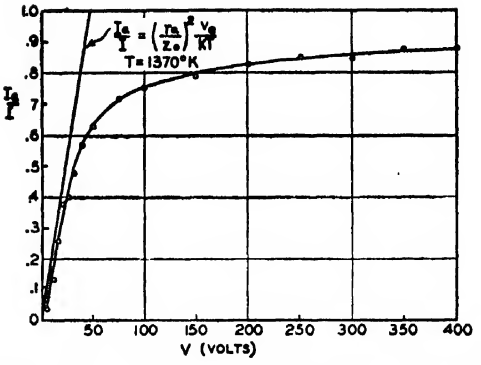

FIG. 16. Variation of beam efficiency with beam voltage. Current space charge limited between cathode and grid.

V, since I_a varies as $V^{\frac{1}{2}}$. Further, it is independent of gun size, since the ratio of x^2/a remains constant during scaling.

It is evident from the table that the SCN guns exceed all others in F value by a considerable factor. An important type of gun not listed in the table is one recently developed by O. Heil, for which very good results have been reported. This is not included, since published data are not yet available. It employs a very concave cathode, a wide-angle beam, and an optimized electrostatic focusing system.

VI. STABILITY

If reference is made to Fig. 11 it will be seen that at low pressures (10^{-5} mm of Hg) the oscilloscope trace is noise-free, but at higher pressures (90×10^{-6} and higher) there is a visible indication of noise. This is shown also in Fig. 19, which was taken with a beam voltage of 300, a current of 40 ma, and a pressure of 1.5×10^{-4} mm of Hg. It is noteworthy that the noise appears quite abruptly at a point where space charge neutralization apparently is completed. There is no evidence of it during the ion build-up period.

Reason to expect noise, and instability, under the observed conditions is found in the discussion of the equilibrium condition in Section III, and particularly in Eqs. (8) and (12). It was shown there that as the pressure increases, ΔV is at first negative, then passes through zero, and becomes positive. When ΔV is negative (potential depression) there is very nearly an exact equality of beam electron density and ion density. However, for ΔV positive, electron trapping starts,

and the electron and ion densities increase to some, at present, undetermined values. Furthermore, the temperature of the trapped electron gas in this case should be much higher than that of the trapped ion gas with ΔV negative. These conditions may well lead to noise production, and oscillations in the beam.

More specifically, noise has been found to be observable first at a pressure of approximately 10^{-4} mm of Hg. It rises to a maximum at 5×10^{-4}, and then remains constant to 10^{-3}, which is the upper limit of the experiments. It is seen that the threshold of 10^{-4} is in fair agreement with the theory, in that it is approximately at this value of p that ΔV changes from $-$ to $+$, as may be seen from Fig. 5.

FIG. 19. Oscillogram showing appearance of noise in SCN beam.

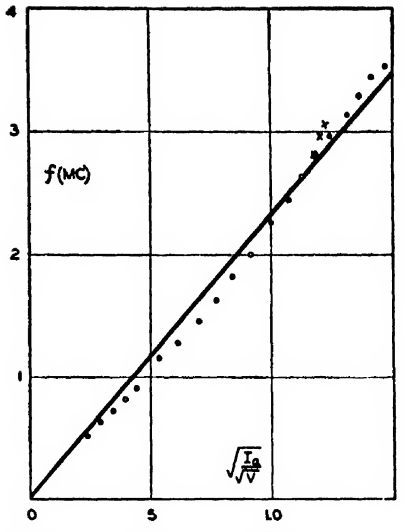

FIG. 20. Experimental beam oscillation frequency as a function of ion density.

Plasma ion oscillations also have been observed in the beam. These were found at the lowest pressures used, i.e., around 10^{-6}. They occurred up to $p=10^{-4}$ where they either ceased or were masked by the noise which begins at that pressure. It was not possible to determine which occurred.

For low pressures, the oscillation frequency was very distinct, and could be synchronized with an oscilloscope, or measured with a calibrated receiver. According to theory,[17] plasma ion oscillations have a frequency given by

$$f=\frac{1}{2\pi}\left(\frac{n_2e^2}{\epsilon_0M}\right)^{\frac{1}{2}}, \tag{19}$$

where M is the ion mass and n_2 the ion density. A measure of the ion density could be obtained from the current density at the aperture, and the beam voltage. Thus

$$f=K(I_a/V^{\frac{1}{2}})^{\frac{1}{2}}, \tag{20}$$

where K is a constant depending on ion mass. The agreement with this formula is shown in Fig. 20. The straight line represents Eq. (20) for a value of molecular weight of 41. This result seems high because the value for N_2 is 28, and O_2, 32, but since the identity of the trapped ions is unknown no definite conclusion can be drawn. However, the agreement is sufficiently good, so that there is little doubt that plasma ion oscillations are occurring.

No plasma electron oscillations were detected although they were sought over the range of from 80 to 1000 Mc, with the same tube as exhibited the ion oscillations.

Stress-Strain Properties of Natural Rubber under Biaxial Strain*

B. B. S. T. Boonstra
Delft, The Netherlands
(Received January 30, 1950)

Tube-shaped samples were stretched in a direction parallel to the tube axis and at the same time inflated to cause a tangential extension. In this way 600 percent axial and 300 percent tangential elongation could be attained simultaneously. The stresses were calculated from the pressure in the tube and the dynamometer readings.

The results are plotted as axial stress-strain curves at different tangential elongations ranging from 0–300 percent.

The curve for a higher tangential elongation lies at higher stresses than that for a lower tangential elongation; the differences are however larger than the theory predicts.

At 600 percent axial elongation stress relaxation was measured at different tangential elongations. It appears that the relaxation constant is independent of the tangential elongation.

INTRODUCTION

STRESS-STRAIN properties for rubber stretched in two directions have been reported by Ariano[1] and by Treloar.[2]

Both authors used rectangular test pieces and neither of them succeeded attaining high elongations because of the low tear resistance of rubber under biaxial stress.

High elongation was reached by the first author by inflating spherical samples, then however the strain in the majority of cases is about identical in the two directions. In this paper a system is described which allows stretching to high elongations in two directions independently of each other.

According to this method tube-shaped samples are stretched in the direction of the tube axis and at the same time inflated to cause a tangential elongation. The axial stress is partly measured on the dynamometer, the rest and the transverse stress is calculated from the air pressure in the tube. In this way stress-strain curves may be obtained for stresses parallel and at right angles to the tube axis as a function of the elongations in the two directions.

The theoretical equations extended to this case may then be checked. Besides, the decay of stress (axis-parallel) with time was measured and the influence of elongation perpendicular to this stress determined.

EXPERIMENTAL PROCEDURE AND RESULTS

Preparation of the Samples

Glass tubes of 16–25-mm diameter were repeatedly dipped in a latex dispersion of the following formula:

Rubber (in form of 40 percent latex)	100	
Colloidal sulfur	2	in form of 33 percent
Zinc oxide	2	dispersion with 0.2
Butyl zimate	1	percent Darvan
Latekoll (ammoniumpolyacrylate)	1	

After a layer of sufficient thickness was obtained (0.25–0.40 mm) the tubes were first dried at room temperature, then for 30 minutes at 80°C and finally vulcanized for 15–30 minutes at 110°C in live steam or hot air.

Dumb-bells punched out of these tubes showed the following properties:

Tensile strength	320–360 kg/cm²	
Elongation at break	750–800 percent	
Load at 300 percent elongation	17– 21 kg/cm²	
Hardness (shore *A*)	38	
Elasticity (shore *B*)	85	
Permanent set after 24 hours 200 percent elong.	measured after 1 hour	2.5 percent
	measured after 24 hour	0 percent

The rubber tubes are fastened on ribbed metal cylinders coated with a layer of vulcanized rubber (carbon black mix).

These cylinders can be attached to the dynamometer clamps; one of them has an air inlet connected to a manometer and a small hand operated air pump.

The tubes are elongated on a Schopper tensile tester (a) with air free to flow in and out, (b) inflated with air to the original diameter, (c) fastened on oversize clamp cylinders so that a constant transverse elongation can be maintained by pumping air into the tube.

The principle is illustrated in Fig. 1; some experimental values in Table I.

In calculating the stress in axis direction in case of definite transverse elongation, it has to be considered that the air pressure not only determines the tangential stress but also gives a contribution to the axial stress in form of pressure against the bottom and top plate of the cylinder.

Therefore the curves for inflated tubes do not begin at elongation zero but at a definite elongation determined by the air pressure necessary for the transverse elongation.

In Fig. 2 a number of curves, measured under different conditions is drawn, with axial stress, calculated on original cross section plotted against axial elongation.

The lowest curves are those measured without inflation, these practically coincide with the dumbbell curve;

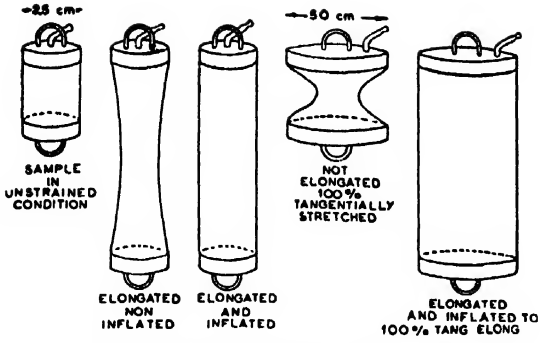

FIG. 1. Test samples for biaxial strain.

somewhat higher lies the curve for a tube which is not elongated sideways but inflated only to retain its original diameter. Considerably higher lie the curves for tubes with definite transverse elongations.

The pressure of the air, necessary to maintain a constant diameter of the tube at the different elongations is plotted as an average of several measurements against axial elongation in Fig. 3.

It will be observed in Fig. 3 that the pressure drops at the highest axial elongation for the 100 percent transverse elongation curve and also for the 300 percent elongation curve. Probably the rubber then has become so rigid that considerable changes in pressure are possible without much effect on the diameter of the tube.

The tangential stretching force on actual cross section is related to the pressure by the formula

$$\sigma = \frac{13.6 r \alpha_s}{1000(d/\alpha_s\alpha_z)} p \text{ kg/cm}^2 \text{ on actual cross section.} \quad (1)$$

Here r = original radius of the sample, mostly 12.5 mm, p = air pressure in cm Hg, α_z = axial extension ratio, α_s = transverse extension ratio, d = thickness of wall of the tube.

So at constant pressure and the same r, the actual stress in transverse direction is proportional to the

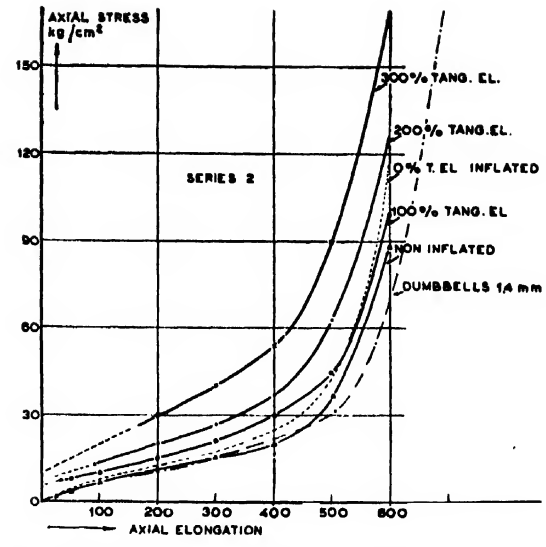

FIG. 2. Stress-strain curves at different tangential elongations.

square of the transverse elongation, (tr. el.)$^2 = \alpha_s^2$, this factor is four at 100 percent tr. el. and nine at 200 percent.

At the same pressures the actual stress at 200 percent tr. el. would be 9/4 of that at 100 percent tr. el. In reality however the stress ratio is lower, so it can happen that the pressure at 200 percent tr. el. is less than at 100 percent tr. el. (Fig. 3).

If the stress is plotted *vs.* the axial elongation, a set of curves is obtained as illustrated by Fig. 4.

In case the tangential tension is very small, for instance if the sample is not tangentially elongated, but only inflated to prevent contraction, the entity plotted in the figures was multiplied by ten; the stress in the direction of the axis is the actual value.

At 100 percent and higher transverse elongations the actual transverse stress has been plotted together with the stress in the direction of the axis, *vs.* axial elongation.

TABLE I. Some experimental values of tensile tests on inflated tube-samples (series 2) at 100 percent tangential elongation. Stresses are calculated in kg/cm² of the original cross section. r = original radius of the tube; α_z = Axial extension ratio; α_s = Tangential extension ratio; d = original thickness of the wall of the tube; p = air pressure in the tube in cm Hg.

Tangential elongation 100 percent		Axial elongation in percent 25	50	100	200	300	400	500	600

[a] General formula: $(13.6\pi r^2\alpha_s^2/2\pi rd1000)p$.
[b] General formula: $(13.6\alpha_s\alpha_s r/1000d)p$.

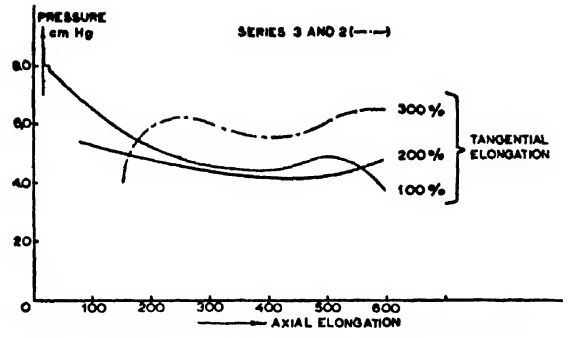

FIG. 3. Air pressure as a function of axial elongation.

It is clear from these figures that the tangential stress in all cases increases with axial elongation. The slope of this line increases with the transverse elongation.

Furthermore at a definite transverse elongation say 200 percent the tension must be equal to the stress parallel to the axis at an axial elongation of the same extent, in this case 200 percent. This is approximately true, however at 300 percent the referred stiffness of the tube caused somewhat higher values for the transverse stress.

RELAXATION

The decay with time of the stress parallel to the tube axis, was measured at the highest axial elongation i.e. 600 percent in the following way. The stress was measured at the moment of attaining the elongation of 600 percent and $\frac{1}{8}$—$\frac{1}{4}$—$\frac{1}{2}$—1—2—4—8—16 and 32 minutes after that.

A linear relationship is obtained if the stress is plotted *vs.* log time as is done for instance in Fig. 5.

The slope of this line $(F_{1/8}-F_{32}/-\log\frac{1}{8}+\log 32)$ is dependent on the original stress.

Instead of the original stress in our case the stress after one minute, F_1, is taken, as this value can be determined more accurately.

We calculated our relaxation constant from:

$$R_2=\frac{F_{1/4}-F_{16}}{6F_1}, \qquad (2)$$

taking the number 2 as a base of our logarithmic system.

The relaxation constant R_2 was calculated for measurements made with tubes under variable conditions. The results are put together in Table II.

It is apparent from these data that the tangential elongation does not exert much influence on the relaxation constant though the actual tension is much increased. Nor is there any influence of the nature of the mix in so far that soft sulfur-vulcanized rubber and thiuram vulcanized rubber show the same relaxation constant. However, if a mix with a greater amount of sulfur (e.g. five parts) is used the relaxation constant falls to considerably lower values. This holds almost independently of the time of cure of this latter compound.

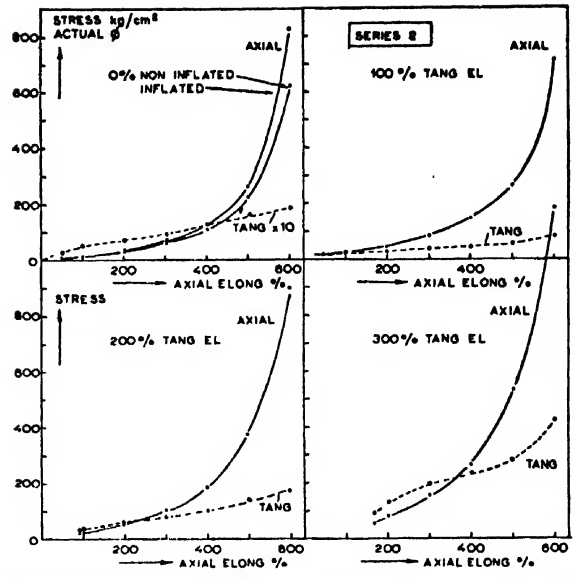

FIG. 4. Axial and tangential stress on actual cross section at biaxial elongation; rate of testing 30 cm per minute.

The relaxation constant is however sensitive to the axial elongation; at 500 percent the value is little more than half that at 600 percent elongation.

DISCUSSION

According to the now established statistical theory of elasticity[8] the elastic tension for unidirectional deformation is:

$$F=C[\alpha-(1/\alpha^2)]. \qquad (3)$$

If one of the cross dimensions (e.g. the circumference of the tube) is kept constant this formula changes into

$$F_c=C[\alpha-(1/\alpha^3)]. \qquad (4)$$

The following simple formulation of James and Guth's theory was kindly suggested by Ir. J. Bronkhorst of the Physical Department of the Rubber Foundation.

In Fig. 6, x, y, and z are dimensions of the rectangular sample. In

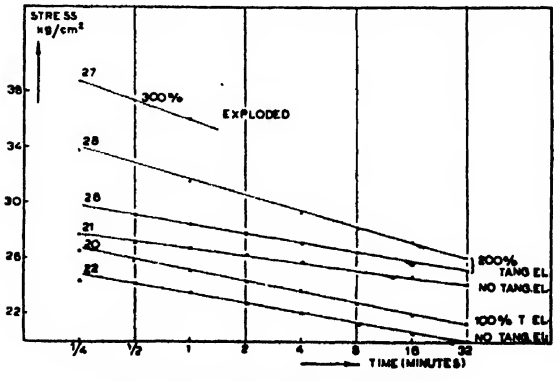

FIG. 5. Relaxation of stress with time.

[8] H. M. James and E. Guth, J. App. Phys. 15, 294 (1944); J. Chem. Phys. 11, 455 (1943).

unstrained condition $x=y=z=1$ cm. Then total molecular stress in x, y or z direction is $C=H$ (hydrostatic pressure in unstrained condition).

In a special strained condition x, y, z caused by forces F_x, F_y and F_z:

$F_x+Hyz=Cx=$ molecular tension
$F_y+Hxz=Cy$ $\quad x, y, z=1$ if the volume is considered constant.
$F_z+Hxy=Cz$

For unidirectional stress parallel to the x axis

$$F_y=F_z=0$$
$$Cy=Hxz$$
$$Cz=Hxy$$
$$F_x=Cx-Hyz=Cx-H/x$$
$$H=Cy/xz=C/x.$$
$$F_x=Cx-(C/x^2)$$

When z is kept constant by a force F_z, only $F_y=0$ (this is not exactly true as the inflation pressure represents a small negative value which is however neglected),

$$F_x+Hyz=Cx$$
$$Hxz=Cy$$
$$F_z+Hxy=Cz \quad H=Cy/xz=Cy^2=(C/x^2z^2).$$
$$F_x=Cx-Cy^2/x=C[x-(y^2/x)]=C[x-(1/z^2x^3)],$$
$$F_z=Cz-C(y^2/z)=C[z-(1/x^2z^3)].$$

Inflation to original diameter means $z=$ constant $=1$

$$F_x=C[x-(1/x^3)],$$
$$F_z=C[1-(1/x^2)].$$

Inflation to 100 percent transverse elongation ($z=2$):

$$F_x=C[x-(1/4x^3)],$$
$$F_z=C[2-(1/8x^3)].$$

Similarly at 200 percent transverse elongation:

$$\left.\begin{matrix}F_x=C[x-(1/9x^3)]\\F_z=C[3-(1/27x^3)]\end{matrix}\right\}.$$

At 300 percent transverse elongation:

$$\left.\begin{matrix}F_x=C[x-(1/16x^3)]\\F_z=C[4-(1/64x^3)]\end{matrix}\right\}.$$

For a definite elongation the second form is larger than the first one so it is to be expected that the stress-strain curve for a tube inflated to original cross section, will lie at higher stresses than the curve for the non-inflated tube. The difference should be relatively most pronounced at the lowest elongations.

The curves of Fig. 4 are not on a convenient scale to test these relations. In Table III several data are compared.

It appears from Table III that the axial stress of the inflated tube is relatively higher than would be expected from the theoretical formula. The stress of the non-inflated tubes at 100 percent and 200 percent corresponds with the less accurate values taken from dumbbells which amount to seven and ten kg/cm² respectively.

Similarly the ratio between axial stresses for non-inflated tubes and tubes inflated to 100 percent elongation is according to the theoretical derivation

$$\frac{\alpha-(1/\alpha^2)}{\alpha-(1/4\alpha^3)} \qquad (5)$$

In Table IV the calculated and experimental values are compared.

[b] These vulcanizates show a value of $R_3=$ about 0.013 at 500 percent axial elongation.

Though these figures are not very accurate they show a decided discrepancy with the calculated values; the experimental stresses being higher than those calculated.

This is even more obvious if we consider the transverse stress. Theory demands that the transverse stress, calculated on original cross section, shall remain practically constant at axial elongations above about 100 percent and under elongations where crystallinity disturbs the random configuration of the molecular network.

This is illustrated in Fig. 7 where the course of the

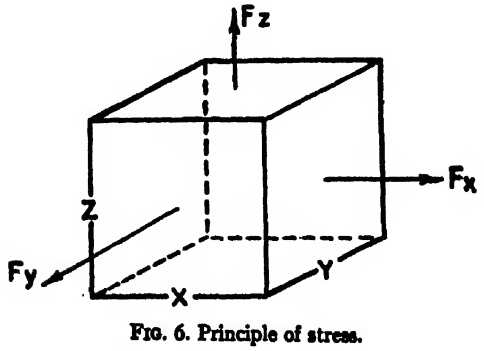

FIG. 6. Principle of stress.

Series 2	Axial elongation 50 percent	100 percent	200 percent
Non-inflated	3.4	6.5	10.8
Inflated	4.4	7.9	12.3
Quotient	0.78	0.82	0.88
Quotient calculated from $\frac{[\alpha-(1/\alpha^2)]}{[\alpha-(1/\alpha^2)]}=$	0.87[5]	0.93[5]	0.97[5]

tangential stress is plotted schematically for a definite value of C (i.e., $C=3.3$). This value of C can be calculated from the stress-strain curve (non-inflated or dumbbell sample) as it is the axial stress where $\alpha-1/\alpha^2=1$ or $\alpha=$about 1.47 (47 percent elongation).

In our series 2 and 3 there is only approximate agreement at the very lowest elongations in axial or tangential direction. For instance at 0 percent tang. el., which means that the tube is inflated only to maintain its original diameter, the calculated curve only at the very beginning is approximately followed by the experiment. At 100 percent trans. el. however the first points up to about 100 percent axial elongation show some slight agreement, at higher elongations the difference increases strongly. It is to be expected that the constancy of volume assumed in theory will not hold exactly but it cannot explain the wide difference between experiment and theory.

Nor is it to be expected that neglecting of the small negative force in the third direction (the air pressure against the inner wall of the tube) would make much difference in the course of the theoretical curves.

So it seems that whereas there is reasonable agreement between experiment and theory for unidirectional stress this is no longer the case as soon as simultaneous elongation in a second direction is applied.

The high stresses above 300 percent axial elongation may point to the fact that no equilibrium is reached; if the tube decreases a little in diameter during axial stretching and afterwards is inflated to the correct diameter a higher pressure will be necessary than when both operations are accurately synchronized.

Treloar in his experiments about two-dimensional strain plotted the force per cm length of the extended sheet[4] (analogous to surface tension). As in his studies

TABLE IV. Calculated and experimental ratio of axial stress for non-inflated tubes and tubes inflated to 100 percent tangential elongation at various axial elongations.

Axial elongation	50 percent	100 percent	200 percent
Ratio calculated from.....(5)	0.74	0.89	0.97
Ratio measured in series 2	0.40	0.60	0.72
Ratio measured in series 3	0.52	0.71	0.80

[4] L. R. G. Treloar, Trans. Faraday Soc. 39, 241 (1943).

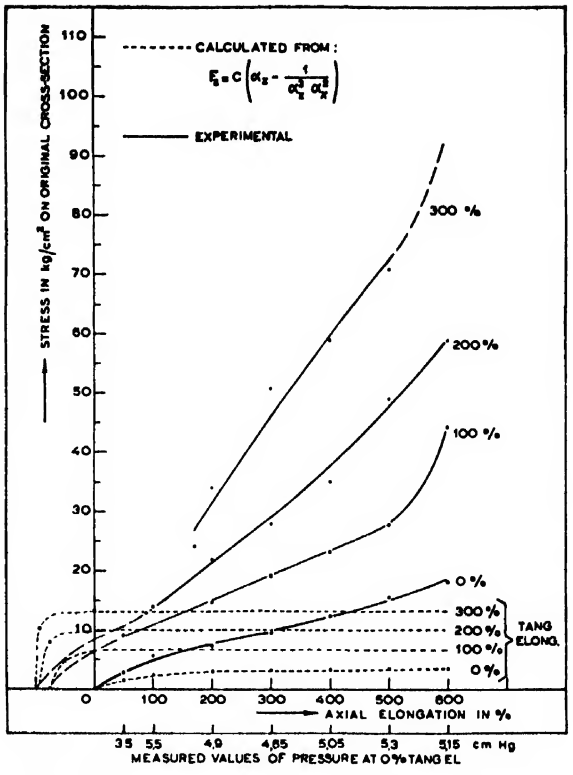

FIG. 7. Tangential stress as a function of axial elongation.

the strain in two dimensions was identical, the force per cm length of the sheet is

$$t=S_z/X^2=F_z/X=C\left(1-\frac{1}{X^6}\right)=C(1-\gamma^3), \quad (6)$$

when γ is the ratio of the final to the original thickness of the sheet and $X=Z$ the extension ratio in a direction parallel to the surface.

Treloar could show that the experimental tension force t at different extensions coincided with the theoretically derived equation

$$t=C(1-\gamma^3) \quad \text{for} \quad C=\text{about 4 kg/cm}^2$$

up to about 200 percent elongation ($\gamma=\frac{1}{3}$).

In our case the strain in the two principal directions is generally not the same but at every tangential elongation we have one moment where axial and tangential elongation are identical. In series V we have these cases at 56 percent, 100 percent, 200 percent, 275 percent and 300 percent elongation. At these points of identity of the two principal strains the stresses in the two perpendicular directions must be identical too; this appears to be the case with a deviation of about the experimental error of the stress measurements.

To compare our results with those of Treloar we have plotted the force t for these cases in Fig. 8 and it is evident from this figure that they agree fairly well with

theoretically calculated values for $C=5.7$ up to 200 percent elongation. This is shown in Table V.

So far there is agreement with theory as had been found by Treloar except that in our case the value of C is 5.7 against 4.0 in Treloar's experiments.

This however may be due to the different types of mixture used.**

In case the strains in the two perpendicular directions across the sheet are not identical we have two principal stresses and following again the method of plotting the entity t (stress per cm length of the sheet) we easily derive:

$$t_x=\frac{S_x}{XZ}=\frac{F_x}{Z}=C\left(\frac{X}{Z}-\frac{1}{X^3Z^3}\right)$$

and

$$t_z=\frac{S_z}{XZ}=\frac{F_z}{X}=C\left(\frac{Z}{X}-\frac{1}{X^3Z^3}\right)$$

for $X/Z=1$ this case simplifies again to the first problem. If we take however the strain situations, where X/Z is for instance $=2$ we would expect to find a similar curve as in Fig. 8 with the same value of C.

What actually is found Table VI illustrates. From Table VI it is evident that the C values do not agree with the C found for homogeneous two-dimensional strain and differ even when calculated from the axial and tangential stress respectively. So here also the deviations from theory are very pronounced. Mathematically these deviations may be accounted for partly by the treatment of Mooney[5] and more completely by that of Rivlin.[6]

The formula governing the relaxation which has been used here is

$$R=\frac{Ft_1-Ft_2}{Ft_1/(\log t_2-\log t_1)}; \qquad (7)$$

this expresses a constant decrease of stress in all time

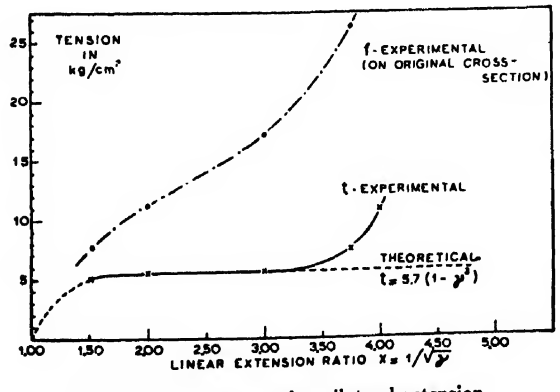

FIG. 8. Two-dimensional equilateral extension.

periods t_2-t_1, where $t_2=2t_1$ and t is counted from the moment the elongation was stopped. It is an approximation of the general formula of Tobolsky and Eyring.[7] It indicates that the decay of stress is the result of slippage of chain molecules along each other.

According to Flory[8] the relaxation results for the greater part from terminal chain slippage. This means that a rubber with longer primary molecules (before vulcanization) will have a lower relaxation constant than a rubber which has been thoroughly broken down to small molecular chains on the mixing mill.

If we compare two rubbers that have undergone the same milling treatment, so that we may assume about equal average molecular weight, but that have different degree of vulcanization, then the one with the highest cure will show the lower relaxation constant as the latter has the highest percentage of cross links and relatively the lowest number of terminal chains.

This is in agreement with the observation that the vulcanizate with five parts of sulfur shows a constant $R=0.014$ whereas the mixes vulcanized with 1.75 parts of sulfur and with thiuram only, show a value of $R=0.020$.

At these high elongations crystallization plays a part in stress-relaxation. The crystallites begin to form at about 250–300 percent elongation; this means that these first crystallites have a comparably low degree of

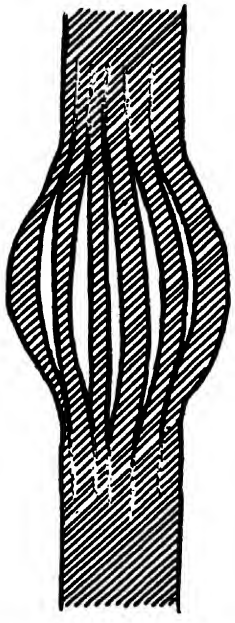

FIG. 9. Effect of inflation on a stretched sample.

orientation, lower than those formed at 400-500 percent elongation and these again are less orientated than crystals formed at 500–600 percent elongation.

In the latter state there are many crystallites that were in equilibrium with the surrounding amorphous mass at elongations much lower than 600 percent.

These strive to reach an equilibrium at the now (600 percent el.) prevailing conditions by re-crystallization and detaching of terminal chains from crystallites. It is probable that such a re-crystallization is a rather slow process as compared with the slippage of terminal chains but it is difficult to distinguish between them..

Mooney *et al.*[9] besides, report indications of a relaxation mechanism of a higher rate than that found in normal analysis; its existence was established on Shore Durometer readings $\frac{1}{10}$ sec. after stretching.

In our case however we would expect that transverse strain would severely hamper orientation and crystallization in axis parallel direction and diminish its contribution to stress-relaxation. The effect on crystallization can be experimentally shown by first strongly elongating one of our tube-samples and then inflating it. Very high air pressure is necessary to cause the first transverse elongation which then does not turn out homogeneously but occurs by a definite tearing of the opaque crystallized material into streaks of thinner and clear amorphous areas and remaining crystallized fiber-like bundles. This situation is schematically drawn in Fig. 9.

There has not been found definite influence of the transverse strain on the axial relaxation. It may be that the measurements, which are technically difficult to perform and absorb much time, have not been sufficiently accurate to distinguish the differences but then the effects could not be very pronounced.

CONCLUSIONS

(1) The stress-strain curves of vulcanized rubber held at definite tangential elongations during stretching differ more from the simple unidirectional-extension-stress curve than the theory predicts. The differences are larger at higher tangential elongations.

(2) The relaxation constant determined at 600 percent elongation is practically unaffected by tangential elongations up to 300 percent. The investigations are part of the work on fundamental properties of rubber of the Research Department of the Rubber-Stichting at Delft.

On the Endurance Limit of a Round Bar with Longitudinal Grooves

H. Ōkubo
Institute of High Speed Mechanics, Tōhoku University, Sendai, Japan
(Received June 2, 1950)

In a previous paper, we reached a consideration that the endurance limit of a material should be determined by the amount of the mean stress in a certain area around a point, instead of the stress at the point, and the extent of the area is determined for several kind of metals, by using the results of tension-compression fatigue tests.

In this paper, the extent of area where the mean value of stress to be taken, is determined for a mild steel in another way, viz., by a torsion fatigue test, and we reached the conclusion that the extent of area chiefly depends on the kind of metal and independent of the course of the experiment.

IN our previous study, the influence of the diameterical hole on the endurance limit of round bars has been investigated.[1] The theory of elasticity shows that the stress concentration around a diameterical hole of a round bar under tension, increases as the diameter of hole decreases and when the diameter of hole decreases infinitely, the stress concentration factor approaches 3.[2] While, according to our experimental results for several kinds of metals, with decrease in the diameter of the hole, the endurance limit increases, when the diameter of the hole is very small. The theory fails to explain the experimental results. The discrepancy between the theoretical and the experimental results arises from a fact that the theory assumes the material to be perfectly homogeneous and isotropic, while the metals in practical use are neither homogeneous nor isotropic. To correct the theory so as to meet the experimental results, we reached the consideration that when we determine the endurance limit, we must consider the mean stress in a certain area around the point, instead of the stress at a point. To simplify the calculation, we took up the mean value of the stress in a certain line, in place of the mean value in the area. The magnitude of the distance h where the mean value is taken, was considered to depend chiefly on the size of crystals of the metal and so it is a constant, determination of which is pending on the kind of metals. Under the above considerations, the values of h for some metals, determined by using our previous fatigue data, were

Mild steel	0.23 mm
Special steel	0.15 mm
Super-duralumin	0.13 mm

Our experiments for these metals were done by means of tension-compression tests using Haigh's testing machine.

In this paper, we shall determine the constant h for a mild steel in another way, *viz.*, by means of a torsion fatigue test, using specimens of round bars with longitudinal grooves as shown in Fig. 1. The specimens are cut out very carefully and the dimensions of grooves checked by a plate gauge which is measured accurately by a Zeiss comparator.

The mechanical properties of the steel are given in Table I.

The testing machine, used in our present experiment is of mechanical type. The specimen is placed in series with a weigh-bar, whose stress-strain relation has been previously obtained by statical loading experiments. The torque acting on the specimen is estimated by observing the twist of the weigh-bar and its twist is measured optically by means of a mirror placed at its moving end.

The scale is so graduated as to allow the direct reading of the maximum shearing stress for specimens of the diameter 10 mm. The fatigue data obtained in connection with the above mentioned program are given in Tables II and III. Figure 2 shows a fractured specimen with longitudinal grooves. The endurance limit of the steel is 11.5 Kg/mm².[3]

The fatigue cracks, appeared on the bottoms of grooves of specimens for different loadings, are shown in Fig. 3. When the magnitude of the reversed stress slightly passes over the endurance limit, very small cracks, as shown in Fig. 3(a), begin to appear locally on the bottom of the groove. According as the stress increases, the small cracks appear at every part of the bottom and join together, and then some of the enlarged cracks spread along the bottom of the groove (Fig. 3(b)), and finally the specimen is broken. We shall define the endurance limit for the specimens with grooves, by the

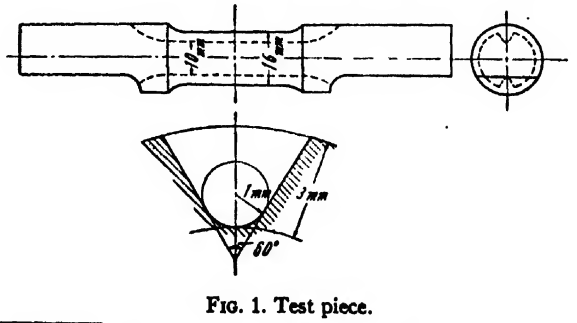

FIG. 1. Test piece.

[3] For the endurance limit of specimens without grooves, the maximum stress is taken, since the variation in the interval h is very small.

FIG. 2.

limiting value of the stress, below which cracks will not occur. Then, the reading corresponding to the endurance limit for the specimens with grooves will be determined from Table III, as 17.3 Kg/mm².

Next, we shall make some calculations to find the stress distribution in the specimen corresponding to the reading.

Let us consider a circular cylinder of the cross section as shown in Fig. 4, and take the axis of z to be parallel to the generators of the cylinder. Then the stresses which do not vanish are

$$X_z=\mu\tau\left(\frac{\partial\phi}{\partial y}-y\right),\quad Y_z=-\mu\tau\left(\frac{\partial\phi}{\partial x}-x\right),\qquad(1)$$

where μ and τ represent the modulus of rigidity and the twist respectively. The function ϕ satisfies the equation

$$\partial^2\phi/\partial x^2+\partial^2\phi/\partial y^2=0,\qquad(2)$$

at all points within the bounding curve of the cross section, and at the boundary the condition

$$\phi-\tfrac{1}{2}(x^2+y^2)=\text{const.}\qquad(3)$$

We shall consider a function ϕ in the form[4]

$$\phi=\frac{(1-r^4)A_0}{1+r^4-2r^2\cos2\theta}+A_1\left\{\frac{1-a_1^2r^2\cos2\theta}{1+a_1^4r^4-2a_1^2r^2\cos2\theta}-\frac{r^4-a_1^2r^2\cos2\theta}{a_1^4+r^4-2a_1^2r^2\cos2\theta}\right\}.\qquad(4)$$

11	*±17.3*	1.000×10^7	uncracked

The above function satisfies the Eq. (2), and is singular at the two points ($\theta=0,\ \pi$) on the bounding circle and at the two points ($r=a_1,\ \theta=0,\ \pi$) within the circle (a_1 being assumed to be smaller than unity).

From Eqs. (3) and (4), the equation which represents the boundary of the cross section is

$$\frac{(1-r^4)A_0}{1+r^4-2r^2\cos2\theta}+A_1\left\{\frac{1-a_1^2r^2\cos2\theta}{1+a_1^4r^4-2a_1^2r^2\cos2\theta}-\frac{r^4-a_1^2r^2\cos2\theta}{a_1^4+r^4-2a_1^2r^2\cos2\theta}\right\}-\tfrac{1}{2}r^2=-\tfrac{1}{2}.\qquad(5)$$

Equation (5) represents a circle of radius unity and the two curves represented by the equation:

$$\frac{A_0}{1+r^4-2r^2\cos2\theta}+\frac{A_1\{a_1^4(1+r^4)-a_1^2(1+a_1^4)r^2\cos2\theta\}}{(1+a_1^4r^4-2a_1^2r^2\cos2\theta)(a_1^4+r^4-2a_1^2r^2\cos2\theta)}+\frac{1}{2(1+r^2)}=0.\qquad(6)$$

When the curve represented by Eq. (6), agrees almost with the shape of the given notch, then we can use the Eq. (4), as an approximate solution for the problem.

To determine the unknown constants A_0 and A_1 in Eq. (4), we shall assume that the curve represented by Eq. (6) passes through the two points ($r=0.625$, $\theta=0°$ and $r=0.81623$, $\theta=12°10'$) on the periphery of the notch, then assuming $a_1=0.7562$, we have

$$A_0=-0.065507,\quad A_1=-0.045069.$$

If we denote the radius of curvature at the bottom of the notch by ρ, then

$$\rho=\frac{b^2}{b-(d^2r/d\theta^2)_0},\qquad(7)$$

where

$$\left(\frac{d^2\chi}{d\theta^2}\right)_0=-\frac{[8A_0b^2(1+b^2)/(1-b^2)^3]+4A_1a_1^2b^2\{[1+a_1^2b^2/(1-a_1^2b^2)^3]+[a_1^2+b^2/(a_1^2-b^2)^3]\}}{b-[4A_0b/(1-b^2)^2]-2A_1a_1^2b\{[1/(1-a_1^2b^2)^2]+[1/(a_1^2-b^2)^2]\}},$$

and b is the distance from the center of the cross section to the bottom of a notch.

Putting $b=0.625$, it becomes $\rho=0.1250$. The curve represented by Eq. (6), is shown by a dotted line in Fig. 4, which agrees practically with the given shape of the notch as is shown in the figure. Accordingly, using the solution given by Eq. (4), we shall proceed with our further calculations.

The stress on the x axis is calculated from Eq. (1), as

$$Y_x=\mu\tau\left\{r-\frac{4A_0r}{(1-r^2)^2}-2A_1a_1^2r\left(\frac{1}{(1-a_1^2r^2)^2}+\frac{1}{(a_1^2-r^2)^2}\right)\right\}, \quad (8)$$

and so the mean value of the stress from the bottom of the notch to a distance h along the x axis is

$$\bar{Y}_x=\frac{1}{h}\int_{b-h}^{b}Y_x dr=\frac{\mu\tau}{h}\left|\frac{r^2}{2}-\frac{2A_0}{1-r^2}-A_1\left(\frac{1}{1-a_1^2r^2}+\frac{a_1^2}{a_1^2-r^2}\right)\right|_{b-h}^{b}. \quad (9)$$

The value of $\bar{Y}_x$ varies with the magnitude of the distance h, and the relation between $\bar{Y}_x$ and h, calculated by Eq. (9), is shown in Fig. 5. The torque acting on the cylinder is[5]

$$T=\mu\tau\left(I-\oint\psi\frac{\partial\phi}{\partial s}ds\right), \quad (10)$$

where I is the polar moment of inertia of the cross section about z axis, ψ is a function conjugate with ϕ and

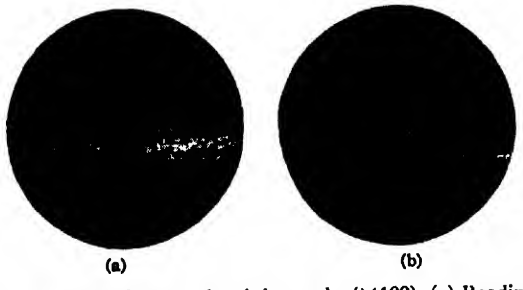

FIG. 3. Micro-photographs of the cracks (×100). (a) Reading of the nominal range of stress, ±17.8 Kg/mm². No. of repetitions $=1.019\times10^7$. (b) Reading of the nominal range of stress, 25.5 Kg/mm². No. of repetitions $=1.043\times10^7$.

[5] H. Love, *The Mathematical Theory of Elasticity* (1927) 4th Ed., p. 312.

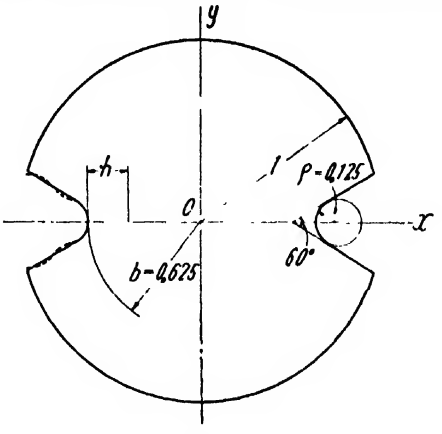

FIG. 4.

given by

$$\psi=-\frac{2A_0r^2\sin2\theta}{1+r^4-2r^2\cos2\theta}-A_1a_1^2r^2\sin2\theta\left\{\frac{1}{1+a_1^4r^4-2a_1^2r^2\cos2\theta}+\frac{1}{a_1^4+r^4-2a_1^2r^2\cos2\theta}\right\},$$

and the integral is taken around the bounding curve of the cross section.

For the section, shown in Fig. 4,

$$I=1.398 \quad \text{and} \quad \oint\psi\frac{\partial\phi}{\partial s}ds=0.311,$$

and hence

$$T=1.087\mu\tau.$$

The torque T_0 acting on a cylinder of radius 0.625 without grooves, when twisted by the amount τ_0 is

$$T_0=0.2397\mu\tau_0.$$

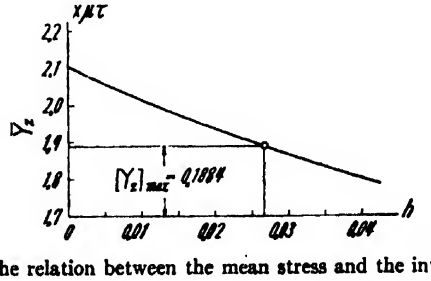

FIG. 5. The relation between the mean stress and the interval h.

Hence, we have

$$T_0/T=0.2205(\tau_0/\tau).$$

According to our fatigue data for a cylinder of radius 5 mm, without grooves, the endurance limit of the metal is 11.5 Kg/mm². While the reading corresponding to the endurance limit for a cylinder of radius 8 mm with grooves is 17.3 Kg/mm². The reading does not denote directly the maximum stress but represents the value proportional to the torque acting on the specimen, when the dimensions of the specimen differ from the standard type (a cylinder of radius 5 mm without grooves), subsequently

$$T_0/T=11.5/17.3,$$

and hence

$$0.2205(\tau_0/\tau)=11.5/17.3,$$

or

$$\tau_0=3.015\tau.$$

The maximum stress arises in a cylinder of radius 0.625, when twisted by the amount τ_0 is

$$[Y_z]_{max}=0.625\mu\tau_0=1.884\mu\tau.$$

The endurance limit of a metal, however, is a constant, which is independent of the form or the size of the specimen. Subsequently, $[Y_z]_{max}$ must be equal to Y_z, by virtue of our previous assumption that for the determination of the endurance limit of specimens, the mean value of stress in the interval h must be taken up instead of the maximum stress.

If we determine h from our fatigue data, so as to satisfy the above mentioned condition (see Fig. 5), it becomes

$$h=0.0265,$$

or

$$h=0.21 \text{ mm}.$$

The value of h for a mild steel, previously obtained by using our tension-compression fatigue data is

$$h=0.23 \text{ mm},$$

and the results almost agree in two cases.

From this result, we can conclude that the value of h depends only on the kind of metal, and independent of the course of the experiment.

The Magnetic Field of a Plane Circular Loop

C. L. BARTBERGER

Naval Air Experimental Station, Philadelphia, Pennsylvania

(Received March 9, 1950)

The axial and radial components of the magnetic field of a plane circular loop are expressed in terms of cylindrical coordinates. The expressions involve two integrals which are related to certain of the complete elliptic integrals. Tables of values of these integrals are presented. Interpolation in these tables facilitates rapid calculation of the field components.

INTRODUCTION

THE problem of calculating the radial and axial components of the magnetic field produced by the current in a plane circular loop of wire is well known and has been treated in numerous textbooks.[1,2] Recently Blewett,[3] making use of the solution in terms of cylindrical coordinates and complete elliptic integrals, has computed and tabulated the values of the field components of numerous points in the vicinity of the loop. Such a tabulation, however, has the difficulty of being two-dimensional, since the field is a function of both the axial and radial coordinates. It is therefore not practical to tabulate the field at a sufficient number of points to permit easy interpolation.

A few years ago the need arose to determine the magnetic field produced by a pair of Helmholtz coils which were used for testing aircraft compasses. The solution was carried out in cylindrical coordinates by a slightly different method from that used by Blewett. The resulting expressions for the field components are relatively simple and involve two integrals which are related to certain of the complete elliptic integrals. Once these integrals have been evaluated, the computation of the field components to high accuracy becomes a simple matter. It is the purpose of this paper

to publish tables of values of the two integrals together with formulas for their use. Values are given for sufficiently small increments of the argument to permit linear interpolation throughout the greater part of the tables.

MAGNETIC FIELD COMPONENTS DUE TO CURRENT IN A PLANE CIRCULAR LOOP

If z and ρ represent axial and radial coordinates measured from the center of the loop, the axial and radial components of the magnetic field can be expressed as follows:

$$H_z=(H_0/s^3)[I_1-(\rho/a)I_2] \tag{1}$$

$$H_\rho=(H_0z/s^3a)I_2, \tag{2}$$

where a = radius of the loop, $s^2=(a^2+z^2+\rho^2)/a^2$, and H_0 = field at center of loop. The integrals I_1 and I_2 are

$$I_1=\frac{1}{\pi}\int_0^\pi \frac{d\theta}{(1-b\cos\theta)^{\frac{3}{2}}} \tag{3}$$

$$I_2=\frac{1}{\pi}\int_0^\pi \frac{\cos\theta d\theta}{(1-b\cos\theta)^{\frac{3}{2}}}, \tag{4}$$

where

$$b=\frac{2a\rho}{a^2+z^2+\rho^2}. \tag{5}$$

The integrals I_1 and I_2 can be expressed in terms of complete elliptic integrals if the following substitutions are made:

$$\phi=\tfrac{1}{2}(\pi-\theta) \tag{6}$$

$$k^2=2b/(1+b). \tag{7}$$

The results are

$$I_1=\frac{2}{\pi}\frac{(1-k^2/2)^{\frac{1}{2}}}{1-k^2}E \tag{8}$$

$$I_2=\frac{2}{\pi}\frac{(1-k^2/2)^{\frac{1}{2}}}{1-k^2}(2B-E), \tag{9}$$

where

$$E=\int_0^{\pi/2}(1-k^2\sin^2\phi)^{\frac{1}{2}}d\phi \tag{10}$$

and

$$B=\int_0^{\pi/2}\frac{\cos^2\phi d\phi}{(1-k^2\sin^2\phi)^{\frac{1}{2}}}. \tag{11}$$

SERIES EXPRESSIONS FOR INTEGRALS

If the integrands are expanded in series and integrated term by term, the following expressions are obtained for I_1 and I_2:

$$I_1=1+\frac{3\cdot5}{4\cdot4}b^2+\frac{3\cdot5\cdot7\cdot9}{4\cdot4\cdot8\cdot8}b^4+\frac{3\cdot5\cdot7\cdot9\cdot11\cdot13}{4\cdot4\cdot8\cdot8\cdot12\cdot12}b^6+\cdots \tag{12}$$

$$I_2=-\frac{3}{4}b+\frac{3\cdot5\cdot7}{4\cdot4\cdot8}b^3+\frac{3\cdot5\cdot7\cdot9\cdot11}{4\cdot4\cdot8\cdot8\cdot12}b^5+\cdots. \tag{13}$$

For values of b near unity these series converge slowly. With the aid of expressions for E and B in the neighborhood of $k=1$, I_1 and I_2 can be expressed as series in powers of $(1-b)$. Let

$$k'^2=1-k^2$$

Then[4]

$$E=1+\sum_{n=1}^{\infty}\frac{1^2\cdot3^2\cdots(2n-3)^2(2n-1)}{2^2\cdot4^2\cdots(2n-2)^2 2n}(\Lambda-e_n)k'^{2n} \tag{14}$$

$$B=1-\sum_{n=1}^{\infty}\frac{1^2\cdot3^2\cdots(2n-3)^2(2n-1)^2}{2^2\cdot4^2\cdots(2n-2)^2 2n}(\Lambda-b_n)k'^{2n}, \tag{15}$$

where

$$e_n=\frac{1}{2n}\left[1+\frac{6n-2}{1\cdot1\cdot3}+\frac{10n-4}{2\cdot3\cdot5}+\cdots+\frac{(2n-1)2n-(2n-2)}{(n-1)(2n-3)(2n-1)}\right] \tag{16}$$

$$b_n=\frac{1}{2n}\left[2n+1+\frac{2n-2}{1\cdot1\cdot3}+\frac{2n-4}{2\cdot3\cdot5}+\cdots+\frac{2}{(n-1)(2n-3)(2n-1)}\right] \tag{17}$$

$\Lambda=\ln 4/k'$.

The integrals I_1 and I_2 become

$$I_1=\frac{\sqrt{2}}{\pi}\left\{\left[\frac{1}{1-b}+\frac{1}{8}-\frac{13}{256}(1-b)-\frac{103}{1024}(1-b)^2-\frac{86567}{786432}(1-b)^3-\cdots\right]+\Lambda\left[\frac{1}{4}+\frac{15}{64}(1-b)+\frac{195}{1024}(1-b^2)+\frac{4935}{32768}(1-b)^3+\cdots\right]\right\} \tag{18}$$

$$I_2=\frac{\sqrt{2}}{\pi}\left\{\left[\frac{1}{1-b}+\frac{9}{8}+\frac{307}{256}(1-b)+\frac{1263}{1024}(1-b)^2+\frac{327219}{262144}(1-b)^3+\cdots\right]\right.$$

[4] F. Jahnke and E. Emde, *Tables of Functions* (Dover Publications, New York, 1933), pp. 73.

$$-\Lambda\left[\frac{3}{4}+\frac{57}{64}(1-b)+\frac{945}{1024}(1-b)^2+\frac{30345}{32768}(1-b)^3+\cdots\right]\Big\} \quad (19)$$

$\Lambda=\ln 4-\frac{1}{2}\ln[(1-b)/(1+b)]$.

THE TABLES

Table I lists values of I_1 for values of b in increments of 0.001 from 0 to 0.800. Table II lists corresponding values of I_2. Table III lists values of I_1, I_2, I_1-I_2, $(1-b)I_1$, and $(1-b)I_2$ for values of b in increments of 0.001 from 0.800 to 1.000. Table IV lists values of the same five functions for values of b in increments of 0.0001 from 0.9950 to 1.0000. The difference I_1-I_2 is included to facilitate the computation of H_s in the vicinity of $b=1$ (near the wire). In this case Eq. (1) involves the subtraction of two large quantities which are nearly equal. This difficulty can be circumvented by using I_1-I_2 as follows:

$$H_s=(H_0/s^3)\{(I_1-I_2)+[1-(\rho/a)]I_2\}.$$

The functions $(1-b)I_1$ and $(1-b)I_2$ are of value in computing I_1 and I_2 in the vicinity of $b=1$, since they lend themselves to linear interpolation.

Effect of Coating Composition of Oxide-Coated Cathodes on Electron Emission

E. G. Widell and R. A. Hellar
Tube Department, RCA Victor Division, Harrison, New Jersey
(Received June 6, 1950)

Investigation of oxide-coated cathodes has been made to determine the effect on electron emission of varying the proportions of emitting oxides. The results show that maximum electron emission under saturation conditions is obtained from a solid solution containing strontium oxide (SrO) and barium oxide (BaO) in an approximate molecular ratio of 7 to 3.

These results also indicate that maximum size of the co-precipitated alkaline-earth carbonate particle occurs at the same molecular ratio as that giving maximum electron emission from the oxides.

When the saturation emission obtained with a square-wave voltage pulse was measured, the current pulse as observed on a synchroscope was also a square wave and showed no measurable decay characteristic for a pulse duration time of 10 microseconds.

INTRODUCTION

MANY investigations have been made of the thermionic emission from alkaline-earth oxide-coated cathodes. However, only a few have considered the relation between emission capability and coating composition. In general, coatings have followed a 50–50 ratio of barium and strontium oxides either as weight percent or as molecular percent and have been applied in the form of a mechanical mixture or co-precipitate of the carbonates.

Arnold[1] in 1920 reported that the highest emission was obtained from BaO alone but an equal quantity of SrO was added to improve life. Simon[2] in 1927 found two emission maxima, the first at about 85 percent SrO–15 percent BaO, and the second at about 85 percent BaO–15 percent SrO (weight percent). BaO alone yielded about 70 percent of the emission obtained from a 50–50 ratio. No other investigator finds two maxima. In 1933, Benjamin and Rooksby[3] reported maximum electron emission from a molecular weight ratio of 63 percent SrO and 37 percent BaO. Huber[4] in 1941 obtained a maximum for the BaO—SrO system at about 55 percent BaO with an emission value about ten times as great as from BaO alone. Veenemans[5] in 1943 published a curve showing maximum emission at approximately 75 molecular percent of SrO. Weinreich[6] reported in 1945 that a BaO—SrO cathode coating containing 98.2 percent SrO yielded approximately the same surface emission as coatings containing lesser amounts of SrO. Eisenstein[7] in 1946 stated that Fineman of the M.I.T. Radiation Laboratory obtained the same pulsed electron emission from BaO alone as from a coating containing 50 percent BaO–50 percent SrO.

In view of all these apparent contradictions and because present-day requirements for high electron-emission currents under pulsed conditions again focus attention on types of oxide coatings which yield maximum currents, it was thought desirable to reinvestigate this subject.

MATERIALS AND CONSTRUCTION

The carbonates were prepared by co-precipitation from nitrate solutions using sodium carbonate as the precipitating agent with constant conditions of precipitation except for change in ratios of the two components. The strontium carbonate actually contained 1.0 percent $BaCO_3$ while the barium carbonate contained 0.2 percent $SrCO_3$, but for purposes of comparison the values are listed as 100 percent for both carbonates and oxides.

The cathode sleeves were made of Grade *A* nickel which, by spectrographic analysis, contained 0.2 percent silicon, 0.045 percent magnesium, 0.10 percent manganese, 0.07 percent iron, 0.04 percent copper, and less than 0.02 percent titanium. Oxide inclusions were not measured. The sleeves were 25 millimeters long and had an outside diameter of 0.762 millimeters. They were cleaned by electropolishing before being coated in order to remove surface contaminations.

The carbonates were milled for 45 hours under identical conditions in the usual organic solvents with nitrocellulose as a binder, and were sprayed on the central 10-millimeter portion of the cathode sleeves. The average weight of the sprayed coating was 3.4 mg/cm² with a thickness of 0.044 millimeter giving an average coating density of about 0.73 g/cm³.

At least five tubes were used for testing each ratio of oxides in order to obtain more dependable results than could be obtained by the use of a single tube. In order to obtain even temperatures throughout the length of the coated cathodes, only 10 millimeters of the central portions of each cathode sleeve were coated. Optical pyrometer measurements showed a variation of less than 10°K between the center and the ends of the coated portion. The bare ends of the sleeves were carefully cleaned to prevent unwanted electron emission. Tests with a specially constructed tube showed that the coated portion gave a thousand times more emission than the bare portions; therefore, emission from the

bare portions could be neglected The cathodes were mounted in a standard diode in which carbonized plates with inside diameters of 1.78 millimeters were used. Each tube received the same exhaust on an all-glass system using liquid air with mercury diffusion pumps and was sealed off after flashing a Ba—Mg getter. All tubes were given the same aging schedule

MEASUREMENTS

Structural Characteristics of the Carbonates

The particle sizes of the carbonates as precipitated were measured by the Andreasen pipette sedimentation method. The "average" particle size reported is the particle size for the 50 percent point on the curve showing cumulative weight percent *versus* particle size. These data are shown in Table I and are compared with emission data in Fig. 6. X-ray diffraction patterns indicate that the carbonate crystals of the 50–50 ratio have an aragonite structure. Electron microscope pictures of 100 percent $BaCO_3$, 70 percent $BaCO_3$–30 percent $SrCO_3$, 30 percent $BaCO_3$–70 percent $SrCO_3$, and 100 percent $SrCO_3$ are shown in Fig. 1. These pictures show the change in particle size with change in ratios of the carbonates. Particle or crystallite measurements of the 70 percent $BaCO_3$–30 percent $SrCO_3$ were made by the method of low angle scattering of x-rays using $K\alpha$-radiation at 35 kilovolts and 15 milliamperes, filtered by nickel; the x-ray film was spaced 50 centimeters from the specimens. These results are shown in Table II. The particle size as determined by this method may be the measurements of single or small groups of crystallites since the diameters are less than 200 angstroms, whereas the particle sizes as measured by the electron microscope or by the Andreasen pipette are a hundred times greater The above data show that both the particles and the crystallites of the 70 percent $SrCO_3$–30 percent $BaCO_3$ are about 1 5 times larger than those of the 30 percent $SrCO_3$–70 percent $BaCO_3$

Cathode Temperatures

Cathode temperature measurements were made with a disappearing-filament type of optical pyrometer ($\lambda = 0.665\mu$). The cathodes were initially adjusted to a brightness temperature of about 1000°K in order to

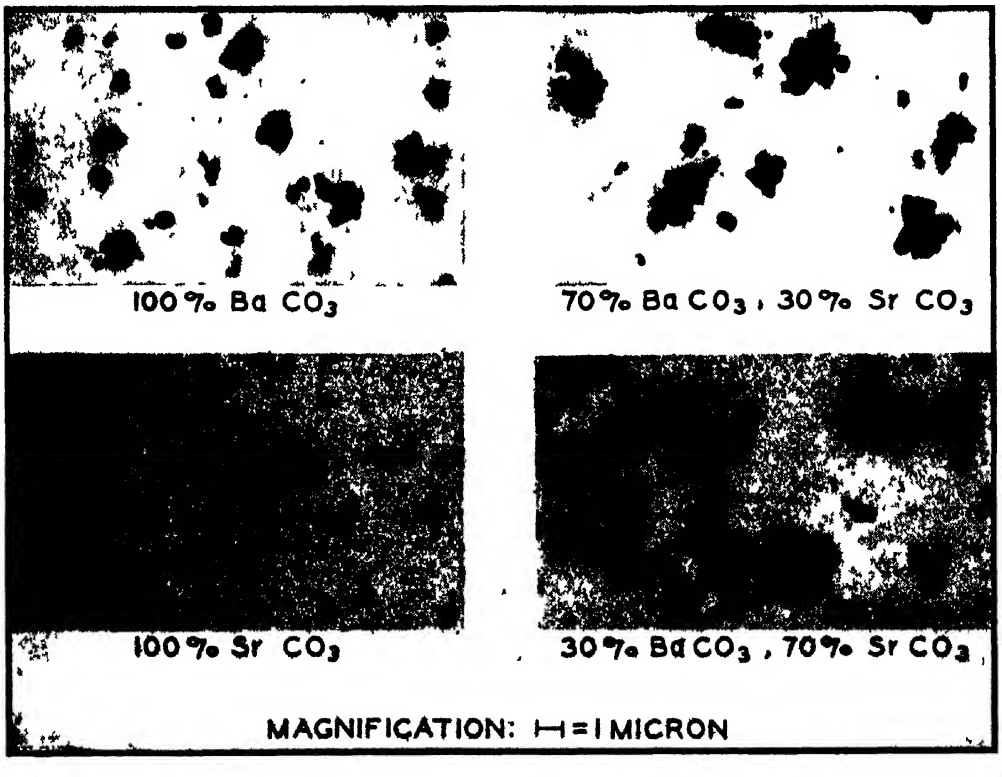

FIG 1 Electron micrographs of carbonate particles.

TABLE II. Particle size measurement by low angle scattering of x-rays.*

Type of carbonate	$r=1.0$	1.5	2.0	2.5	3.0
70% $SrCO_3$–30% $BaCO_3$	$R=105$	79	67	48	38
30% $SrCO_3$–70% $BaCO_3$	$R=63$	58	44	34	32

* r = distance from center of beam on film in millimeters. R = radius of particle in angstrom units.

limit electron emission and thus limit the heating up of the tube parts and cathode coatings during testing. The true temperature was then about 1030°K based on a spectral-emissivity (0.665μ) value of 0.56 for this type of coating obtained from unpublished data in this laboratory. The cathode temperatures shown in Table I are brightness temperatures (with no correction for glass absorption) and are averages for five tubes in each test.

Electron Emission

The emission measurements were made on a pulse emission tester designed to produce microsecond rectangular pulses. The pulse duration was set at 3 microseconds and the repetition rate at 500 pulses per second. A synchroscope showed wave forms of voltage and current to be square. Each measurement plotted represents an averaged reading for five or more tubes. The results are shown in Figs. 2, 3, and 4. Figure 5 compares these data with those of Benjamin and Rooksby, and of Veenemans.

Emission Decay

For measurements of relative values of emission for the various ratios of oxides under pulse-testing conditions, it may be necessary to consider the effect of emission decay characteristics as reported by Sproull[8] who found a considerable decay of emission during a 10-microsecond pulse. Coomes[9] also mentions this effect, stating that Ramsay of the Bartol Foundation found

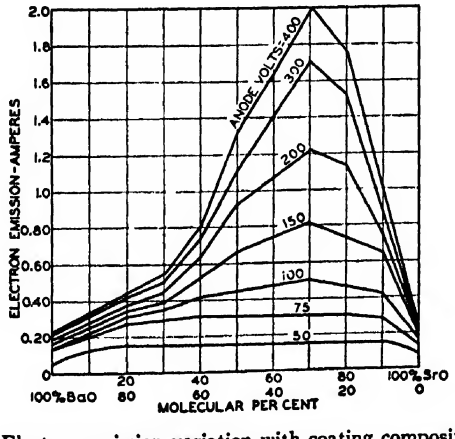

FIG. 2. Electron emission variation with coating compositions at different anode potentials.

short-time (10^{-6} second) emission decay in aged cathodes but not in very active cathodes. Observations for this effect were made on the cathodes with a 10-microsecond pulse. The emission pulse, observed on a synchroscope, had a square wave form and showed no measurable decay during this pulse period.

Decay effects have been observed in this laboratory from cathodes in tubes of the same construction but made for testing different materials. The decay effect in this case, about 40 percent decay during a 10-microsecond pulse, occurred only in those tubes which showed a heavy cathode poisoning effect as evidenced by

slumping emission when measured under steady d.c. testing conditions.

DISCUSSION

The Effect of Oxide Ratios on Electron Emission

Figure 2 shows the variation in electron emission for various percentages of BaO and SrO and at various anode voltages. At saturation the curves peak at 70 percent SrO–30 percent BaO (molecular percent). The emission for 100 percent BaO is lower than that observed in previous tests on similar cathodes but this difference may partly be accounted for by the 25° lower operating temperature of this set as shown in Table I. A previous test by Wolfgang Panofsky* of this laboratory showed a much flatter curve with the emission from the BaO about 80 percent of that from the 50–50 ratio but the emission values for the higher percentages of BaO were not stable and decreased during operation.

Figure 4 shows the emission data plotted according to the $\frac{3}{2}$-power law. The large deviations from the normal in the Schottky region for the very highest emission values are due to heating up of the cathodes which could have been lessened if a shorter pulse duration and a lower pulse repetition rate were used.

Comparison with Previous Investigations

When the data obtained in this investigation are compared with those of previous investigators, as shown in Fig. 5, emission values were selected at an anode voltage of 200 volts (about 6500 volts/cm at the cathode) because at that voltage all of the cathodes approached emission saturation. A better comparison might have been made if all investigators had reported zero field emission. Values of emission are given in terms of percent of maximum to facilitate comparison with the published curves of Benjamin-Rooksby and of Veenemans. All three curves have approximately the same general shape except that the Benjamin-Rooksby curve peaks at 63 percent SrO–37 percent BaO while the curve from this investigation peaks at 70 percent $SrCO_3$–30 percent $BaCO_3$.

The Effect of Particle Size on Electron Emission

There has been some discussion in the literature as to the effect of crystal size and particle size on electron emission from oxide-coated cathodes. The change in particle size with variation in ratios of the carbonates when precipitated under identical conditions was measured and the data are shown in comparison with electron emission data in Fig. 6. The curve for the particle size of the carbonates peaks at the same molecular ratio which yields maximum electron emission from the oxide. Although the agreement between the two curves may be merely a coincidence, this subject is being further investigated.

CONCLUSIONS

Maximum electron emission from oxide-coated cathodes consisting of solid solutions of BaO and SrO occurs when the oxides have a molecular percentage of 70 percent SrO and 30 percent BaO.

The maximum size of the precipitated carbonate crystal in the system of $BaCO_3$—$SrCO_3$ occurs at the same molecular ratio which gives the maximum electron emission from the oxides.

There is a close relationship between the size of the carbonate particles and the size of their crystallites as shown by comparing the measurements obtained by the Andreasen pipette with those obtained by the low angle scattering of x-rays on the 70–30 and the 30–70 ratios of carbonates.

The tubes of this test exhibited no measurable electron-emission decay during a 10-microsecond pulse duration.

ACKNOWLEDGMENTS

The authors wish to acknowledge their indebtedness to Miss Irene Kakascik for making the electron micrographs, and to Mr. R. B. DeLong for making the determinations of crystal size by low angle scattering of x-rays.

Surface Waves and Their Application to Transmission Lines

GEORG GOUBAU
Radio Communication Branch, Coles Signal Laboratory, Fort Monmouth, New Jersey
(Received March 10, 1950)

In this paper the applicability of non-radiating surface waves for transmission lines is investigated. Two types of waves are considered. The first one, originally studied by A. Sommerfeld, is guided by a cylindrical conductor of finite conductivity. Although this wave type has (under comparable conditions) much lower attenuation than the waves in coaxial cables or rigid wave guides, its practical application is restricted by the fact that the extension of the field is very large. Efficient excitation and undisturbed propagation of this wave mode are feasible only for very high frequencies. The other wave type considered in this paper has not been treated in the literature. It is guided by a conductor which is coated with a dielectric layer or the surface of which is otherwise modified; for example, by being threaded. The field of this wave type has a structure similar to that of Sommerfeld's wave, but the extension of the field can be controlled by the surface modification. Thus low loss transmission lines on the basis of this wave type become feasible for frequencies above 100 megacycles. The information necessary for the design of such lines is given and the agreement between the theoretically expected transmission losses and the measured transmission losses is checked.

I. INTRODUCTION

IN 1899, A. Sommerfeld[1] published a paper about wave propagation along an infinitely long cylindrical wire of finite conductivity. The type of wave he investigated is a non-radiating mode which has had little consideration in the modern literature, although the attenuation is theoretically much smaller than that of waves in coaxial cables. There may have been some doubt about the possibility of generating this wave type, as there is in the case of Zenneck's[2] ground wave in wave propagation along the earth. The latter wave is guided by a plane interface separating a non-conducting medium from a conducting one, while in Sommerfeld's case the interface is cylindrical. Both waves are possible solutions of Maxwell's equations satisfying given boundary conditions. However, the solutions are special ones insofar as they refer to *plane* electro-magnetic waves and thus provide that the power sources are infinitely far removed. There has been much discussion about the physical reality of Zenneck's ground wave and there is no convincing answer as yet. However, recent experiments on wave propagation along cylindrical conductors prove that cylindrical surface waves can be generated with high efficiency, and thus they can be employed for guided power transmission. The wave type actually used in these experiments differed from Sommerfeld's wire wave insofar as the surface of the conductor was threaded or coated with a dielectric layer. Such modifications of the conductor surface were made in order to reduce the radial extension of the field and hence the dimensions of the excitation device. The field structure of the modified wave is similar to that of Sommerfeld's wave. There is, however, one interesting difference. Sommerfeld's wave exists only for a conductor of finite conductivity. If the conductivity were increased without limit, the extension of the field would increase in such a manner that the power carried by a wave of finite amplitude would become infinite. The wave propagated by a conductor with a thin coat of dielectric or with an otherwise modified surface however, would exist also in the case of perfect conductivity. The field is only slightly affected by the conductivity, provided the conductivity is above a certain limit.

In order to eliminate misunderstandings, it shall be mentioned that the surface waves considered here are not related to the usual waves on long wire antennas, which are extensively discussed in the literature.[3]

The subject of this paper is a discussion of cylindrical surface waves with regard to their practical application to transmission lines. Two kinds of waves are investigated: The waves on a conductor having a plain surface (Sommerfeld's wave) and the waves on a conductor having a modified surface, in particular on a conductor with a dielectric coat.

II. SOMMERFELD'S WIRE WAVE

An infinitely long cylindrical conductor of circular cross section is embedded in an infinite homogeneous dielectric. The particular solution of this boundary-value problem given by Sommerfeld,[1] describes a radially symmetric transverse magnetic wave travelling along the cylinder. There are also solutions describing waves with cyclic periodicity around the cylinder. These solutions have been investigated by D. Hondros.[4] Because most of the field energy of these unsymmetrical modes is inside the conductor their attenuation is extremely large. Thus, they are of no practical interest and will be excluded from further discussion.

If the coordinate system shown in Fig. 1 is used, the field components of the symmetric wave travelling in

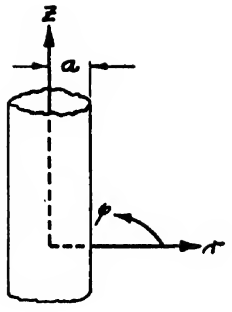

FIG. 1. Coordinate system.

the positive z-direction can be written in the form:

$$E_r = jA\frac{h}{\gamma}Z_1(\gamma r)e^{j(\omega t-hz)},$$
$$E_z = AZ_0(\gamma r)e^{j(\omega t-hz)}, \quad (1)$$
$$H_\varphi = jA\frac{k^2}{\omega\mu\gamma}Z_1(\gamma r)e^{j(\omega t-hz)},$$

as well for the space inside as for the space outside the conductor. The propagation constant h of the guided wave is the same for both parts of the field. The free wave propagation constant k is

$$\text{inside: } k_c=(\omega\mu_c\sigma_c)^{\frac{1}{2}}e^{-j\pi/4}; \quad \text{outside: } k=\omega(\epsilon\mu)^{\frac{1}{2}} \quad (2)$$

(ϵ = dielectric constant, μ = permeability, σ = conductivity). The subscript c refers to the interior of the conductor. The parameters γ and γ_c are defined by

$$\gamma_c^2=k_c^2-h^2; \quad \gamma^2=k^2-h^2. \quad (3)$$

The cylinder functions Z_0 and Z_1 which describe the field inside the conductor are the Bessel functions J_0 and J_1. They are finite at $r=0$. For the outside the Hankel functions $H_0^{(1)}$ and $H_1^{(1)}$ are taken, since they ensure the proper decrease of the field at infinity and give the proper direction of energy flow if the complex parameter γ is in the first quadrant of the complex plane.

The boundary conditions require that E_z and H_φ be continuous at the surface ($r=a$) of the conductor. Thus, we obtain the equations:

$$\mu\frac{\gamma}{k^2}\frac{H_0^{(1)}(\gamma a)}{H_1^{(1)}(\gamma a)}=\mu_c\frac{\gamma_c}{k_c^2}\frac{J_0(\gamma_c a)}{J_1(\gamma_c a)}, \quad (4)$$

$$\gamma^2-\gamma_c^2=k^2-k_c^2=k^2\left(1+j\frac{\sigma\mu_c}{\omega\epsilon\mu}\right)\simeq k^2 j\frac{\sigma\mu_c}{\omega\epsilon\mu}, \quad (5)$$

from which γ and γ_c can be determined and consequently also h. If we restrict our considerations to conductors the radii of which are large compared with the skin depth ($\gamma_c a\gg 1$), J_0 and J_1, in (4) can be replaced by their asymptotic representations:

$$J_0(x)\underset{x\to\infty}{\simeq}\left(\frac{\pi}{2}x\right)^{-\frac{1}{2}}\cos(x-\pi/4);$$
$$J_1(x)\underset{x\to\infty}{\simeq}\left(\frac{\pi}{2}x\right)^{-\frac{1}{2}}\cos(x-3\pi/4). \quad (6)$$

If furthermore the conductor radius is not too large, so that $\gamma a\ll 1$, we can use in (4) the approximations:

$$H_0^{(1)}(x)\underset{x\to 0}{\simeq}\frac{2j}{\pi}\ln(-j0.89x); \quad H_1^{(1)}(x)\underset{x\to 0}{\simeq}-\frac{2j}{\pi x} \quad (7)$$

($0.89\cdots=\frac{1}{2}\times 1.781\cdots=e^C$, where C = Euler's constant $=0.577\cdots$). Equation (4) is then simplified to

$$-\mu\frac{\gamma^2 a}{k^2}\ln(-j0.89\gamma a)=\mu_c\frac{\gamma_c}{k_c^2}\cot(\gamma_c a-\pi/4) \quad (8)$$

where $\cot(\gamma_c a-\pi/4)$ approaches $+j$ since γ_c becomes complex. We shall see later that all these approximations are justified for the considered conductor diameters and frequency range.

Now, (8) can be written in the form:

$$\xi\ln\xi=\eta \quad (9)$$

with

$$\xi=(-j0.89\gamma a)^2,$$
$$\eta=2(0.89)^2\frac{k^2 a\mu_c}{|k_c|\mu}e^{j3\pi/4}=|\eta|e^{j3\pi/4}. \quad (10)$$

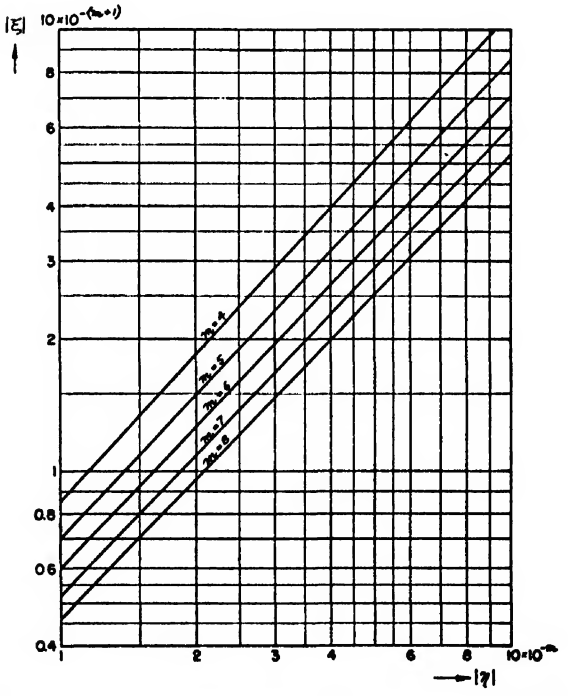

FIG. 2. Graph for determining the absolute value of ξ (see Eq. (12)).

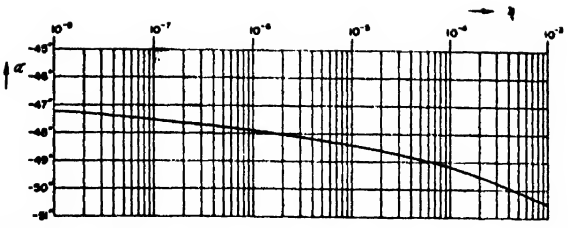

FIG. 3. Graph for determining the argument of ξ (see Eq. (12)).

For copper wire in air

$$|\eta| = 3.27\times10^{-19} af^{\frac{1}{2}} = 1.70\times10^{-3} a\lambda^{-\frac{1}{2}}. \quad (11)$$

f is the frequency and λ the free space wave-length. λ and a are measured in cm. Equation (9) has been used by Sommerfeld for numerical evaluation of γ. With regard to the following discussion about the applicability of these waves for transmission lines, we are concerned with solutions of (9), within a wide range of f and a. If we consider frequencies from 10^8 to 10^{10} cycles/sec. and radii from 0.1 to 1 cm; then, in the case of a copper wire, $|\eta|$ ranges between 3×10^{-8} and 3×10^{-3}. Within this wide range the complex Eq. (9) can be split into two real equations which are more convenient for numerical evaluation. As shown in the Appendix, the absolute value $|\xi|$ and the argument α of $\xi = |\xi| e^{i\alpha}$ can be determined from the equations:

$$|\xi| \ln|\xi| = -|\eta|; \quad \alpha = -\frac{\pi}{4}\left(1 - \frac{1}{\ln|\xi| + 1}\right) \quad (12)$$

$|\xi|$ and α are plotted in Figs. 2 and 3 as functions of $|\eta|$. Each of the 5 curves for $|\xi|$ in Fig. 2 refers to one decade in $|\eta|$, identified by the exponent m. α varies only slightly with $|\eta|$ as seen in Fig. 3.

Having $\xi = |\xi| e^{i\alpha}$, one can determine γ from (10):

$$a\gamma = 1.12(|\xi|)^{\frac{1}{2}} e^{j((\alpha+\pi)/2)}. \quad (13)$$

Within the range of $|\eta|$ considered in Figs. 2 and 3 $|a\gamma| < 1.1\times10^{-2}$, $Re[a\gamma_c] > 15$ and $Im[a\gamma_c] > 5$. Hence the simplifications which lead to Eq. (9) are justified.

The propagation constant h of the surface wave is determined by k and γ (see (3)). As γ/k is very small we can write $h \simeq k - \gamma^2/2k$ or, if γ^2 is expressed in terms of ξ with Eq. (10):

$$h = \left(k + 0.63\frac{|\xi|\cos\alpha}{ka^2}\right) + j\left(0.63\frac{|\xi|\sin\alpha}{ka^2}\right). \quad (14)$$

The real part of h yields the phase velocity of the wave:

$$v = c\left(1 - \frac{0.63|\xi|\cos\alpha}{(ka)^2}\right). \quad (15)$$

The phase velocity of the surface wave is somewhat smaller than the phase velocity c of a free wave in the same dielectric. Consider, for instance, a wave with a frequency of 3000 mc, propagating on a copper wire of 0.1 cm radius, stretched in air. From Eq. (11) we obtain $|\eta| = 5.38\times10^{-6}$ and from Figs. 2 and 3 the corresponding $|\xi| = 3.6\times10^{-7}$ and $\alpha = -48°\ 15'$. Inserting in (16) we find that the reduction in phase velocity is less than 0.004 percent.

The imaginary part of h gives the attenuation β of the wave. β in nepers per cm is

$$\beta = -\frac{0.63|\xi|\sin\alpha}{ka^2}[n/\text{cm}]. \quad (16)$$

The loss L in db per 100 feet becomes:

$$L = -2.66\frac{\lambda}{a^2}|\xi|\sin\alpha\times10^3[db/100\text{ ft.}]. \quad (17)$$

It may be mentioned that β and L are positive because $\sin\alpha$ is negative.

In Fig. 4, L/100 ft. is plotted for various conductor diameters and a frequency range, $10^2 \cdots 10^4$ mc ($\lambda = 3 \cdots 300$ cm). The conductor is assumed to be of copper. It is of interest that even for a wire of only 1 mm radius the losses are considerably smaller than for recommended wave guides. From this fact the application of single conductors for transmission lines appears very promising. However, there is an important question of how to excite efficiently the surface waves. The efficiency of any launching device will be greater the better the agreement between the field built up by the launching device and the field of the wave. The launching device can be considered as a field transformer which transforms the field of a coaxial cable or wave guide into the field of the surface wave. Because the field of the wave extends to infinity, the matching between the field of the launching device and the field of the wave can never be perfect. The larger the launching device the better the chances for good matching conditions. In Section VI we will estimate the loss of a launching device and for this reason we determine in the following that

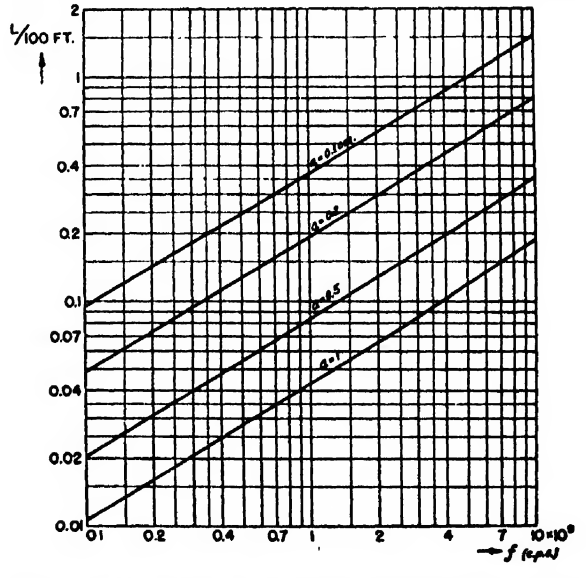

FIG. 4. Transmission loss of copper wires of 0.1, 0.2, 0.5, and 1 cm radius in the case of Sommerfeld's wave.

fraction of the total power of the wave which travels outside of a cylinder of radius ρ surrounding the wire.

The energy flow through the area $\infty > r > \rho$ is given by

$$N_\rho = Re\left[2\pi \int_\rho^\infty r E_r H_\varphi^* dr\right]. \tag{18}$$

(The asterisk denotes the conjugate complex quantity.) The total energy flow N outside the wire is obtained by extending the lower limit of the integral to the wire surface. The quantity we are interested in is N_ρ/N. Inserting for E_r and H_φ the values of Eq. (1) with $Z_0 = H_0^{(1)}$, $Z_1 = H_1^{(1)}$ and considering that $[H^{(1)}(\gamma r)]^* = H^{(2)}(\gamma^* r)$, the power N_ρ at $z=0$ becomes:

$$N_\rho = -Re\left\{2\pi A A^*(\epsilon/\mu)^{\frac{1}{2}} \frac{hk}{\gamma\gamma^*(\gamma^2-\gamma^{*2})} \times[\gamma^*\rho H_1^{(1)}(\gamma\rho) H_0^{(2)}(\gamma^*\rho) - \gamma\rho H_1^{(2)}(\gamma^*\rho) H_0^{(1)}(\gamma\rho)]\right\}. \tag{19}$$

Unfortunately the numerical evaluation of Hankel-functions with complex arguments is cumbersome. However, as we are not too much concerned with high accuracy, we will use the zero representation of the functions up to $|\gamma\rho| < 0.3$, though we have to expect errors of the order of 15 percent for the upper limit of $|\gamma\rho|$. For the wire radii and frequencies considered in Fig. 4, the range $|\gamma\rho| < 0.3$ covers an area around the wire in which the major part of the energy is transmitted.

Using the zero representations of the Hankel functions, shown in (7), and replacing γ by ξ from (10), Eq. (19) becomes:

$$N_\rho = -AA^*(\epsilon/\mu)^{\frac{1}{2}} \frac{ka^4 Re[h]}{|\xi|^2\pi} \times 4(0.89)^4(\ln|\xi|\rho^2/a^2 + \alpha\cot\alpha). \tag{20}$$

The total power N is obtained from (20) by setting $\rho = a$. The expression for N becomes very accurate, since $\gamma a \ll 1$. For the ratio N_ρ/N we get:

$$\frac{N_\rho}{N} \simeq 1 + \frac{2\ln(\rho/a)}{\ln|\xi| + \alpha\cot\alpha}. \tag{21}$$

Within the entire range of $|\xi|$ considered above, α is close to $-\pi/4$. Thus

$$\alpha\cot\alpha \simeq (\pi/4) (\ll |\ln|\xi||)$$

and

$$\frac{N_\rho}{N} \simeq 1 + \frac{2\log(\rho/a)}{\log|\xi| + 0.34} \simeq 1 + \frac{2\log(\rho/a)}{\log 2.2|\xi|}. \tag{22}$$

This equation can be used for determining the radius of that area through which a certain percentage of the power is transmitted. Figure 5 shows the half power radius $\rho_{50\%}$ and the radius for 75 percent power $\rho_{75\%}$ within the same frequency range and for the same wire radii as in Fig. 4. The 75 percent radii are not very accurate for reasons mentioned above. Figure 5 shows that the extension of the field is very large, especially for low frequencies and large wire diameters. For instance, for $f = 1000$ mc/sec., $a = 1$ cm, the half power radius is 28 cm and the 75 percent power radius about 150 cm. A transmission line of this dimension would require a clearance around the conductor of several meters, if frequencies of 1000 mc or less should be transmitted.

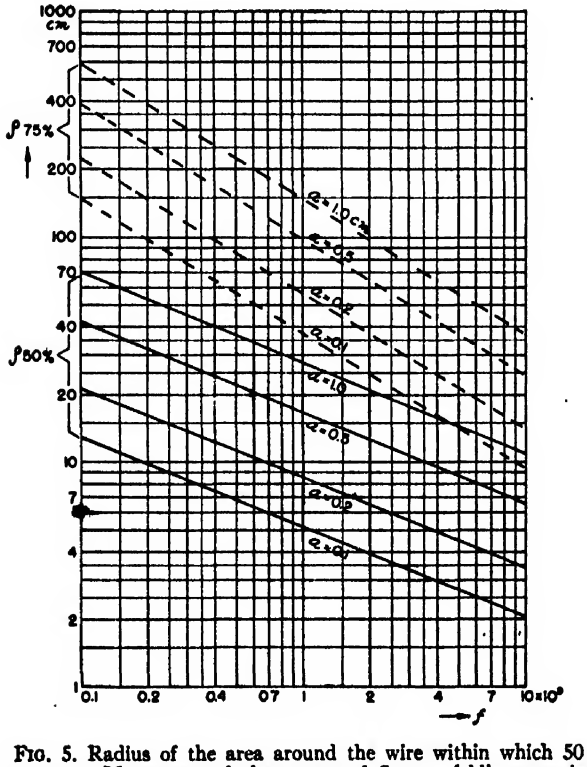

FIG. 5. Radius of the area around the wire within which 50 percent or 75 percent of the power of Sommerfeld's wave is propagated.

In the introduction it was stated that the existence of Sommerfeld's surface wave requires a conductor of finite conductivity. If σ were increased to infinity, $|\eta|$ would become zero and consequently so would $|\xi|$. From (22) we see that N_ρ/N would approach 1 for any finite value of ρ. This means that the power transmitted through a finite area surrounding the wire would be zero if the total power were finite. Thus, the solution of Maxwell's equations loses its sense.

Though a single wire transmission line based on Sommerfeld's surface wave is favorable with regard to the losses effected by the conductor itself, the practical application is restricted to very high frequencies by reason of the large extension of the field. Below 3000 mc the size of low loss launching devices and the clearance area around the wire become too large. It will be shown in the next section how the extension of the field can be

reduced to such an amount that surface wave transmission lines become feasible also for lower frequencies.

III. WAVES ON A CONDUCTOR WITH MODIFIED SURFACE

The waves propagated in coaxial cables or in wave guides differ from Sommerfeld's surface wave in that the finite conductivity of the conductors is an undesired property rather than a necessary condition for the existence of the waves. The question arises: is it possible to modify the surface of a wire so that the conductivity is no longer important for the existence of a surface wave. It is evident that the field of a surface wave on such a guide would not extend as far in the radial direction as the field of Sommerfeld's wave; the latter wave is constrained to the wire only by reason of the finite conductivity while in the other case an additional constraint must be present which concentrates the field around the wire if the conductivity becomes infinite.

In answering the question we first consider the boundary conditions for a surface wave if there is no dissipation present.

An unattenuated surface wave of axial symmetry has field components which are also described by Eq. (1). The cylinder functions in question are the Hankel-functions $H_0^{(1)}$ and $H_1^{(1)}$ with positive imaginary argument. Hence

$$Z_0=H_0^{(1)};\quad Z_1=H_1^{(1)};\quad \gamma=j\gamma';\quad \gamma'^2=h^2-k^2. \tag{23}$$

The Hankel function $H_1^{(1)}$, for positive imaginary argument is negative real and the Hankel function $H_0^{(1)}$, for positive imaginary argument is negative imaginary. Hence E_z has a phase shift of 90° with respect to E_r and H_φ. The boundary conditions at the surface of a guide which propagates a wave of this type demand that E_z and H_φ and therefore their ratio

$$(E_z/H_\varphi)_{r=a'}=\frac{\omega\mu\gamma'}{k^2}\frac{H_0^{(1)}(j\gamma'a')}{H_1^{(1)}(j\gamma'a')}\simeq -j(\mu/\epsilon)^{\frac{1}{2}}\frac{\gamma'^2a'}{k}\ln 0.89\gamma'a' \tag{24}$$

be continuous. a' is the radius at which the internal field and the field of the surface wave meet. Equation (24) states that at the surface of the guide the ratio $(E_z/H_\varphi)_{r=a'}$ must be positive imaginary.

Now we investigate whether the required ratio E_z/H_φ can be obtained by a suitable modification of the surface of a perfectly conducting wire. Consider a cylinder of radius $r=a'$ surrounding a wire which may have any periodic "micro" structure in the z-direction as indicated in Fig. 6. The space between the conductor surface and said cylinder may be partly or wholly filled with dielectric material. This space should be small compared with the wave-length, but large enough compared with the structure on the wire that at $r=a'$ the effect of this structure on the field is averaged. The region bounded

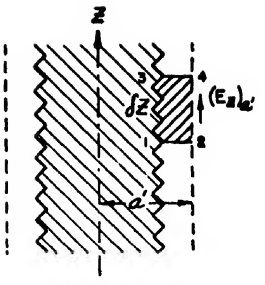

FIG. 6. Conductor with modified surface.

by the cylinder of radius a' is the "guide." With these assumptions the field in the guide can be considered quasi-stationary. The magnetic field is determined by the current I in the wire. The contribution of the electric z-component to the magnetic field can be neglected. The electric field consists in its major part of a potential field originated by the electric charges on the conductor and in its minor part of a curl-field induced by the magnetic field. Current I and charge Q per unit length are connected by the relation

$$\partial I/\partial z+\partial Q/\partial t=0. \tag{25}$$

Since the current distribution propagates in the z-direction with the same phase velocity as the surface wave, (25) can be written in the form

$$-jhI+j\omega Q=0\quad\text{or}\quad Q=hI/\omega. \tag{26}$$

Faraday's induction law applied to the area 1–3–4–2 in an axial plane (see Fig. 6) gives:

$$\delta z\frac{\partial\Phi}{\partial t}=(E_z)_{a'}\delta z+\left(\int_1^2 E_r dr-\int_3^4 E_r dr\right). \tag{27}$$

The length δz, like the distance 1–2, must be small compared with the wave-length. Φ is the magnetic induction flux through a unit length of the area and is proportional to I. In the equation

$$\phi=LI, \tag{28}$$

L can be considered as an inductance per unit length. $(E_z)_{a'}$ in (27) is the longitudinal electric field component at $r=a'$. The integral of the radial electric field component between the points 1 and 2 is proportional to the charge density at 1. A radial induced component of the electric field can be neglected because the dimensions of the roughness of the conductor are assumed to be small compared with the dimensions of the area under consideration. Hence,

$$\int_1^2 E_r dr=Q/C \tag{29}$$

where C has the meaning of a capacitance per unit length. With (29) and (26) the difference between the two integrals in (27) can be written in the form

$$\int_1^2 E_r dr-\int_3^4 E_r dr=-\frac{1}{C}\frac{\partial Q}{\partial z}\delta z=j\frac{h^2}{\omega C}I\delta z. \tag{30}$$

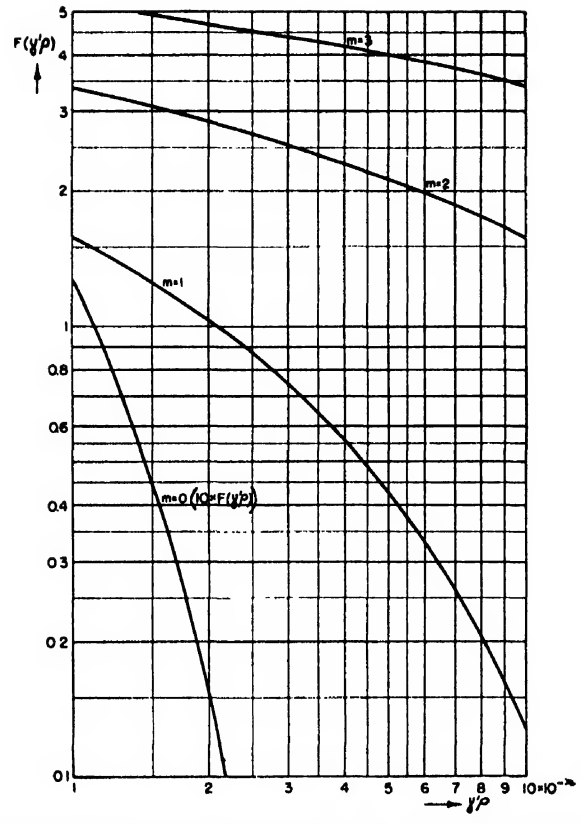

FIG. 7. Graph for determining the extension of the field on surface treated wires (see Eq. (37)).

With (28) and (30) inserted, Eq. (27) becomes:

$$j\omega LI\left(1-\frac{h^2}{\omega^2 LC}\right)=(E_z)_{a'}. \tag{31}$$

Assume for the moment that $(E_z)_{a'}$ is zero. Then, the conditions are like those in a coaxial line having the structure of our guide inclosed in a conductive tube of radius a'. The propagation constant h' of such a line is given by (31) for $(E_z)_{a'}=0$:

$$1-\frac{h'^2}{\omega^2 LC}=0 \quad \text{or} \quad h'^2=\omega^2 LC.^* \tag{32}$$

$\omega^2 LC$ in (31) can now be expressed by h', the propagation constant of a wave which would be translated if the surface wave guide were surrounded by a cylindrical conductor of radius a'. Thus Eq. (31) reads:

$$j\omega LI\left(1-\frac{h^2}{h'^2}\right)=(E_z)_{a'}. \tag{33}$$

As the magnetic field at $r=a'$ is $I/2\pi a'$, the ratio E_z/H_φ at $r=a'$ becomes:

$$(E_z/H_\varphi)_{r=a'}=j2\pi a'\omega L(1-h^2/h'^2). \tag{34}$$

* In truth L and C would change somewhat if the guide were surrounded by a conductor.

The surface wave requires according to (24) an E_z/H_φ having a positive imaginary value. Hence, h' must be greater than k. Because $h=(k^2+\gamma'^2)^{\frac{1}{2}}$ is greater than k, the condition for the existence of the wave considered is that *the guide, inclosed in a conducting cylinder, form a transmission line the phase velocity of which is smaller than the normal velocity in the surrounding dielectric.* Any surface modification of the wire which reduces the phase velocity is suitable for converting the wire into a surface wave guide. Threading of the wire or a dielectric layer on it, for example, accomplishes the required reduction in phase velocity. It may be mentioned that Sommerfeld's wave also is made possible by the fact that the phase velocity is reduced. In that case the reduction is effected by the finite conductivity of the wire. Several steps in the preceding development might require more detailed discussions for their justification. For the sake of brevity such discussions have been omitted.

After having established the existence of a non-radiating surface wave we investigate the extension of the field, still with the assumption that dissipation is negligible. As in the case of Sommerfeld's wave we determine first the amount of power which is transmitted outside a cylinder of radius ρ surrounding the wire. This power is given by (18) and since $H_1^{(1)}(j\gamma' r)$ is real,

$$N_\rho=2\pi AA^*(\epsilon/\mu)^{\frac{1}{2}}\frac{hk}{\gamma'^2}\int_\rho^\infty r[H_1^{(1)}(j\gamma' r)]^2 dr$$

$$=AA^*\pi(\epsilon/\mu)^{\frac{1}{2}}\frac{hk}{\gamma'^2}F(\gamma'\rho) \tag{35}$$

where

$$F(\gamma'\rho)=(\gamma'\rho)^2\left\{-\frac{2}{\gamma'\rho}jH_0^{(1)}(j\gamma'\rho)H_1^{(1)}(j\gamma'\rho)\right.$$

$$\left.-[H_0^{(1)}(j\gamma'\rho)]^2-[H_1^{(1)}(j\gamma'\rho)]^2\right\}. \tag{36a}$$

Hankel functions with imaginary argument are tabulated;[5] thus, the function $F(\gamma'\rho)$ can be calculated easily. In the range $\gamma'\rho<0.1$ the Hankel functions can be approximated by their zero developments with good accuracy. In this way the function $F(\gamma'\rho)$ becomes

$$F(\gamma'\rho)\simeq 8/\pi^2[-\ln 0.89\gamma'\rho-0.5] \quad \text{for} \quad \gamma'\rho<0.1. \tag{36b}$$

The function $F(\gamma'\rho)$ is plotted in Fig. 7. The parameter m indicates the decade in $\gamma'\rho$ to which each curve refers. In the case $m=0$ the function $10\times F(\gamma'\rho)$ is plotted in order to get the curve on the diagram.

The circle of radius ρ_p within which a certain percentage p of the total power of the surface wave travels is given by the equation:

$$p=1-\frac{F(\gamma'\rho_p)}{F(\gamma'a')}. \tag{37}$$

[5] E. Jahnke and F. Emde, *Tables of Functions*, (Dover Publications, New York, 1943).

Figure 8 shows the ratio ρ_p/a as a function of $\gamma' a'$ for $p=50$ percent, 75 percent, 90 percent and 99 percent. For a given diameter a' of the guide the field decreases faster with increasing γ'. Assume, for instance, $a'=1$ cm, $\gamma'=2\times10^{-2}$; then half the power is within a radius of about 6 cm, 75 percent of the power is within $\rho=16$ cm, 90 percent is within $\rho=33$ cm and 99 percent is within $\rho=86$ cm. γ' can be varied by modifying the conductor surface. Thus, we have the possibility of restricting the extension of the field within limits to any desired value. A part of the energy travels in the space between the conductor surface and a', the radius of the guide. But this part is so small within the considered γ' range, that it can be neglected. (See Section IV.)

IV. CONDUCTOR WITH DIELECTRIC COAT

The simplest method for reducing the phase velocity and the extension of the field is the application of a dielectric coat to a plain wire. This case will now be considered in detail. The field in the dielectric layer can be described by Bessel functions (J_0, J_1) and Neumann functions (N_0, N_1). In Eq. (1) Z_0 and Z_1 are to be replaced by

$$Z_0=J_0+bN_0; \quad Z_1=J_1+bN_1, \tag{38}$$

where b is determined from the boundary condition. γ and k are provided with the subscript i indicating that they refer to the insulating layer:

$$\gamma_i^2=k_i^2-h^2; \quad k_i=\omega(\epsilon_i\mu_i)^{\frac{1}{2}}. \tag{39}$$

Let a be the radius of the wire and a' the radius of the outer surface of the dielectric coat; then we obtain from the boundary condition $E_z=0$ at the wire of infinite conductivity:

$$b=-J_0(\gamma_i a)/N_0(\gamma_i a), \tag{40}$$

and the ratio E_z/H_φ at the surface of the coat, $r=a'$, becomes:

$$\left(\frac{E_z}{H_\varphi}\right)_{r=a'}=-j(\mu_i/\epsilon_i)^{\frac{1}{2}}\frac{\gamma_i}{k_i} \times\frac{J_0(\gamma_i a')N_0(\gamma_i a)-J_0(\gamma_i a)N_0(\gamma_i a')}{J_1(\gamma_i a')N_0(\gamma_i a)-J_0(\gamma_i a)N_1(\gamma_i a')}. \tag{41}$$

This equation can be simplified if we are interested only in conditions for which the phase velocity of the surface wave is slightly reduced. These conditions are established if either the dielectric layer is thin compared with the wire radius, or the layer is of the same order of magnitude as the wire radius, but the radius itself is very small compared with the wave-length. In the first case we can write

$$J_0(\gamma_i a)\simeq J_0(\gamma_i a')+\gamma_i J_1(\gamma_i a')(a'-a); \quad N_0(\gamma_i a')\simeq N_0(\gamma_i a')+\gamma_i N_1(\gamma_i a')(a'-a). \tag{42}$$

With these relations (41) becomes:

$$\left(\frac{E_z}{H_\varphi}\right)_{r=a'}\simeq j(\mu_i/\epsilon_i)^{\frac{1}{2}}\frac{\gamma_i^2}{k_i}(a'-a). \tag{43}$$

In the other case we use the zero representations of the cylinder functions. Thus (41) becomes:

$$\left(\frac{E_z}{H_\varphi}\right)_{r=a'}\simeq j(\mu_i/\epsilon_i)^{\frac{1}{2}}\frac{\gamma_i^2}{k_i}a'\ln\frac{a'}{a}. \tag{44}$$

Both Eqs. (43) and (44) are immediately obtained from Eq. (34). If the guide, consisting of the wire and the dielectric layer is thought to be surrounded by a metal tube of radius a', the inductance L per unit length and the propagation constant h' of the coaxial line formed by the guide and the tube are:

$$L=\frac{\mu_i}{2\pi}\ln\frac{a'}{a}; \quad h'=\omega(\epsilon_i\mu_i)^{\frac{1}{2}}=k_i. \tag{45}$$

With these quantities Eq. (34) leads to (44) which we consider more general since it yields, for thin layers, Eq. (43).

At $r=a'$ where the field in the guide and the field of the surface wave meet, $(E_z/H_\varphi)_{r=a'}$ must be continuous. Hence, by comparison of (24) and (44) we get the relation:

$$(\mu/\epsilon)^{\frac{1}{2}}\frac{\gamma'^2}{k}a'\ln 0.89\gamma' a'=-(\mu_i/\epsilon_i)^{\frac{1}{2}}\frac{\gamma_i^2}{k_i}a'\ln\frac{a'}{a} \tag{46}$$

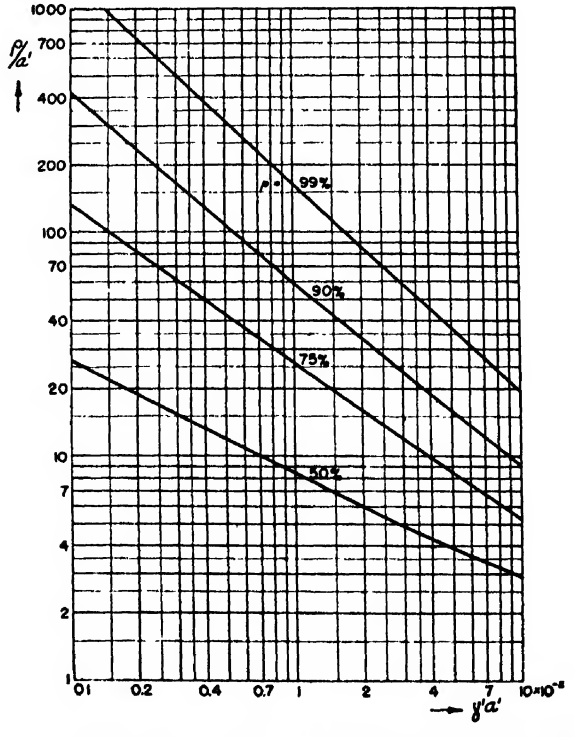

FIG. 8. Relative radius of the area around the wire within which 50 percent, 75 percent, 90 percent and 99 percent of the power is propagated in the case of a conductor with modified surface.

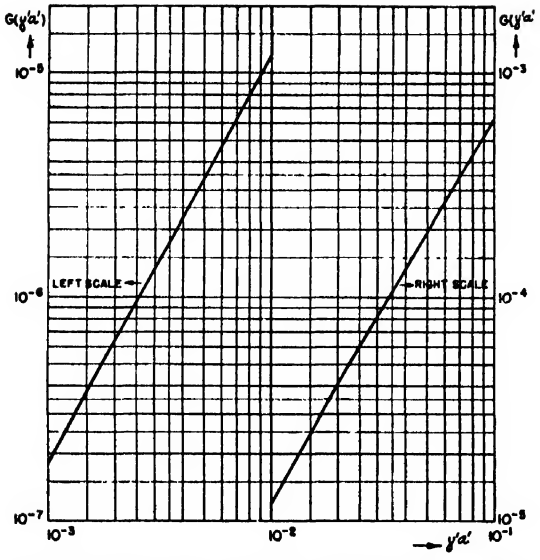

FIG. 9. Design curve in the case of dielectric coated wires (see Eq. (48)).

from which the ratio a'/a is determined:

$$\ln\frac{a'}{a}=-\frac{\epsilon_i}{\epsilon}\frac{\gamma'^2}{\gamma_i^2}\ln 0.89\gamma'a'. \tag{47}$$

As $\gamma_i^2=k_i^2-h^2=k_i^2-k^2-\gamma'^2$ (see Eqs. (39) and (23)) and $\gamma'^2\ll k^2$ Eq. (47) becomes for $\mu_i=\mu$:

$$\ln\frac{a'}{a}\simeq\frac{\epsilon_i}{\epsilon_i-\epsilon}\left(\frac{\lambda}{a'}\right)^2 G(\gamma'a')$$

with

$$G(\gamma'a')=-\left(\frac{\gamma'a'}{2\pi}\right)^2\ln 0.89\gamma'a'. \tag{48}$$

The function $G(\gamma'a')$ is plotted in Fig. 9.

We consider the following example: $a'=1$ cm; $\lambda=50$ cm. The radius within which 90 percent of the power of the surface wave is transmitted, $\rho_{90\%}=50$ cm. What is the required thickness of the dielectric layer if $\epsilon_i/\epsilon=4$?

From Fig. 8 we obtain the required value of $\gamma'a'$ for which $\rho_{90\%}=50$ cm. It is $\gamma'a'=1.21\times10^{-2}$. The corresponding value for $G(\gamma'a')$ is found with Fig. 9 to be 1.68×10^{-5}. Inserted in Eq. (48), these values give the thickness of the layer as 5.6×10^{-2} cm.

The next question to be answered is, how much power is transmitted inside the guide, i.e., within the dielectric coat. This power is determined by E_r and H_φ in the dielectric which are, in terms of the current I,

$$E_r=\frac{Q}{2\pi r\epsilon_i}=\frac{h}{2\pi\epsilon_i\omega r}I \text{ (see (26))}$$
$$H_\varphi=I/2\pi r. \tag{49}$$

Hence:

$$N_i=2\pi\int^{a'} rE_rH_\varphi^*dr=\frac{h}{2\pi\omega\epsilon_i}\ln\frac{a'}{a}II^*. \tag{50}$$

The power N of the surface wave itself is given by (35) with $\rho=a'$. For $F(\gamma'a')$ the approximation (36b) can be used; thus

$$N\simeq-\frac{8}{\pi}AA^*(\epsilon/\mu)^{\frac{1}{2}}\frac{hk}{\gamma'^4}(\ln 0.89\gamma'a'+0.5). \tag{51}$$

The amplitude A can be expressed in terms of the current. Since $(H_\varphi)_{r=a'}=I/2\pi a'$ we find from the field Eq. (1) with the substitutions of (23),

$$AA^*\simeq II^*\frac{\mu\gamma'^4}{16\epsilon k^2}. \tag{52}$$

With (50), (51), (52), (47) and (23) the ratio between N_i and N becomes:

$$\frac{N_i}{N}=-\frac{\epsilon}{\epsilon_i}\frac{\ln(a'/a)}{\ln 0.89\gamma'a'+0.5}$$
$$=\frac{h^2-k^2}{k^2(\epsilon_i/\epsilon)-h^2}\frac{\ln 0.89\gamma'a'}{\ln 0.89\gamma'a'+0.5}. \tag{53}$$

Within the range of $\gamma'a'$ between 10^{-3} and 10^{-1} the term $(\ln 0.89\gamma'a')/(\ln 0.89\gamma'a'+0.5)$ is smaller than 1.25. If we consider reductions in phase velocity of less than 3 percent and assume $\epsilon_i/\epsilon>2.4$, N_i/N is smaller than 6 percent. Thus N_i can be neglected in most practical cases.

V. ATTENUATION ON DIELECTRIC COATED CONDUCTORS

All preceding relations derived for a surface wave guide consisting of a conductor with modified surface are valid under ideal conditions where no dissipation is present. The effect of dissipation can be calculated in the usual manner with the assumption that the field distribution in an equiphase plane is approximately the same as in the dissipationless case.* This means that the losses are calculated for the undisturbed field. The power loss within the path from z to $z+dz$ is proportional to the total power

$$d\bar{N}=-2\beta\bar{N}dz, \tag{54}$$

where β is the attenuation factor in neper/cm.

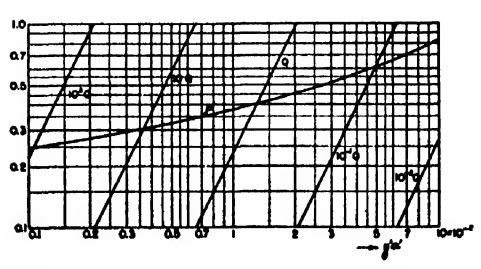

FIG. 10. Chart for determining P and Q (for Eq. (60)).

* This method could not be used in the case of Sommerfeld's wave for obvious reasons.

We consider only the case of a conductor with a dielectric layer. Then the loss consists of two parts, the conductivity loss and the dielectric loss. The conductivity loss, expressed in terms of the current I in the wire, is given by:

$$d\bar{N}_c = -\frac{1}{2\pi a}\left(\frac{\omega\mu_c}{2\sigma_c}\right)^{\frac{1}{2}} II^* dz \tag{55}$$

where μ_c and σ_c are the permeability and the conductivity of the wire. The dielectric loss is

$$d\bar{N}_i = -\frac{h^2}{2\pi\omega\epsilon_i}\ln\frac{a}{a}\tan\delta\, II^* dz$$

$$\simeq -\frac{h^2\gamma'^2}{2\pi\omega\epsilon\gamma_i^2}\ln(0.89\gamma' a')\tan\delta\, II^* dz. \tag{56}$$

$\tan\delta$ is the loss factor of the dielectric material. The total power $\bar{N} = N + N_i$ is obtained from (51)-(53):

$$\bar{N} = -\frac{1}{2\pi}(\mu/\epsilon)^{\frac{1}{2}}\frac{h}{k}\left[\left(1+\frac{\gamma'^2}{\gamma_i^2}\right)\ln 0.89\gamma' a' + 0.5\right] II^*. \tag{57}$$

Equations (54)-(57) give the attenuation factor β_c caused by the conductivity losses and the attenuation factor β_i caused by the dielectric losses. Since $(\gamma'/\gamma_i)^2 \ll 1$, $h \simeq k$

$$\beta_c \simeq -\frac{1}{2a}\left(\frac{\omega\epsilon\mu_c}{2\sigma_c\mu}\right)^{\frac{1}{2}}\frac{1}{\ln 0.89\gamma' a' + 0.5}\ [\text{neper/cm}], \tag{58}$$

$$\beta_i \simeq \frac{1}{2}\frac{\epsilon}{\epsilon_i - \epsilon}\frac{\gamma'^2}{k}\left(1 - \frac{0.5}{\ln 0.89\gamma' a' + 0.5}\right) \times \tan\delta\ [\text{neper/cm}]. \tag{59}$$

With (58) and (59) the total transmission loss L in db per 100 feet becomes

$$L_{100\text{ ft.}} = \frac{P(\gamma' a')}{a(\lambda)^{\frac{1}{2}}} + \frac{\epsilon}{\epsilon_i - \epsilon}\tan\delta\frac{\lambda}{a'^2}Q(\gamma' a')[db] \tag{60}$$

with

$$P(\gamma' a') = -1.33\times 10^4(\epsilon/\mu)^{\frac{1}{2}}\left(\frac{\pi\mu_c}{\sigma_c\mu}\right)^{\frac{1}{2}}\frac{1}{\ln\gamma' a' + 0.38},$$

$$Q(\gamma' a') = 2.11\times 10^3\left(1 - \frac{0.5}{\ln\gamma' a' + 0.38}\right)(\gamma' a')^2. \tag{61}$$

For a coated copper wire stretched in air,

$$P(\gamma' a') = 1.60\frac{1}{-\ln\gamma' a' - 0.38}. \tag{62}$$

The functions $P(\gamma' a')$ (for copper) and $Q(\gamma' a')$ are plotted in Fig. 10.

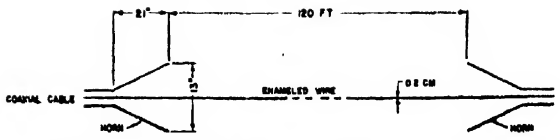

FIG. 11. Sketch of a surface wave transmission line.

For the example considered in the preceeding section ($\lambda = 50$ cm, $\gamma' a' = 1.21\times 10^{-1}$, $a = 0.94$ cm, $a' = 1.00$ cm, $\epsilon_i/\epsilon = 4$) we obtain from Fig. 10: $P = 0.38$, $Q = 0.29$. The loss due to the conductivity is given by the first term in (60) and is 0.057 db/100 ft. Assuming $\tan\delta = 10^{-3}$, the dielectric loss, given by the second term of (60), is 0.005 db/100 ft. Thus the total loss is 0.062 db/100 ft. As may be seen from Fig. 4 for a plain wire of the same radius guiding a Sommerfeld surface wave, the loss would be only half as large. However, the extension of the field would be so high that the conditions for undisturbed propagation and efficient excitation could not be achieved. Figure 5 shows that for $a = 1$ cm and $\lambda = 50$ cm, $\rho_{50\%} = 34$ cm and $\rho_{75\%} = 200$ cm. The corresponding radii for the coated wire given in Fig. 8 ($\gamma' a' = 1.21\times 10^{-1}$) are $\rho_{50\%} = 7.6$ and $\rho_{75\%} = 22.5$ cm; this means they amount to only 22 percent and 11 percent of the other radii.

VI. LAUNCHING OF SURFACE WAVES

In order to excite the desired wave mode with high efficiency a launching device is required which develops within a cross section a field having a structure similar to that of the surface wave. The structure of the fields of both types of surface wave considered in this paper is, within a large area around the conductor, somewhat like in a coaxial cable. The radial electric field component and the circular magnetic field component decrease with $1/r$ as can be seen from the zero representation of the Hankel function $H_1^{(1)}$. Furthermore the ratio E_r/H_φ is very close to $(\mu/\epsilon)^{\frac{1}{2}}$. As the major part of the energy of the waves travels within the area in which the $1/r$ decrease of the field strength is valid, the waves can be launched with good efficiency by means of the device sketched in Fig. 11. The outer conductor of the coaxial feed line is gradually expanded in the form of a horn and the inner conductor of the line is connected to the surface wave guide. The device can be considered as a tapered coaxial line. The arrangement on the receiving end is the same. In the case of Sommerfeld's surface wave the area in which the field should be simulated is very large especially for lower frequencies. Hence, the efficient excitation of this wave would require an extremely large horn. In the other case, where the extension of the field is reduced by means of a suitable modification of the conductor surface, the dimensions of launching devices can be kept within reasonable limits.

The efficiency of the launching device of Fig. 11 can be determined approximately if the opening of the horn does not too much exceed the area within which the field decreases with $1/r$. In this case, considering the receiving

end, that portion of the wave will be received which falls within the area of the horn. If the radius of the horn is equal to $\rho_{75\%}$, for instance, about 75 percent of the energy will be received. Because of the reciprocity theorem the efficiency of the horns for transmission and reception must be the same.

The tapering of the horns is important too, insofar as in the case of large angles higher modes may develop inside the horns, and besides, the wave front at the end of the horns may deviate too much from the required plane wave front. It is desirable to have the surface modification started within the horns, in order to have the surface wave build up therein.

In the case of a surface wave guide consisting of a wire with modified surface, the efficiency of a horn can be determined with the aid of Fig. 7. If the parameter γ' and the radius a' of the guide are known $F(\gamma'a')$ can be obtained. Let b be the radius of the horn at the open end; then the efficiency is given by $1-F(\gamma'b)/F(\gamma'a')$ where $F(\gamma'b)$ is also obtained from Fig. 7.

VII. EXAMPLES

The set-up considered here is shown in Fig. 11. The surface wave guide consists of an enameled wire of 120-foot length having a diameter of 0.2 cm ($a=0.1$) and an enamel coat of 0.005 cm thickness. The dielectric constant and the power factor of the enamel are $\epsilon_i/\epsilon=3$ and $\tan\delta=8\times10^{-3}$, for low frequencies. $\tan\delta$ will probably be much larger for the high frequencies under consideration; however, having no better data available, we will use the quoted figure. The diameter of the horns is $2b=33$ cm.

First we determine the loss of the wire, assuming a frequency of 3300 mc. With (48) we find, $G(\gamma'a')=4.04\times10^{-6}$. From Fig. 9 we obtain the corresponding $\gamma'a'=5.6\times10^{-3}$; Fig. 10 gives for $P(\gamma'a')$ and $Q(\gamma'a')$ the values $P=0.33$, $Q=0.072$. These values inserted in (60) deliver the transmission loss per 100 feet as 1.35 db. Hence the loss for 120 feet is 1.62 db.

In order to determine the loss due to the launching device we determine $F(\gamma'a')$ and $F(\gamma'b)$ from Fig. 7, $F(\gamma'a')=4.9$, $F(\gamma'b)=0.17$. The efficiency of each horn is then 95.6 or the loss is 0.20 db. As both horns together contribute 0.40 db, the total theoretical loss of the transmission line becomes 2.0 db. The measured loss was 2.3 db. It should be mentioned that the loss of the setup does not vary more than 0.1 db within the frequency range from 1500 to 3400 mc.

As another example we consider a transmission line with the same launching device and an enameled wire of 600-foot length and 0.322 cm. diameter. The thickness of the insulation is 0.0025 cm. We calculate the loss for a frequency of 1600 mc. From (48) we obtain $G(\gamma'a')=0.75\times10^{-7}$ and from Fig. 9, $\gamma'a'=2.4\times10^{-3}$. The corresponding values for $P(\gamma'a')$ and $Q(\gamma'a')$ are found in Fig. 10. They are $P(\gamma'a')=0.28_3$ and $Q(\gamma'a')=0.013_1$. If these values are inserted in (60) the loss for the length of 600 feet is 2.65 db. The loss contributed by one horn is obtained with Fig. 7 which gives the values $F(\gamma'a')=4.6$ and $F(\gamma'b)=0.88$. Hence the efficiency is 80.9 percent or the loss 0.9_3 db. As the two horns contribute 1.8_6 db, the total loss of the transmission line becomes 4.5 db. The measured loss was approximately 5 db. It may be mentioned that the wire was supported at 100 feet intervals by strings about 6 feet above the ground.

VIII. ACKNOWLEDGMENT

Thanks are due Mr. A. Meyerhoff for his invaluable assistance in the preparation of the manuscript and Mr. C. Sharp and Mr. L. Battersby for valuable suggestions and for their cooperation in the performance of the experiments of which part of the results are quoted in this paper.

IX. APPENDIX

Derivation of Eq. (12):

If we write for ξ and η

$$\xi=|\xi|e^{j\alpha}=|\xi|e^{-j(\pi/4+x)};\quad \eta=|\eta|e^{j3\pi/4}\ (-\pi<x<\pi) \tag{A1}$$

(9) becomes

$$|\xi|e^{-jx}\left[\ln|\xi|-j\left(\frac{\pi}{4}+x\right)\right]=-|\eta|. \tag{A2}$$

This equation can be split into two equations if the real and imaginary parts are separated:

$$|\xi|\ln|\xi|\cos x\cdot\left(1-\frac{\pi/4+x}{\ln|\xi|}\tan x\right)=-|\eta|; \tag{A3}$$

$$\tan x=-\frac{\pi/4+x}{\ln|\xi|}. \tag{A4}$$

Inserting (A4) into (A3),

$$|\xi|\ln|\xi|\cos x\cdot(1+\tan^2 x)=-|\eta| \quad\text{or}\quad \frac{|\xi|\ln|\xi|}{\cos x}=-|\eta|. \tag{A5}$$

Within the range considered, $|\eta|<10^{-3}$, and $|\xi|\ll1$ (because $\gamma\ll k$). As $|\cos x|$ is certainly ≤1, $|\xi|$ will be smaller than 1.1×10^{-4} and $-\ln|\xi|>9$. From (A4) we see that for $-\ln|\xi|>9$, x becomes small:

$$x\simeq\frac{\pi}{4}\frac{1}{-\ln|\xi|-1}\left(<\frac{\pi}{32}\right). \tag{A6}$$

For such small angles $\cos x$ in (A5) can be replaced by 1. Thus the Eqs. (12) are obtained.

A Note on Control Area

THOMAS M. STOUT
Electrical Engineering Department, University of Washington, Seattle, Washington
(Received May 29, 1950)

Control area, or the integrated error for a step function input, has been used as a measure of control system performance. For systems described by

$$\frac{\theta_0(s)}{\theta_i(s)}=e^{-sT_d}\frac{(\tau_1 s+1)(\tau_2 s+1)\cdots(\tau_m s+1)}{(T_1 s+1)(T_2 s+1)\cdots(T_n s+1)},$$

it is proved that the control area is

$$A=T_d+\sum_{i=1}^{n}T_i-\sum_{i=1}^{m}\tau_i.$$

A simple method of evaluation is presented and some limitations of the control area criterion are mentioned.

A COMMON measure of the response of a control system[1–3] to a unit step function is the "control area," shown as the shaded area in Fig. 1. The control area is defined mathematically as the integral of the error with respect to time from zero to infinity, the error being defined as the difference between input and output. An optimum adjustment of the system parameters is obtained when the control area is a minimum.

Evaluation of the control area in terms of the system parameters by conventional methods is a difficult task if the system is complicated. However, for systems described by the equation

$$\frac{\theta_0(s)}{\theta_i(s)}=\frac{(\tau_1 s+1)(\tau_2 s+1)\cdots(\tau_m s+1)}{(T_1 s+1)(T_2 s+1)\cdots(T_n s+1)} \tag{1}$$

$$=\frac{P(s)}{Q(s)}, \tag{2}$$

subject to a step function of magnitude M, it will be shown that the control area is simply

$$A=1/M\int_0^\infty e(t)dt$$

$$=(T_1+T_2+\cdots+T_n)-(\tau_1+\tau_2+\cdots+\tau_m). \tag{3}$$

In these equations, θ_0, θ_i, and e are standard symbols[4] for the output, input, and error, respectively, functions of s are the Laplace transforms of the corresponding functions of time, and $\tau_1\cdots\tau_m$, $T_1\cdots T_n$ are time constants of the system. Equation (1) describes systems with any number of "lag" or "lead" (delay or anticipatory) elements having zero steady-state error for a step function input. If the steady-state error is not zero, the control area as defined above is infinite and therefore useless as a measure of system performance.

PROOF

By means of Eq. (2), the error may be expressed in terms of the input by the equation

$$e(s)=\left[\frac{Q(s)-P(s)}{Q(s)}\right]\theta_i(s). \tag{4}$$

If the input is a unit step function whose Laplace transform is $1/s$, the transform of the error is

$$e(s)=\frac{Q(s)-P(s)}{sQ(s)}. \tag{5}$$

Denote by $I(t)$ the indefinite integral of the error

$$I(t)=\int e(t)dt. \tag{6}$$

Since $I(0)$ is necessarily zero, the Laplace transform of $I(t)$ is

$$I(s)=e(s)/s. \tag{7}$$

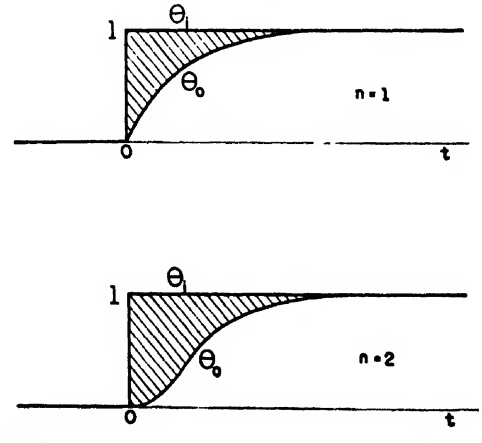

FIG. 1. Response and control area for simple control systems.

The control area may now be found from Eq. (7) by means of the final value theorem,[5,6] giving

$$A=\lim_{t\to\infty}[I(t)]$$
$$=\lim_{s\to 0}[sI(s)]$$
$$=\lim_{s\to 0}[e(s)]. \tag{8}$$

Substituting the expression for $e(s)$ from Eq. (5) into Eq. (8) gives

$$A=\lim_{s\to 0}\left[\frac{Q(s)-P(s)}{sQ(s)}\right], \tag{9}$$

which is indeterminate, since $Q(0)=P(0)=1$. Differentiating numerator and denominator, we obtain

$$A=\lim_{s\to 0}\left[\frac{Q'(s)-P'(s)}{sQ'(s)+Q(s)}\right] \tag{10}$$
$$=\lim_{s\to 0}[Q'(s)-P'(s)]. \tag{11}$$

At this point it will be convenient to write

$$P(s)=\prod_{i=1}^{m}p_i$$
$$Q(s)=\prod_{i=1}^{n}q_i, \tag{12}$$

where $p_i=\tau_i s+1$ and $q_i=T_i s+1$. The derivative of $P(s)$ or $Q(s)$ with respect to s is the sum of all the products formed by multiplying the derivative of one factor by all the other factors, or

$$P'(s)=\sum_{j=1}^{m}\tau_j\Big[\prod_{i=1}^{j-1}p_i\Big]\Big[\prod_{j+1}^{m}p_i\Big]$$
$$Q'(s)=\sum_{j=1}^{n}T_j\Big[\prod_{i=1}^{j-1}q_i\Big]\Big[\prod_{j=1}^{m}q_i\Big]. \tag{13}$$

Since p_i and q_i approach one as s approaches zero, we get

$$\lim_{s\to 0}P'(s)=\tau_1+\tau_2+\cdots+\tau_m$$
$$\lim_{s\to 0}Q'(s)=T_1+T_2+\cdots+T_n \tag{14}$$

and the proof of Eq. (3) is complete.

In systems characterized by "dead time," the output response does not begin immediately but starts at a later time, $t=T_d$. In this case,

$$\frac{\theta_0(s)}{\theta_i(s)}=\frac{e^{-sT_d}P(s)}{Q(s)} \tag{15}$$

and a similar proof will show that now

$$A=T_d+\sum_{i=1}^{n}T_i-\sum_{i=1}^{m}\tau_i. \tag{16}$$

This conclusion is also evident from the previous result upon consideration of the nature of the response.

DISCUSSION

Using conventional methods, the error would be written

$$e(t)=\sum_{i=1}^{m}K_i e^{-t/T_i}, \tag{17}$$

where the coefficients K_i are functions of $\tau_1\cdots\tau_m$ and $T_1\cdots T_n$, and the control area found by direct integration. The coefficients may be determined from the initial conditions* or from Eq. (5) by the use of partial fractions or residues. For the simple first- and second-order systems, whose responses are shown in Fig. 1, the error is

$$e_1(t)=e^{-t/T_1} \tag{18}$$

$$e_2(t)=\frac{T_1}{T_1-T_2}e^{-t/T_1}+\frac{T_2}{T_2-T_1}e^{-t/T_2}. \tag{19}$$

In these simple cases, the validity of Eq. (3) is easily demonstrated. However, the algebraic difficulties encountered in treating the general case by this method are staggering; the direct attack made possible by the Laplace transformation is simpler and more successful.

If $P(s)$ and $Q(s)$ should be given in the form

$$P(s)=B_m s^m+B_{m-1}s^{m-1}+\cdots+B_1 s+1$$
$$Q(s)=A_n s^n+A_{n-1}s^{n-1}+\cdots+A_1 s+1, \tag{20}$$

the control area can be found directly without solving for the individual time constants. Expansion of the factored forms of $P(s)$ and $Q(s)$ used in Eq. (1) will show that

$$B_1=\tau_1+\tau_2+\cdots+\tau_m$$
$$A_1=T_1+T_2+\cdots+T_n. \tag{21}$$

The control area is therefore given by A_1-B_1 directly. Using the control area criterion, the objective of system design would be to minimize (A_1-B_1). It should be remembered that allowable values of A_1 will be fixed by stability considerations, as given by Routh's stability criterion.[6,7] In particular, if $A_1\leqq 0$, the system will be unstable.

[6] M. F. Gardner and J. L. Barnes, *Transients in Linear Systems* (John Wiley and Sons, Inc., New York, 1942).

* For a unit step function, the error is equal to one and the first $n-1$ derivatives with respect to t are equal to zero.

[7] E. J. Routh, *Advanced Rigid Dynamics* (Macmillan Company, Ltd., London, 1930).

If the time constants are complex, Eq. (3) is still applicable. In physical systems complex time constants occur in conjugate pairs, such as

$$T=1/(a+j\omega_n),$$
$$\bar{T}=1/(a-j\omega_n),$$

where a is a damping factor and ω_n is the natural frequency. For such a pair of complex time constants,

$$T+\bar{T}=2a/(a^2+\omega_n^2). \quad (22)$$

This result indicates nicely one limitation of control area as a criterion for system design, since the minimum value of $T+\bar{T}$ is obtained when the damping is zero. Other systems, with equally undesirable responses, can be imagined for which the control area might be zero or even negative. These observations indicate the need for simultaneous consideration of the relative stability of the system. In systems for which the control area is a suitable measure of response, the methods of evaluation proposed in this note may be useful.

A Small Electron Microscope

JOHN H. REISNER AND EDMUND G. DORNFELD
Radio Corporation of America, Camden, New Jersey
(Received May 25, 1950)

A new electron microscope of greatly simplified design has been constructed. The instrument has a resolution of 100 Angstroms, yet is small enough to be mounted on a desk or laboratory table. Magnetic lenses are energized by permanent magnets. An accelerating voltage of 50 kilovolts is varied over a narrow range to provide means of focus. Images may be photographed on 2×2 plates. Plates may be changed in a minute, and specimens in fifteen seconds. Direct magnifications of 1500, 3000 and 6000 are possible depending on pole pieces used. Photographic images may be enlarged up to ten times. The instrument is free of x-radiation and completely interlocked and provided with shorting devices for protection from high voltage.

INTRODUCTION

ALL electron microscopes have been characterized heretofore by large size and weight, and usually by complexity of design. These characteristics are a result of extremely great operational flexibility of the instruments. In the early days of electron microscopy, such flexibility was essential to the determination of the best means of utilizing the optical components and to the development of new techniques. Complexity is still a necessary evil of the highest resolution instruments, and of those engaged in an extremely wide range of problems. However, many of the uses to which the electron microscope is now put[1] require only the moderately high resolution which may be realized on comparatively simple instruments.

A first step in the direction of smaller, simpler microscopes was made several years ago,[2] culminating in a well-known commercial instrument.[3] Additional simplification is possible by utilizing permanent magnets to replace coil windings, cables, control circuits, and power supplies. Unfortunately, the use of permanent magnets fixes the magnification for a given set of lens pole pieces. However, at the same time, alignment problems largely disappear so that transverse adjustments may be omitted, along with the attendant vacuum difficulties. By being content with ultimate resolutions of 100 Angstroms or less, the condenser lens may be omitted and its beam control function delegated to an aperture. By limiting direct magnification to 3000 or 6000 times, the column may be shortened, the volume of the vacuum system greatly reduced, and in turn, the vacuum diffusion pump may be reduced in size. Utilization of new materials such as silicone diffusion pump oil, combined with a new treatment of old valving and stage problems, have resulted in the greatly simplified electron microscope shown in Figs. 1 and 2.

DIMENSIONAL CONSIDERATIONS

The first step toward simplification is the reduction of size. The minimum dimensions for the microscope optical system are determined primarily by the highest magnification required, and by the focal lengths of the lenses. For the highest magnification, the lenses are so powerful that the magnification may be expressed to good approximation by the expression $M\simeq p/f$, where "M" is the magnification, and "p" and "f" are the image and focal distances of a lens. It is simply demonstrated that the most favorable utilization of the column length "L" is that where both lenses have the same image distances, i.e., where $p_1=p_2\cong L/2$, since f is very small compared to p. The minimum required column length then becomes $L_{\min}\cong 2(M_t f_1 f_2)^{\frac{1}{2}}$, where "$M_t$" is the total magnification, and "f_1" and "f_2" are the focal lengths of the objective and projector lenses respectively. For the microscope described, $f_1=0.25$ cm, and $f_2=0.20$ cm, when the accelerating voltage is 50 kilovolts and the over-all magnification is 6000 times. Under these circumstances, the minimum length turns out to be about 35 centimeters or 14 inches. It is inter-

[1] R. W. G. Wyckoff, *Electron Microscopy Technique and Applications* (Interscience Publishers, Inc., New York, 1949), pp. 22–25, Chapters VI and VII.
[2] V. K. Zworykin and J. Hillier, J. App. Phys. 14, 658 (1943).
[3] P. C. Smith and R. G. Picard, Radio News 32, 41 (1944).

esting that a saving of 10 centimeters in length could be accomplished by limiting the top direct magnification to 3000 times.

The distance from the specimen to the illuminating source is also limited by magnification. The higher the magnification, the smaller must become the distance in order to maintain illumination. Unfortunately, this distance also influences resolution adversely as it is decreased. The actual values of the distances between optical parts are shown in Fig. 3. It is seen that the distance between the objective and projector lens gaps is substantially smaller than $L/2$. The distance is actually $0.37L$, decreasing the maximum magnification possible in length L by six percent, which is negligible. Design considerations governing the lens energizing system and the mechanical construction of the pole pieces determine the spacing between the two lens gaps.

The short space below the column provided for the opening of the plate holder door, and the space above the column necessary to provide protection against high voltage flash-over, raise the total length of the microscope assembly to 30 inches from base to top of the hood. The diameter of the body of the microscope is determined by the lens. Smaller diameters than 4.75 inches result in the operation of the permanent magnets at too high a demagnetization coefficient.

THE OPTICAL SYSTEM

The optical elements of the microscope are all fixed, with the exception of the electron gun assembly which is externally adjustable. This need for adjustment in the gun system is occasioned by the demountable nature of the filament which must be replaced from time to time. Since filaments differ somewhat in shape and in the position of the point of maximum electron emission, adjustment must be provided for the gun assembly. The gun assembly comprises a filament-grid assembly, rigidly attached to an anode. The anode is positioned with respect to the other optical elements by means of two screws loaded by a return spring, Figs. 4 and 5. The filament-grid portion of the gun is physically described[4] and its operation is discussed[5] in the literature. The electrodes are connected in a self-biased circuit, giving rise to a very intense solid cone of illumination. It is the function of the transverse gun adjustment controls to select that element of the cone of illumination which is parallel to the optical axis of the system and position it on that axis.

The alignment reference of the entire optical system is the bore of the lens energizing spool. The projector pole piece assembly and the lower element of the objective pole piece are positioned in the spool hole to the tolerance of the machining, nominally 0.0003 inch. The position of the upper element of the objective lens must be experimentally determined and fixed when the instrument is initially put in operation. Early embodiments of the instrument positioned the upper lens ele-

FIG. 1. The small electron microscope column completely assembled.

[4] J. H. Reisner and R. G. Picard, Rev. Sci. Inst. 19, 556 (1948).
[5] J. Hillier and S. G. Ellis, J. App. Phys. 20, 700 (1949).

ment by its accurate fit into the energizing spool bore. However, the lateral positioning of the objective pole piece is extremely critical. The nominal build-up of fabrication tolerances amounting to 0.0003 inch can provide an image shift at the final screen of 0.15 inch per kilovolt change in accelerating voltage at fifty kilovolts and at a magnification of 6000 times. So large a shift is objectionable. To permit accurate electrical alignment of the upper objective element, a reference yoke is provided to assure position of that element. The yoke is transversely adjustable by means of four tapered screws (Fig. 5), which also serve to lock it in position so that the lens element may be removed and replaced without affecting alignment. Once aligned, the adjustment for the yoke is correct for all sizes and combinations of objective elements.

The objective aperture is referenced to the hole of the upper objective lens element, and is positioned 0.058 inch below the upper surface of the pole piece. The specimen is positioned 0.023 inch above the upper surface of the pole piece.

An aperture placed 0.434 inch above the specimen is used to exercise the beam control function normally accomplished by the condenser lens system of larger microscopes. Actually, the lack of a condenser lens ultimately limits the resolution of the instrument to that commensurate with the angular aperture of the electron gun. The disk-shaped aperture fits accurately in a hole of a heavy aperture holder, which is in turn referenced to the same yoke as that which aligns the upper lens element of the objective (Fig. 5). The massive aperture holder firmly held in the yoke does not move under the heating from the gun bombardment and shields the specimen rod from the heating and contamination of the gun.

Since permanent magnets energize the magnetic lenses, change in focal length may be accomplished only by changing the accelerating voltage applied to the microscope gun. The range of voltage necessary to provide focus for a wide range of specimens and holders is of the order of 500 volts at 50 kilovolts. A wider range is desirable for checking alignment and for checking the gap spacing of the objective pole pieces. A four-kilovolt swing produced through continuous coarse and a fine control has been found most suitable.

In order to assure the occurrence of a focused image at given voltage, e.g., 49 kilovolts, some variation in one of the focal lengths or object distances must be provided by mechanical means to compensate for differences in the build-up of mechanical tolerances of components and variations in the strength of energizing magnets. This required adjustment is provided in the gap spacing of the objective lens. The upper pole face of the objective pole piece seats against the energizing spool, and is, therefore, fixed with respect to the specimen. The lower pole of the objective, and the complete projector pole piece assembly are rigidly attached to one another. Motion of the lens group along the axis

FIG. 3. A dimensional diagram of the optical system showing lens dimensions for magnifications of 3000× and 6000×.

of the lens energizing spool is possible, and permits adjustment of the spacing of the objective pole piece gap. The axial movement is possible in fine increments with reproducibility by means of the screw thread which advances the projector pole piece as it is turned.

Changing the gap separation shifts the principal planes of the lens in the direction of the change. Since focal length is relatively independent of gap separation, the change in focal length due to gap increase is small compared to shift of the principal plane.[6] The result is that the lens system may be positioned so as to bring the focal plane of the objective into coincidence with the specimen plane for any of the available range of voltages by simply changing the objective gap.

In the initial adjustment of the instrument, too small a gap will result in a focal plane on the gun side of the specimen which manifests itself in an approach toward focus at the low voltage end of the focus controls. Such evidence indicates that the pole piece gap must be increased by turning the projector pole piece counterclockwise. Likewise, approaching focus at the high voltage end of the focus control means that the objective gap is excessive, which must be corrected by a clockwise rotation of the projector pole piece. The amount of the rotation depends upon the objective pole piece in use and upon the accelerating voltage. The required pole piece rotation may be estimated

[6] Zworykin, Morton, Ramberg, Hillier and Vance, *Electron Optics and The Electron Microscope* (John Wiley and Sons, Inc., New York, 1945), p. 153.

from the relation:

$$\frac{1}{f}=\frac{K}{V}$$

taken from the magnetic lens formula, where "f" is the focal length, "V" the accelerating voltage, and "K" a constant depending upon factors fixed for this application. From this relation, it is apparent that:

$$\frac{df}{f}=\frac{dV}{V}$$

In powerful lenses, used at large magnification as herein, it may be assumed that $f\cong q$, the object distance, so that for small increments:

$$\frac{\Delta q}{\Delta V}=\frac{q}{V}.$$

For the 3000× objective of Fig. 6, $q=0.138$ inch, and $V=50{,}000$ volts.

$$\frac{\Delta q}{\Delta V}\cong 0.0028 \text{ mils/volt.}$$

Since the gap change results from turning a 32 thread,

$$\frac{\Delta\theta}{\Delta V}\cong 0\ 033 \text{ degree/volt,}$$

where "θ" is the rotation of the pole piece required to advance it. Hence, if the voltage at which focus occurs is to be increased from 46 to 49 kilovolts, the pole piece must be turned 99 degrees counterclockwise.

The necessity for cleaning off contamination deposited on pole pieces during operation is the reason for the demountable construction of lens elements. Such con-

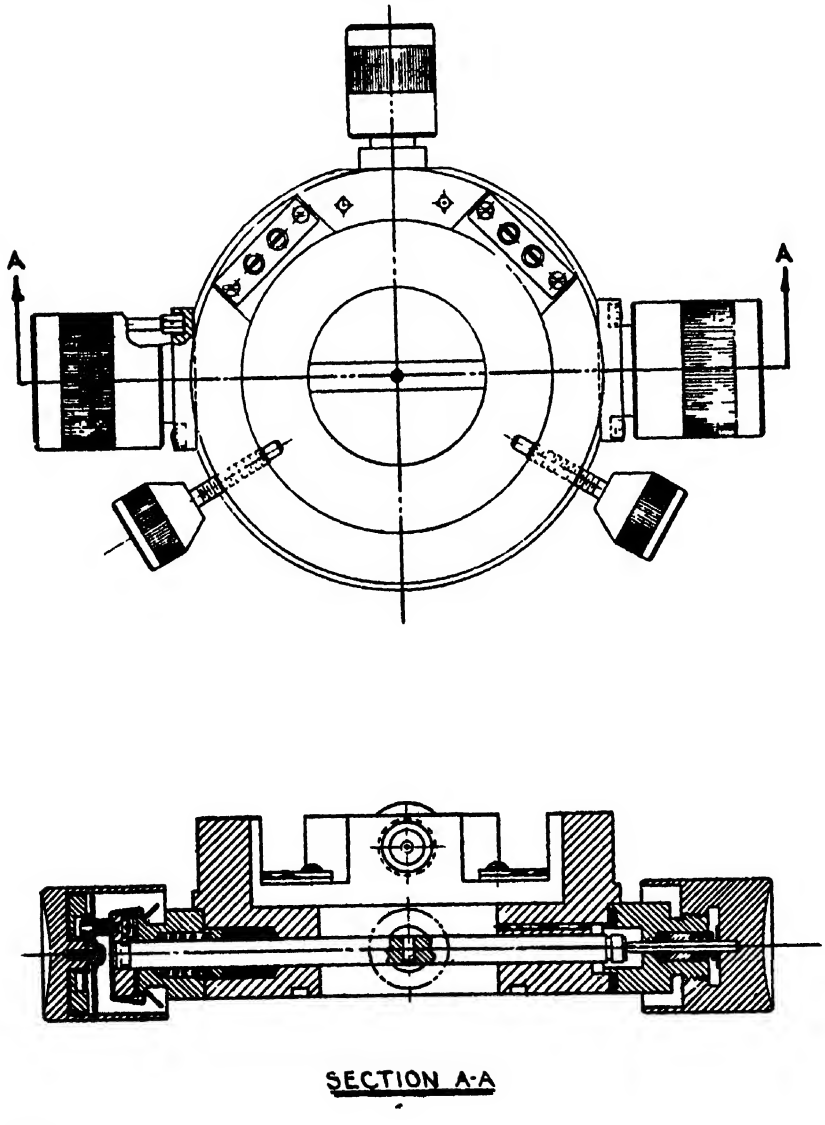

FIG. 4. Cross-sectional view of specimen and electron gun controls.

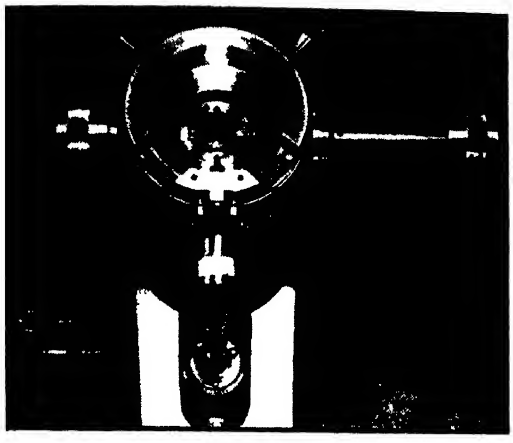

FIG. 5. Rear view of the upper end of the column with the gun assembly removed to show philister head screws used to align the upper element of the objective lens. The large circular body in the center of the chamber is the holder for the "condenser" aperture. The two knobs at the top of the picture adjust the position of the gun assembly.

tamination occurs in all objectives, but negligibly in projector lenses where the beam intensity is very low and the pole faces are completely shielded from the gun. The objective lens of the described microscope is easily demounted for cleaning and replacing apertures. The upper element may be removed through the specimen chamber, at which time the lower element of the objective pole piece is exposed for inspection and minor cleaning. Occasionally, it is necessary to remove the lower objective element. To do this, the projector pole piece is screwed out of its adjustment threads and the assembly pushed down and out of the lens energizing spool. The plate door and shutter should be open to admit the fingers to guide the pole piece out of the viewing chamber. Since the projector pole piece does not contaminate to any appreciable extent, its two pole piece elements are forced permanently onto its nonmagnetic spacer. Large holes in the spacer wall permit access to the pole faces for blowing out dust and for permitting minor cleaning.

The lower objective pole piece element is held tightly to the projector pole piece by set screws which pull down on a conical surface in such a way that the two iron pieces register along an inside surface. Such close registry minimizes stray fringe flux which might influence the electron beam.

Apertures are used (1) to restrict the beam striking the specimen, (2) to intercept electrons scattered from the specimen and thus increase image contrast, and (3) to prevent unused electrons from the powerful projector lens from reflecting off the viewing chamber walls onto the viewing and photographing area to cause "fog." The first two functions are achieved with accurately centered 75 micron platinum apertures. The apertures are identical and may be shifted from the objective to the collimating position as they become too contaminated for use in the objective gap. The small size of the aperture hole protects the specimen from damage from the intense electron beam and from radiant heat and evaporation products from the hot filament. The hole size is large enough to assure alignment of apertures without auxiliary mechanical positioning means and yet is small enough to give good contrast in the objective. The aperture following the projector is a 0.145 inch hole and is not critical in position or dimension.

ALIGNMENT

Alignment of the upper objective pole piece is a problem in vectors. Since the objective misalignment is manifested by an essentially linear shift of the image as the accelerating voltage is varied, the degree of misalignment may be measured by comparing shifts occurring for unit changes of voltage. It is found that the direction of image shift is different from the direction in which the center of the upper objective pole piece deviates from the true optical axis of the microscope. At 6000×, for medium misalignments, corresponding to less than 0.5 inch/1000 volts, the directions differ by about 120°, the misalignment direction being counterclockwise from the image shift when looking along the axis of the instrument toward the viewing screen. The magnitude of the change in image shift per kilovolt change in accelerating voltage is about 0.5 inch/1$K.V.$ for an 0.001 inch misalignment, or 75° turn on the yoke adjustment screws. Once an image shift has been noted as to direction and magnitude, the pole piece many be adjusted a compensating amount

FIG. 6. A side view of the microscope with back cover removed to show arrangement of the vacuum system.

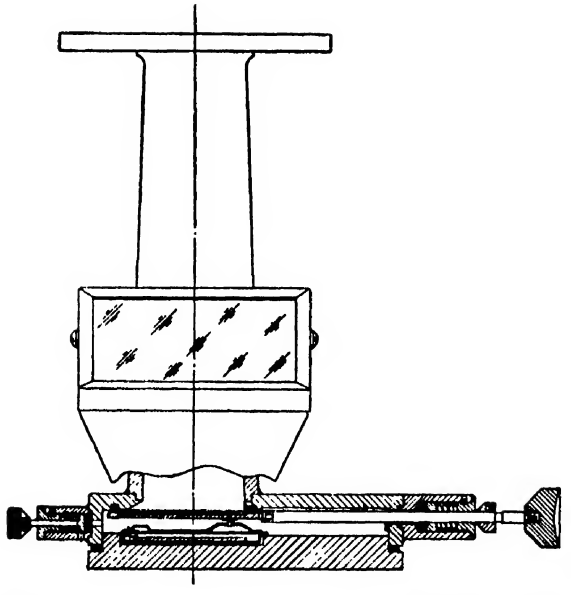

FIG. 7. Cross section showing the sliding value of the photographic chamber. The knob on the right is the activating means. The knob on the left admits air to the photographic chamber to permit opening the chamber door.

in the opposite direction 120° counterclockwise from that of the image shift. Usually, two or three attempts will reduce the image shift to a negligible value so that the only image change with voltage change is that of magnification. As previously stated, once the alignment yoke is adjusted and tightened, the alignment will hold while pole pieces are removed and changed through very long periods of use.

LENS ENERGIZATION

The lens pole piece gaps are energized by permanent magnets appropriately disposed in a magnetic circuit to reduce the deleterious effects of stray fields.* The magnetic means is Alnico V in four rectangular magnets placed parallel to the optical axis of the microscope. The two gaps are energized in parallel, but in the opposite sense, so that the outside shell of the magnetic assembly is sensibly a surface of constant mmf. This largely eliminates stray fields which can reduce magnification, produce asymmetries and distortions in the images, and make alignment difficult. The upper, objective gap gives a magnetomotive force of 1300 gilberts, while the lower projector gap gives a magnetomotive force of 900 gilberts. These values are comparable with those from electromagnetic energizers of the same size. The magnetic circuit parameters are designed so as to give high flux leakage; i.e., to operate the magnets at a large demagnetization coefficient. Such design makes possible the frequent insertion and removal of pole pieces without fear of demagnetization of the energizing magnets. The magnets are energized after assembly. If the spool assembly is ever disassembled, the magnets will be demagnetized to the point where the lenses are not adequately energized.

In spite of the use of powerful magnets, it is not difficult to insert or remove pole piece elements from the bore of the magnetic spool assembly.

VACUUM SYSTEM

The volume of the entire microscope, excluding pumping elements, is approximately one liter. This volume is divided into two pumping circuits. The plate chamber and viewing chamber comprise about 70 percent of the evacuated space, and are pumped directly into the diffusion pump through a $1\frac{3}{8}$ inch opening. The specimen chamber and gun are pumped through a half-inch line disposed along the back of the instrument. The plate chamber accounts for eight percent, the gun 25 percent, and the specimen chamber three percent of the total volume. Figure 6 shows the vacuum system.

Two specialized valving means are provided to replace the versatile, but complex valve systems generally used on electron microscopes. Basically, only two reasons for breaking the vacuum exist in routine electron microscopy; the insertion or removal of specimens, and the insertion and removal of photographic plates. Simple, multi-purpose assembles have been devised to fulfill these specialized functions. The vacuum sealing surface of the specimen lock is also the bearing through which all specimen motion is transmitted into the chamber, while the valve plate which seals the photographic chamber also provides a fluorescent screen and serves as a photographic shutter.

Insertion of a specimen admits only 0.02 cc of air into the vacuum system, while withdrawal of a specimen admits no air. The pumping system will recover safe operating vacuum within six seconds after the admission of a specimen. The introduction of a photographic plate into the vacuum enclosure introduces an appreciable amount of air, 80 cc. This is a result of the necessity for providing space for a sliding valve plate and cassette cover during photographic exposures. Figure 7 shows the valving mechanism. The valve is a sliding door which is moved on and off a circular gasket cemented in the wall of the chamber casting. To pump a plate, the knob outside the chamber is pulled to slide the valve off its gasket. This action breaks the vacuum seal between the viewing chamber and the photographic chamber, permitting the latter to be pumped out. Returning the knob to its initial position seals off the photo-chamber. Air is admitted to the photo-chamber so that it may be opened by pulling a simple relief valve on the left side of the photo-chamber. The vacuum valve system is very dependable. Air may be admited to the photochamber after plate exposure, without turning off the electron beam. A time of about 60 seconds is required to recover operating vacuum after the introduction of a dry photographic plate.

All air introduced with specimens and plates must

* J. H. Reisner, J. App. Phys. 21, 68 (1950). (In process of publication in full.)

pass through the diffusion pump. In spite of the deleterious effect which air has upon diffusion pump oil, octoil has been used for several months of general operation. With the much more stable silicone oil, very much longer periods of operation are possible.

When, in occasional maintenance, any of the components of the microscope are to be adjusted or removed from the vacuum, it is necessary to turn off the diffusion pump for several minutes before admitting air to the system through the relief valve on the photochamber.

The diffusion pump is a small air cooled D.P.I. VMF-10, using a Pressovac as a fore pump. The pump-down time from a cold start is about twenty-five minutes. A thermocouple gauge is used to indicate the vacuum. The meter employed is the test meter of the power supply which may be switched in when a pressure indication is desired.

SPECIMEN CONTROL

An unusual treatment of the specimen introduction and control has resulted in very great simplification in the operation and construction of the microscope. Grommet vacuum seals about shafts have long been used to obtain displacement and rotation through the confines of vacuum systems. By putting small cut-outs in such shafts, it is possible to introduce objects placed in the cut-out space into the vacuum, if the grommet is longer than the cut-out space. Such is the basis for the specimen holder to be described. Figures 4 and 5 show the actual specimen control system. A cylindrical hole 0.140 diameter, to accommodate the specimen holder, is open perpendicularly through a $\frac{5}{16}$ diameter shaft to bottom 0.012 inch from the surface of the shaft. A $\frac{1}{16}$ hole is continued through the shaft wall to permit egress of the electron beam. The transverse hole is roughly at the center of the six inch shaft. It is so positioned that when the shaft is pushed into the instrument up to the plunger of the right hand control, the specimen holder will be positioned over the lens opening. The area of the specimen is scanned in one direction by driving the shaft axially with the right-hand knob and plunger, and in a perpendicular direction by rotating with the left-hand knob.

The shaft rotation amounts to but 3° from its center position and permits scanning of three openings of a 200 mesh specimen support screen. The screen is situated 0.139 inch from the axis of rotation of the specimen shaft. In the extreme rotation positions, the specimen is only five microns closer to the objective lens than in its mean position. Such a displacement represents about 70 volts difference in focal voltages with the 3000× pole piece, and about 200 volts with the 6000× pole piece. The depth of focus is so great with the electron microscope that it is generally not necessary to refocus the field in going from the center to the extremes of specimen holder rotation. A total of about 36 mesh openings may be observed, 12 along the axis of the rod, three by rotation.

The axial movement of the specimen rod is provided through the right-hand knob by means of screw threads which advance a plunger registering against a hard metal plate on the end of the specimen holder rod. The rod is held tightly against the plunger by springs in the left-hand knob which grip a conical surface on the microscope housing. A limit spring slips into a groove at the right end of the specimen holder rod to prevent the rod from being pulled out of its sealing grommet and to prevent it from sliding back into the instrument under atmospheric pressure. The ability to remove the holder entirely from the path of the beam is useful in initially lining up the gun with the other optical elements.

Because of the sensitivity of the transverse control, six degrees of rotation to give full range of motion, the left-hand control knob is geared down 1:3. It has been found from experience that under these circumstances, control is quite adequate. The left-hand knob is highly damped in action to resist twist in the vacuum sealing grommet. In order that the specimen rod be correctly oriented to pass the electron beam through the specimen, a guide pin on the microscope must fit into a slot on the left hand knob before the rod can engage its springs on the advancing cone.

In order to keep the vacuum sealing grommet from wearing or binding, the specimen holder shaft is very lightly lubricated periodically with clear octoil.

VIEWING CHAMBER ASSEMBLY

In all electron microscopes, the viewing screen and plate must be normal to the beam. Direct viewing, desirable for brightness and sharpness, means that the fluorescent screen must be viewed obliquely. Therefore, the fifteen degree slope of this microscope column has been applied to facilitate direct viewing of the image. A wide window permits viewing with both eyes, and viewing by two people simultaneously.

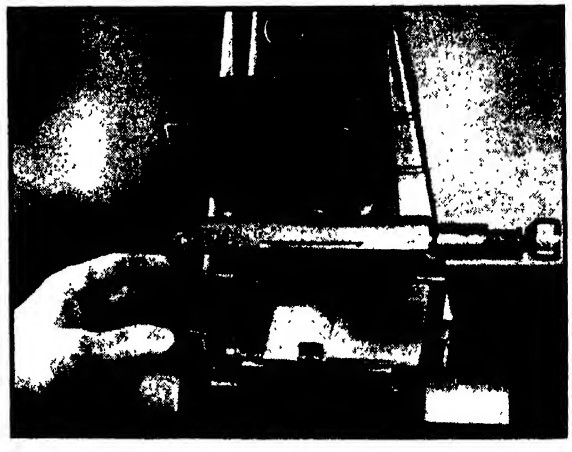

FIG. 8. Insertion of a photographic plate cassette.

Valving and plate exposure are accomplished by two moving parts, a rod with a hand knob on the end, and a metal plate. The plate has a circular depressed area on its upper surface to hold the electron sensitive phosphor and yet protect it from the vacuum sealing gasket across which the metal plate slides in the various phases of its valving cycle. A pin on the lower surface of the metal plate engages the cover to the photographic plate cassette. The description of a complete photographic cycle will make the operation of the mechanism more apparent.

With the camera door dropped open, a 2×2 plate cassette is clipped into an orienting slot and hold-down springs, Fig. 8. The door is snapped shut. The photochamber is pumped by sliding the movable plate far enough to the right to slip off the sealing gasket and open the chamber to the column. A stop on the shaft prevents more than the correct displacement. As soon as the photo chamber is evacuated, the high voltage may be turned on and an image focused. To expose the photographic plate, the same right hand knob is pulled to its extreme right position. This withdraws the valve plate from before the photographic plate. At the same time, a catch on the valve plate has engaged the cassette cover and slid it to the side, thus exposing the photographic plate. To end the exposure, the knob is pushed back to its inmost position, which closes the cassette cover and returns the valve plate to cover the vacuum gasket. A pull on a release valve on the left side of the photochamber admits air to the chamber which may then be opened for cassette removal.

The sliding valve plate is held against the vacuum gasket by light spring runners. The opening in the base of the viewing chamber is $1\frac{7}{8}$ inches in diameter, permitting exposure of a circular area of the same diameter on the photographic plate. The pole piece may be inserted and withdrawn through this hole with the aid of simple tools. The objective gap may be varied by engaging the screw slots on the projector by means of another simple tool inserted through the bottom hole when the valve plate is pulled aside.

POWER SUPPLY

Accelerating voltage and filament heating current are supplied by a fifty kilovolt supply almost identical with that used on commercial microscopes.[3] A driver unit which can sit on the table near the microscope permits control of voltage for focusing and control of emission for beam intensity. Once set with the variable controls, the chosen voltage and filament current reappear with every turn-on of the high voltage power switch. A meter reads, over its full scale, the reference voltage corresponding to the output range of voltages from 46 to 50 kv. Thus the focus voltage may be observed accurately on the meter. Such a feature is an excellent check on nearness to focus. It is useful in making through-focus series of photographs. It is a necessity in adjusting pole pieces to attain the desired focal voltage.

All electrical controls cause a voltage increase with a clockwise rotation. This means that the focal length of the lenses increases with a clockwise rotation of the high voltage focus control. As a result of the same electrical convention, electromagnetic lenses have their focal length decreased by the clockwise rotation. Using voltage focusing, the experienced electronmicroscopist finds the changes of appearance of fringes in the image occurring in reverse order to that which is encountered with current focusing. No other difference is apparent in the focusing process.

In an instrument designed for use by personnel untrained in electrical practice, safety precautions must be extensive. Circuit interlocks necessitate the correct positioning of the high voltage cable on the instrument and the attachment of the protective gun hood before voltage can be applied to the instrument. A quick-acting grounding mechanism is provided to discharge the high voltage supply when the gun hood is raised from its seat more than $\frac{3}{8}$ of an inch. If the high voltage has not been turned off before raising the hood, grounding the output in this manner will cause an overload relay system on the power supply to turn off the power.

A lead glass viewing window is provided to prevent the escape of x-rays generated by the electrons incident upon the viewing screen.

GENERAL FEATURES

The electron gun is the only externally adjustable optical element of the electron microscope. A heavy brass anode structure supports the filament grid and glass insulator components which are rigidly affixed to it. The brass anode is also the movable element, permitting sliding movement in a plane perpendicular to the optical axis of the microscope. The flat lower wall of the anode structure has holes to pass the electron beam and to permit evacuation of the gun volume through the specimen chamber. A gasket seat is provided on the bottom surface to carry the rubber gun gasket which provides a sliding vacuum seal between the anode and the specimen chamber. The position of the gun axis is determined by two adjustable plungers which register radially against the cylindrical outside wall of the anode. These plungers are activated by knobs, the two highest knobs on the column (Fig. 5), working through screw threads. A spring-loaded plunger extending radially backward on the microscope holds the anode tightly against the adjusting plungers to make the anode follow the plungers. The complete gun assembly may be removed from the column by removing the spring loaded plunger and sliding the gun to its extreme rear position so as to clear the adjusting plungers. If the position of the gun adjustment knobs is not changed, a gun may be removed and reinserted without changing alignment enough to lose illumination.

Since filaments, apertures, and diffusion pump oil

must be replaced occasionally and pole pieces must be removed for cleaning, all these components may be reached without major disassembly of the instrument or removal from its stand.

Stray alternating magnetic fields and vibration have always been two serious environmental hazards in high resolution electron microscopy. Careful consideration has been given toward overcoming these dangers in this instrument. From the objective pole piece to the photographic plate, the microscope beam is shielded behind heavy iron walls. In the extremely sensitive field region between lenses, the shielding from external fields is complete. Operation in the vicinity of relatively strong fields has shown little effect on the microscope image.

Vibration problems are largely eliminated by rigid construction throughout. Lens elements are held fast by the magnetic field in a one-piece housing. The viewing and specimen chambers are rigidly bolted to the lens housing. The two moving parts are the specimen rod and gun, both strong and well supported. The column of the instrument is supported at the base of the lens housing, not far from the center of gravity of the column, with the result that environmental vibration acts on the whole rather than on various parts.

SUMMARY

The instrument herein described has shown itself to be excellent for almost all types of electron microscopy not requiring resolutions better than 100A. Its unusual reproducibility makes it ideal for routine microscopy. Long sequences of pictures may be taken without touching gun adjustment, focus, or emission controls.

The direct magnifications of 1500, 3000, and 6000 times are chosen for convenience of observation and are not to be taken as a measure of resolution. Well-focused photographic images frequently reveal useful detail up to 20,000 diameters over-all magnification. The 1500× lens system is useful where studies are to be made on specimens familiar to the light microscopist and on specimens such as sections of tissue where fine structure must be viewed in relation to familiar gross structure such as cell walls. The 6000× magnification is useful where the highest resolution is routinely desired, such as in virus studies, and may most easily be achieved by virtue of the ability to focus the high magnification optical image most accurately. Figure 9 shows a high resolution photomicrograph taken with the described instrument.

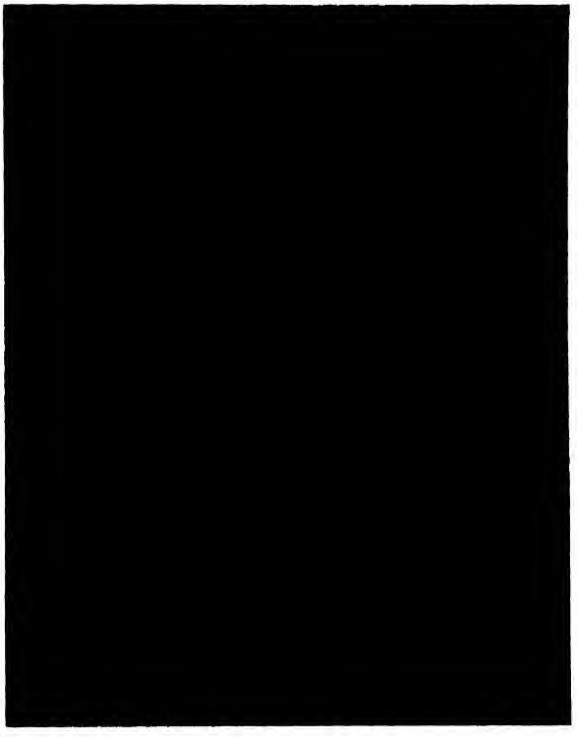

FIG. 9. Photomicrograph of a shadowed replica of an etched stainless steel surface. Magnification 20,000×. Taken at 3000×.

ACKNOWLEDGMENT

The authors wish to acknowledge the guidance and technical assistance of Perry C. Smith, under whose direction the work was carried out, and of Robert G. Picard, who frequently collaborated on the project. The electrical circuitry was carried out by Samuel M. Zollers. Acknowledgment is due Charles Yearsley, Richard McGarry, and A. M. Rennie for their assistance on mechanical design, and to Gustave Burger for much of the actual construction.

Artificial Field Equations for a Region Where μ and ϵ Vary with Position

P. D. P. SMITH
Westmount, Province of Quebec, Canada
(Received March 6, 1950)

I. Theory. The field equations developed admit of solutions in regions where μ and ϵ vary with position. For regions of zero conductivity, they are symmetrical with respect to electric and magnetic quantities, and the TM case can be derived from the TE. Fields derivable from a single component 4-potential are examined, and their propagation equations are found. A table relates the tensor and pseudo-tensor components to the usual vector components.

II. Applications in cylindrical polar coordinates. For the TE case, three types of solution exist, called A, B, or C, where the **E** field is parallel to the elementary vectors **dz**, **dr** or **rdθ**, respectively (for the TM case, **H** replaces **E**). In each TM or TE case, two possible distributions of μ and ϵ occur, leading to separable propagation equations. TEM waves can be derived from both TM and TE cases, but the impedances are different.

TE, TM and TEM waves for certain specific distributions of μ and ϵ, and their applications to curved guides, horns, and co-axial lines are considered. Some expressions are obtained for the fields, propagation constants, cut-off frequencies, and impedance. These solutions are not necessarily of the most general type, for to meet the conditions that restrict their choice, μ and ϵ are taken to be independent of the coordinate to which the transverse component of **E** (in TE) or **H** (in TM) is parallel.

I. THEORY

THE usual methods of procedure yield solutions of Maxwell's equations only in the following cases: (a) where space is everywhere homogeneous, (b) where space is subdivided into several homogeneous regions, (c) where the inductivity varies so slowly that it may be considered homogeneous.

This has been pointed out by Liebowitz,[1] who showed that it is possible to derive separable wave equations in a space where ϵ* is a function of position, by making use of a metric

$$ds^2=1/\epsilon\cdot\{(du^1)^2+(du^2)^2+(du^3)^2\}$$

and an auxiliary scalar function which is determined from ϵ. He proceeded to investigate the static field of a point charge. By assuming suitable distributions of ϵ, the field energy could be rendered finite.

However, a statement of the distribution of ϵ is a statement of the variation of the speed of light, and therefore of the variation of gravitational potential. It appears that his attack is really equivalent to guessing the solutions of Einstein's field equations for the space around a point charge. This particular instance does not concern the reduction in light velocity by scattering from many centers, as occurs in a dielectric, but a reduction in light velocity supposed inherent in the properties of space itself, such as that which causes the deviation of a light ray passing a heavy body. The problem of the gravitational field of a point charge has been solved by Weyl[2] and others, so that it is not necessary to guess at the result. The more fruitful use of equations of this type may be in problems of applied physics, to find solutions of Maxwell's equations for regions where μ and ϵ are known functions of position.

An alternative approach to Liebowitz's problem is formulated in this paper. The procedure used here is to set up a set of tensor field equations for a space where μ and ϵ are functions of position, and then investigate certain simple types of transverse electric and transverse magnetic waves, and the conditions for their propagation. The equations give results for regions where both μ and ϵ vary with position, and this respect are more general than Liebowitz's. On the other hand, solutions have only been found for certain simple cases where the four potential has only one component.

It turns out to be profitable to seek distributions of μ and ϵ leading to separable equations of propagation, rather than to seek general solutions for arbitrary μ and ϵ.

The field equations used are "artificial," in the sense that they are an artifice to help obtain solutions for the case of variable μ and ϵ. They have the appearance of being relativistic, but actually are only exact when the medium is at rest with respect to the observer. There is no practical disadvantage in this from an engineering point of view, as the velocity of the medium with respect to the observer is always far smaller than the velocity of light in the medium.

The equations, which have been published previously,[3] are

$$F^i=\partial_j F^{ij}, \tag{1.01}$$

$$0=\partial_i\varphi_{jk}+\partial_j\varphi_{ki}+\partial_k\varphi_{ij}, \tag{1.02}$$

$$F^{ij}=g^{\frac{1}{2}}\cdot(\epsilon/\mu)^{\frac{1}{2}}\varphi^{ij}, \tag{1.03}$$

$$F^i=g^{\frac{1}{2}}\rho\cdot dx^i/ds, \tag{1.04}$$

$$ds^2=g_{ij}dx^i dx^j=c^2dt^2/\mu\epsilon-\alpha^2(dx^1)^2-\beta^2(dx^2)^2-\gamma^2(dx^3)^2\simeq c^2dt^2/\mu\epsilon. \tag{1.05}$$

Equation (1.03) differs from the usual form because of the factor $(\epsilon/\mu)^{\frac{1}{2}}$. The current tensor, (1.04), becomes in an orthogonal coordinate system

$$F^4=\alpha\beta\gamma\rho\dot{x}^4/c(1-v^2/v_0^2)^{\frac{1}{2}},$$
$$v_0=c/(\mu\epsilon)^{\frac{1}{2}}.$$

[1] Liebowitz, Phys. Rev. 64, 294 (1943).
* ϵ, the dielectric "constant."
[2] Weyl, *Space, Time, Matter* (Methuen and Company, Ltd., London, 1920), pp. 252–262.
[3] P. D. P. Smith, J. App. Phys. 20, 633 (1949).

This shows that the expressions are only accurate when $v \ll v_0$, and are not truly relativistic.

Ohm's law, for this system, becomes

$$f_i = \sigma \varphi_{a,i} \bar{u}^a, \quad i<4, \tag{1.06}$$

where $\bar{u}^a$ is the mean velocity defined by

$$\bar{u}^a = \int u^a \cdot dN \Big/ \int dN,$$

$\int dN$ being the number of electrons in a volume that is small enough so that g_{ij} may be considered a constant, σ representing the conductivity. The Eq. (1.01) becomes

$$\{\sigma \cdot (\mu/\epsilon)^{\frac{1}{2}} \bar{u}_j + \partial_j\} F^{ij} = 0, \quad i<4 \tag{1.07}$$

equivalent to

$$\sigma\{\mathbf{E} + (1/c)[\bar{\mathbf{v}} \times \mathbf{B}]\} = \text{curl}\mathbf{H} - \dot{\mathbf{D}}/c \tag{1.08}$$

in vector notation.

In regions where $\sigma = 0$, there is complete symmetry between the electric and magnetic fields when the roles of μ and ϵ are interchanged. This symmetry can be brought out by introducing a new four-potential, ψ_i, the counterpart of the usual φ_i. We had

$$\varphi_{ij} = \partial_i \varphi_j - \partial_j \varphi_i \tag{1.09}$$

from which can be defined the pseudo-tensor

$$B^{ij} = (-)^{p(i,j,k,l)} \varphi_{kl}, \tag{1.10}$$

where $p(i, j, k, l)$ is the number of inversions of i, j, k, l from the order 1, 2, 3, 4. Thus it follows

$$F^{ij} = (g\epsilon/\mu) g^{ia} g^{jb} (-)^{p(a,b,c,d)} B^{cd} \tag{1.11}$$

and conversely

$$B^{ij} = (\mu/g\epsilon) g_{ka} g_{lb} (-)^{p(i,j,k,l)} F^{ab}. \tag{1.12}$$

At this point the second type of field will be introduced, namely that produced by the alternative four-potential ψ_i. For these fields

$$\psi_{cd} = \partial_c \psi_d - \partial_d \psi_c, \tag{1.13}$$

$$\partial_b \psi_{cd} + \partial_c \psi_{db} + \partial_d \psi_{bc} = 0 \tag{1.14}$$

and

$$F^{ab} = (-)^{p(a,b,c,d)} \psi_{cd}. \tag{1.15}$$

Using this in (1.12),

$$B^{ij} = (-)^{p(i,j,k,l)+p(a,b,c,d)} (\mu/g\epsilon) g_{ka} g_{lb} \psi_{cd}. \tag{1.16}$$

The majority of practical problems will be set up in orthogonal coordinates, in which (1.16) simplifies to

$$B^{ij} = (-)^{p(i,j,k,l)+p(k,l,i,j)} \cdot (\mu/g\epsilon) g_{kk} g_{ll} \psi_{ij}$$
$$= (\mu/g\epsilon) g_{kk} g_{ll} \psi_{ij}. \tag{1.17}$$

Thus in orthogonal coordinate systems

$$B^{ij} = (\mu/\epsilon)^{\frac{1}{2}} (g_{kk} g_{ll}/g_{ii} g_{jj})^{\frac{1}{2}} \psi_{ij} \tag{1.18}$$

TABLE I. The co-variant and contra-variant fields generated from the four potentials φ_i and ψ_i, and their equivalents in vector notation. The components generated by φ_3 or ψ_3 are indicated by an asterisk.

$\varphi_{12} = \alpha\beta B_3$	$\psi_{12} = -i\alpha\beta D_3$
$\varphi_{23} = \beta\gamma B_1$ *	$\psi_{23} = -i\beta\gamma D_1$ *
$\varphi_{31} = \gamma\alpha B_2$ *	$\psi_{31} = -i\gamma\alpha D_2$ *

and corresponding to this in the first type field

$$F^{ij} = (\epsilon/\mu)^{\frac{1}{2}} (g_{kk} g_{ll}/g_{ii} g_{jj})^{\frac{1}{2}} \varphi_{ij}. \tag{1.19}$$

From (1.18) and (1.19) is built the following table connecting the tensor and pseudo-tensor components with the usual vector components. As before[3] $\varphi_{41} = i\alpha E_1$, $\varphi_{12} = \alpha\beta B_3$, and use is made Eqs. (1.03), (1.10), and (1.15).

Thus corresponding to any solution of the field equations generated by the 4-potential φ_i there can be found another solution generated by the alternative potential ψ_i. This use of two alternative solutions is very common in wave guide theory, one solution yielding transverse electric, or TE, waves, the other transverse magnetic, or TM, waves.

The TE Case

For the sake of simplicity, the examples solved will be restricted to the case where there is only one non-vanishing component of the 4-potential, so that

$$\varphi_i = \delta_{i3} \varphi. \tag{1.20}$$

The field equations give immediately

$$\begin{aligned} &\varphi_{12} = 0, && \varphi_{41} = 0, \\ &\varphi_{23} = \partial_2 \varphi, && \varphi_{42} = 0, \\ &\varphi_{31} = -\partial_1 \varphi, && \varphi_{43} = \partial_4 \varphi. \end{aligned} \tag{1.21}$$

The contravariant field components are, from (1.19) and (1.21),

$$\begin{aligned} &F^{12} = 0, && F^{41} = 0, \\ &F^{23} = \alpha/\beta\gamma\mu \cdot \partial_2 \varphi, && F^{42} = 0, \\ &F^{31} = -\beta/\gamma\alpha\mu \cdot \partial_1 \varphi, && F^{43} = (\epsilon\alpha\beta/\gamma) \partial_4 \varphi. \end{aligned} \tag{1.22}$$

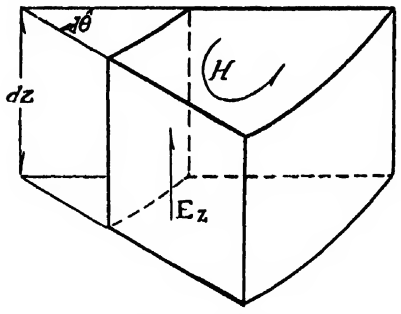

FIG. 1. TE waves of Type A. Fields generated by a single component 4-potential. The electric field is parallel to the z-axis, propagation is radial, or perpendicular to the axial planes.

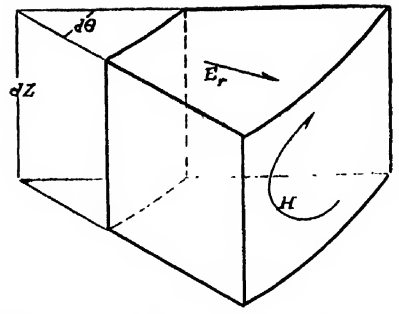

FIG. 2. TE waves of Type B. Fields generated by a single component 4-potential. The electric field is radial, and propagation is along the z-axis, or perpendicular to axial planes.

These non-vanishing components arising from φ_3, ψ_3 are marked with an asterisk in Table I, when their vector counterparts may be read.

Thus the contravariant group of field equations

$$0=\partial_j F^{ij}$$

become

$$0=\partial_1(\beta/\gamma\alpha\mu\cdot\partial_1\varphi)+\partial_2(\alpha/\beta\gamma\mu\cdot\partial_2\varphi)+\partial_4(\epsilon\alpha\beta/\gamma\cdot\partial_4\varphi)=0 \quad (1.23)$$

and also the three equations

$$\partial_3 F^{i3}=0. \quad (1.24)$$

These equations obviously give a TE wave propagated in directions perpendicular to dx^3. The electric field is parallel to the third coordinate dx^3.

If α, β, γ are independent of x^3, the equations (1.24) are identically satisfied if μ, ϵ, and φ are also independent of x^3. This restriction has been used in all cases examined in this paper.

On the other hand, it is simple to eliminate the field quantities from Eqs. (1.24), obtaining a pair of differential equations involving μ and ϵ. These, included merely for completeness, are

$$\partial_3 \log\{\partial_1 X/\partial_3(n^2\alpha^2)\}=0, \quad (1.25)$$

$$\partial_3 \log\{\partial_2 X/\partial_3(n^2\beta^2)\}=0, \quad (1.26)$$

$$n^2=\mu\epsilon, \quad X=\partial_3 \log\{\gamma/\epsilon\alpha\beta\}. \quad (1.27)$$

The TM Case

The TM case is obtained immediately from the TE case by interchanging the roles of μ and ϵ, ψ and φ. There follows for the non-vanishing field components

$$\psi_{23}=\partial_2\psi, \quad \psi_{31}=-\partial_1\psi, \quad \psi_{43}=\partial_4\psi, \quad B^{12}=\alpha/\beta\gamma\epsilon\cdot\partial_2\psi, \quad (1.28)$$

$$B^{21}=-\beta/\gamma\alpha\epsilon\cdot\partial_1\psi, \quad B^{43}=\mu\alpha\beta/\gamma\cdot\partial_4\psi. \quad (1.29)$$

The propagation equation becomes

$$0=\partial_1(\beta/\gamma\alpha\epsilon\cdot\partial_1\psi)+\partial_2(\alpha/\beta\gamma\epsilon\cdot\partial_2\psi)+\partial_4(\mu\alpha\beta/\gamma\cdot\partial_4\psi) \quad (1.30)$$

and also

$$\partial_3 B^{12}=0. \quad (1.31)$$

As before, 1.31 are satisfied if α, β, γ, μ, ϵ, and ψ are independent of x^3. If this is not so, then it would be necessary to ensure that μ and ϵ satisfy

$$\partial_3 \log\{\partial_1 Y/\partial_3(n^2\alpha^2)\}=0,$$
$$\partial_3 \log\{\partial_2 Y/\partial_3(n^2\beta^2)\}=0,$$

where

$$Y=\partial_3 \log(\gamma/\mu\alpha\beta).$$

This completes the theoretical part of this work. The next part involves the application of the theory to certain problems in cylindrical polar coordinates.

II. SOLUTIONS IN CYLINDRICAL POLARS

1. General Properties in Cylindrical Coordinates

Before proceding to consider specific examples using the theory developed in Section I, the general nature of the solutions which can arise from a single component of potential will be considered. The TM case has to be restricted to coordinate systems in which x^1 constant, x^2 constant, is a closed curve, because there is only one B component, and the corresponding lines of flux must be closed curves.

The possible choices are shown in Table II and Table III, along with the identifications of dx^1, dx^2, dx^3, α, β, and γ, and the corresponding propagation equation. The nature of the fields is shown diagrammatically in Figs. 1, 2, and 3 for TE waves, Fig. 4 for TM waves.

The fields are classified as Type A, B, or C, according as the coordinates (dx^1, dx^2, dx^3) are taken as (dr, $d\theta$, dz), ($d\theta$, dz, dr) or (dz, dr, $d\theta$).

The non-vanishing field components can be verified by referring to Table I of Section I, and remembering that only the third component of potential, φ_3 or ψ_3, is to be considered.

The form of TM waves conjugate to the TE waves of type C are shown in Table III. The equations $\partial_3 B^{12}$ are automatically satisfied if ψ, μ, ϵ are independent of θ, since α, β, and γ are independent of θ.

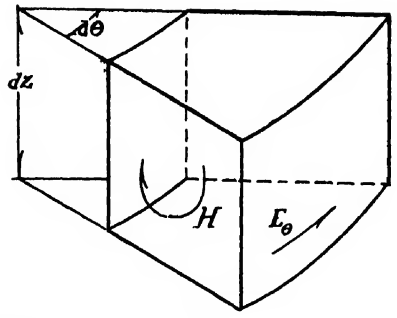

FIG. 3. TE waves of Type C. Fields generated by single component 4-potential. The electric field is perpendicular to planes through the axis, and propagation is radial or along the axis.

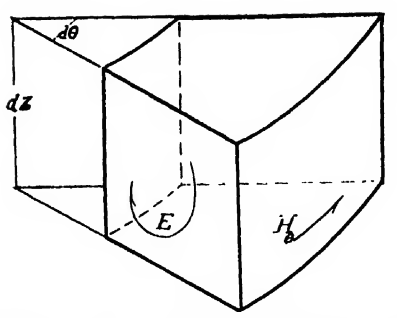

FIG. 4. TM waves of Type C. Fields generated by a single component of the alternative 4-potential. The magnetic field is perpendicular to planes through the axis, and propagation is radial, or along the axis.

TEM Waves

In addition to TE and TM waves, TEM waves can be propagated also. These are characterized by the potential depending on only one coordinate variable. For example, in the TM case the electric fields are given by

$$-i\beta\gamma\cdot D_1=\partial_2\psi, \quad -i\gamma\alpha\cdot D_2=-\partial_1\psi. \tag{2.01}$$

For TEM waves in a co-axial line, $D_z=0$, and hence it is necessary that $\partial\psi/\partial r=0$. The propagation equation reduces to

$$\frac{\partial}{\partial z}\left\{1/\epsilon\cdot\frac{\partial\psi}{\partial z}\right\}+\omega^2/c^2\mu\psi=0. \tag{2.02}$$

The field components are then given by

$$D_r=-i/r\cdot\partial\psi/\partial z, \quad H_\theta=-\omega/cr\cdot\psi. \tag{2.03}$$

The ratio

$$Z=E_r/H_\theta=ic/\omega\epsilon\cdot\partial/\partial z\log\psi. \tag{2.04}$$

The TE fields of type B, with $B_z=0$, can also yield a TEM wave. If $B_z=0$, then referring to the propagation equation for type B waves on Table II, in this case, where

$$B_z=-1/r\cdot\partial\varphi/\partial\theta=0, \tag{2.05}$$

it becomes

$$\partial/\partial z\{1/\mu\cdot\partial/\partial z(r\varphi)\}+\omega^2/c^2\cdot\epsilon\cdot r\varphi=0. \tag{2.06}$$

The field impedance ratio in this case becomes

$$Z'=E_r/H_\theta=(\omega\mu/ic)/\partial/\partial z\log\varphi. \tag{2.07}$$

If ψ and φ are proportional to $e^{S \text{ or } T}$, then for the TEM waves derived from TM waves

$$Z=\{\mu/\epsilon+c^2/\omega^2\epsilon^2\cdot(S''-S'\epsilon'/\epsilon)\}^{\frac{1}{2}}, \tag{2.08(a)}$$

while for those derived from TE waves

$$Z'=\{\epsilon/\mu+c^2/\omega^2\mu^2(T''-T'\mu'/\mu)\}^{-\frac{1}{2}}. \tag{2.08(b)}$$

When μ and ϵ are constant,

$$Z=Z'.$$

The next sections deal with specific examples of the method in greater detail. Only a few of the many possible examples have been solved.

Section 2. TE Waves of Type A

In this case

$$dx'=dr, \quad dx^2=d\theta, \quad dx^3=dz, \quad \alpha=1, \quad \beta=r, \quad \gamma=1. \tag{2.09}$$

The non-vanishing field components are

$$E_z=\omega/ic\cdot\varphi,$$
$$B_r=1/r\cdot\partial\varphi/\partial\theta, \quad B_\theta=-\partial\varphi/\partial r. \tag{2.10}$$

The propagation equation becomes, in this case

$$0=\frac{\partial}{\partial r}\left\{\frac{r}{\mu}\frac{\partial\varphi}{\partial r}\right\}+\frac{\partial}{\partial\theta}\left\{\frac{1}{r\mu}\frac{\partial\varphi}{\partial\theta}\right\}+\frac{\omega^2}{c^2}\epsilon r\varphi. \tag{2.11}$$

The remaining equations,

$$\partial/\partial z(F^{i3})=0 \tag{2.12}$$

are automatically satisfied if φ, μ, and ϵ are independent of z, because α, β, γ are all independent of z.

The next problem is to obtain a possible pair of functions

$$\mu=\mu(r,\theta), \quad \epsilon=\epsilon(r,\theta)$$

that make (2.11) separable. Let

$$\mu=a(r)b(\theta), \quad \epsilon=c(r)f(\theta) \tag{2.13}$$

and let

$$\varphi=R(r)\Theta(\theta).$$

Then Eq. (2.11) becomes

$$\frac{ra(r)}{R}\frac{d}{dr}\left\{\frac{r}{a(r)}\frac{dR}{dr}\right\}+\frac{b(\theta)}{\Theta}\frac{d}{d\theta}\left\{\frac{1}{b(\theta)}\frac{d\Theta}{d\theta}\right\}$$
$$+\omega^2/c^2\cdot r^2a(r)c(r)b(\theta)f(\theta)=0.$$

This equation is separable if either

$$r^2a(r)c(r)=k_r \text{ a constant, or,} \tag{2.14}$$

$$b(\theta)f(\theta)=k_\theta \text{ a constant.} \tag{2.15}$$

These two cases will be referred to as k_r-separability and k_θ-separability.

	TYPE C						

For k_r-separability

$$\frac{ra(r)}{R}\frac{d}{dr}\left\{\frac{r}{a(r)}\frac{dR}{dr}\right\}=\lambda^2, \tag{2.16}$$

$$0=\frac{b(\theta)}{\Theta}\frac{d}{d\theta}\left\{\frac{1}{b(\theta)}\frac{d\Theta}{d\theta}\right\}+\{\lambda^2+\omega^2/c^2\cdot k_r b(\theta)f(\theta)\}. \tag{2.17}$$

On the other hand, k_θ-separability gives

$$\frac{ra(r)}{R}\frac{d}{dr}\left\{\frac{r}{a(r)}\frac{dR}{dr}\right\}=\{\eta^2-\omega^2/c^2\cdot k_\theta\cdot r^2a(r)c(r)\}, \tag{2.18}$$

$$\frac{b(\theta)}{\Theta}\frac{d}{d\theta}\left\{\frac{1}{b(\theta)}\frac{d\Theta}{d\theta}\right\}+\eta^2=0. \tag{2.19}$$

An Example of TE Waves of Type A Using k_θ-Separability

Either of these last two alternatives can be attacked as a new differential equation, the values of μ and ϵ being given. An alternative attack is to choose the values of $a(r)$ and $c(r)$ in such a way as to generate known differential equations, or, what is equivalent, to choose the functions R and Θ and seek as solutions $a(r)$ and $c(r)$. This provides a great flexibility for design of apparatus. The function $b(\theta)$ must be periodic if θ can vary over a range greater than 2π; for example, it could be

$$b(\theta)=1+A\cos k\theta$$

or it could even be represented by a Fourier series.

Equation (2.19) can also be written

$$d^2\Theta/d\theta^2+d\Theta/d\theta\cdot d/d\theta(\log 1/b(\theta))+\eta^2\Theta=0. \tag{2.20}$$

For the case where $b(\theta)=\theta^{-n}$, the solution is

$$\Theta=\theta^{\frac{1}{2}(1-n)}\{CJ_{\frac{1}{2}(n-1)}(\eta\theta)+DN_{\frac{1}{2}(n-1)}(\eta\theta)\}. \tag{2.21}$$

As materials of zero or infinite magnetic permeability are unknown, the plane $\theta=0$ must be outside the region filled with this particular medium. This could occur in a V-shaped horn with metal walls lying in the planes $\theta=\theta_1$, $\theta=\theta_2$, where

$$0<\theta_1<\theta_2<2\pi.$$

In such a horn η will be determined from the boundary condition that

$$E_z=\omega/ic\cdot\varphi=0$$

at

$$\theta=\theta_1 \quad\text{and}\quad \theta=\theta_2.$$

From this it follows that for a horn the boundary conditions are

$$J_{\frac{1}{2}(n-1)}(\eta\theta_1)/N_{\frac{1}{2}(n-1)}(\eta\theta_1)=J_{\frac{1}{2}(n-1)}(\eta\theta_2)/N_{\frac{1}{2}(n-1)}(\eta\theta_2). \tag{2.22}$$

The differential equation for the radial factor can be written from (2.18)

$$0=R''+R'(1/r-a'/a)+\{\omega^2/c^2\cdot k_\theta a(r)c(r)-\eta^2/r^2\}R. \tag{2.23}$$

At some radius

$$r_0 \text{ let } a_0=a(r_0),\quad c_0=c(r_0) \tag{2.24}$$

and let

$$v=\omega/c\cdot(k_\theta a_0c_0)^{\frac{1}{2}}\cdot r=\omega/c\cdot(\mu_0\epsilon_0)^{\frac{1}{2}}r. \tag{2.25}$$

Then we find

$$0=\frac{d^2R}{dv^2}+\frac{dR}{dv}\cdot\left\{\frac{1}{v}-\frac{d}{dv}\log a\right\}+\left\{\frac{a(r)c(r)}{a_0c_0}-\frac{\eta^2}{v^2}\right\}R. \tag{2.26}$$

TABLE III. Propagation equations and field components for TM waves generated by a single component of 4-potential.

dx^1	dx^2	dx^3	α	β	γ	Propagation Equation & Field Components	Character of Waves.
dy	dr	$d\theta$	1	1	r	$\frac{\partial}{\partial z}\{\frac{1}{re}\frac{\partial \psi}{\partial z}\}+\frac{\partial}{\partial r}\{\frac{1}{re}\frac{\partial \psi}{\partial r}\}+\frac{\omega^2}{c^2}\frac{\mu}{r}\psi=0$	(a) TM wave propagated in direction dz in a cylindrical guide or co-axial line.
TM WAVES TYPE C						$H_\theta=-\omega/cr\cdot\psi$ $\quad D_z=i/r\cdot\frac{\partial \psi}{\partial r}$ $\quad D_r=-i/r\frac{\partial \psi}{\partial z}$	(b) TM waves propagated radially in a 360° horn. (c) TM waves propagated radially in a cavity with cylindrical walls.

Comparing this with the last equation given by Janke and Emde in their Chapter VIII,[4] Section 7*, which is, with x replaced by v

$$\frac{d^2y}{dv^2}+\frac{dy}{dv}\cdot\left(\frac{1}{v}-2u\right)+\left\{1+u^2-\frac{du}{dv}-\frac{u}{v}-\frac{p^2}{v^2}\right\}y=0 \quad (2.27)$$

it is clear the two Eqs. (2.26) and (2.27) are identical if

$$2u=d/dv\cdot\log a=(a'/a)\cdot c/\omega(\mu_0\epsilon_0)^{\frac{1}{2}}, \quad (2.28)$$

$$1+u^2-\frac{du}{dv}-\frac{u}{v}=\frac{a(r)c(r)}{a_0c_0}=\frac{a(v)c(v)}{a_0c_0}, \quad (2.29)$$

$$p^2=\eta^2. \quad (2.30)$$

Thus the solution becomes

$$R=a(r)^{\frac{1}{2}}\{CJ_\eta(\omega/c\cdot(\mu_0\epsilon_0)^{\frac{1}{2}}\cdot r)+DN_\eta(\omega/c\cdot(\mu_0\epsilon_0)^{\frac{1}{2}}r). \quad (2.31)$$

The function $c(v)=c(r)$

$$=\frac{a_0c_0}{a(r)}\left\{1-\frac{c^2}{2\omega^2\mu_0\epsilon_0}\left(\frac{a''}{a}-\frac{3}{2}\left(\frac{a'}{a}\right)^2+\frac{a'}{ra}\right)\right\}. \quad (2.32)$$

Thus we have, collecting results, for the case where this medium fills a conducting horn from $\theta=\theta_1$ to $\theta=\theta_2$,

$$\mu=a(r)\cdot\theta^{-n}, \quad (2.33)$$

$$\epsilon=(\mu_0\epsilon_0\theta^n/a(r))\{1-c^2/2\omega^2\mu_0\epsilon_0\cdot(a''/a-\tfrac{3}{2}(a'/a)^2+a'/ra)\}, \quad (2.34)$$

$$\varphi=\theta^{-q}\{J_q(\eta\theta)/J_q(\eta\theta_1)-N_q(\eta\theta)/N_q(\eta\theta_1)\}\times a(r)^{\frac{1}{2}}\cdot H_\eta^{(1)\text{ or }(2)}(\omega(\mu_0\epsilon_0)^{\frac{1}{2}}r/c),$$

$$E_z=\omega/ic\cdot\varphi, \quad B_r=1/r\partial\varphi/\partial\theta, \quad B_\theta=-\partial\varphi/\partial r, \quad (2.10)$$

where

$$q=\tfrac{1}{2}(n-1).$$

These solutions contain an arbitrary function $a(r)$.

[4] Janke and Emde, *Tables of Functions* (Dover Publications, New York, 1943), p. 147.

An Example of TE Waves of Type A Using k_r-Separability

In the case of k_r-separability, the differential equation for R is, from (2.16),

$$R''+(1/r-a'/a)R'-\lambda^2/r^2\cdot R=0. \quad (2.35)$$

This becomes a very simple equation, if the medium is constructed so that

$$a(r)=Cr^A, \quad (2.36)$$

$$a'/a=A/r, \quad (2.37)$$

for then R satisfies the homogeneous equation

$$R''+(1-A)R'/r-\lambda^2R/r^2=0, \quad (2.38)$$

so that the solution is $R=Pr^{m_1}+Qr^{m_2}$; with m_1 and m_2 the two roots of $m(m-1)+m(1-A)-\lambda^2=0$ or

$$m=\tfrac{1}{2}A\pm(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}. \quad (2.39)$$

Thus when $a(r)=Cr^A$ $c(r)=k_rC^{-1}r^{-A-2}$ the factor R is

$$R=r^{\frac{1}{2}A}\{P\exp[\log r(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}]+Q\exp[-\log r(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}]\}. \quad (2.40)$$

The Θ factor satisfies (2.17), or

$$0=\Theta''+\Theta'\cdot d/d\theta\cdot\log 1/b(\theta)+\{\lambda^2+\omega^2k_rf(\theta)b(\theta)/c^2\}\Theta. \quad (2.41)$$

Again, considering the case where $b(\theta)=\theta^{-n}$, the equation becomes

$$\Theta''+n\Theta'/\theta+\{\lambda^2+\omega^2k_rf(\theta)/c^2\theta^n\}\Theta=0. \quad (2.42)$$

As in the previous section, the factor is taken as

$$\Theta=\theta^{\frac{1}{2}(1-n)}J(\theta). \quad (2.43)$$

J then satisfies

$$0=J''+J'/\theta+\{\lambda^2+\omega^2k_rf(\theta)/c^2\theta_n-\tfrac{1}{4}(1-n)^2/\theta^2\}J. \quad (2.44)$$

The equation evidently becomes a Bessel's equation if

$$f(\theta)=L^2\theta^n+\theta^{n-2}$$

the solutions being

$$\Theta=\theta^{\frac{1}{2}(1-n)}H_p^{(1)\text{ or }(2)}(\lambda_0\theta), \tag{2.45}$$

where $p^2=\frac{1}{4}(n-1)^2-\omega^2k_r/c^2$, p and λ_0 are constants, $\lambda_0^2=\lambda^2+\omega^2k_rL^2/c^2$.

Summarizing the results of this example, in a medium where

$$\mu=Cr^A\theta^{-n}, \tag{2.46}$$

$$\epsilon=k_rC^{-1}r^{-A-2}(L^2\theta^n+\theta^{n-2}) \tag{2.47}$$

the function φ is

$$\varphi=r^{\frac{1}{2}A}\{P\exp[\log r(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}] +Q\exp[-\log r(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}]\} \times\theta^{\frac{1}{2}(1-n)}\{EH_p^{(1)}(\lambda_0\theta)+FH_p^{(2)}(\lambda_0\theta)\}, \tag{2.48}$$

$$p^2=\tfrac{1}{4}(n-1)^2-\omega^2k_r/c^2, \quad \lambda_0^2=\lambda^2+L^2\omega^2k_r/c^2. \tag{2.49}$$

For a more specific example, a curved wave guide, bounded by highly conducting metal sheets at two planes of constant z, and by two cylinders of radii r_0 and r_1, may be considered. The variable r may be written

$$r=e^\sigma$$

and to make $\varphi(r_0)=0$ and $\varphi(r_1)=0$ (so that E_z vanishes at its outer and inner wall), let

$$P=e^{i\alpha_0},$$
$$Q=-e^{-i\alpha_0}.$$

Then in this case

$$R=r^{\frac{1}{2}A}\{\exp[\sigma(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}+i\alpha_0] -\exp[-\sigma(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}-i\alpha_0]. \tag{2.50}$$

This can have zeros for real values of r or σ if

$$\lambda^2+\tfrac{1}{4}A^2<0.$$

Writing

$$\lambda^2=-m^2,$$
$$(\lambda^2+\tfrac{1}{4}A^2)^{\frac{1}{2}}=i(m^2-\tfrac{1}{4}A^2)^{\frac{1}{2}}$$

and this makes

$$R=r^{\frac{1}{2}A}\cdot 2i\cdot\sin\{(m^2-\tfrac{1}{4}A^2)^{\frac{1}{2}}\sigma+\alpha_0\}. \tag{2.51}$$

When $r=r_0$, $\sigma=\sigma_0$, and $r=r_1$, $\sigma=\sigma_1$, $R=0$, so

$$(m^2-\tfrac{1}{4}A^2)^{\frac{1}{2}}\sigma_0+\alpha_0=0,$$
$$(m^2-\tfrac{1}{4}A^2)^{\frac{1}{2}}\sigma_1+\alpha_0=l\pi, \quad l=\text{integer}$$
$$m^2-\tfrac{1}{4}A^2=l^2\pi^2/(\sigma_1-\sigma_0)^2.$$

Since the Hankel's functions contain exponential factors of the type $\exp(\pm i\lambda_0\theta)$, in this case they become proportional to

$$\exp\pm i\{\omega^2k_rL^2/c^2-l^2\pi^2/(\sigma_1-\sigma_0)^2-\tfrac{1}{4}A^2\}^{\frac{1}{2}}\cdot\theta.$$

This guide will pass all frequencies above f_c where

$$4\pi^2f_c^2k_rL^2/c^2>l^2\pi^2/(\sigma_1-\sigma_0)^2+\tfrac{1}{4}A^2.$$

It will be noted f_c depends upon the two constants A and L.

Section 3. TE Fields of Type C

The specific case considered will be one whose

$$\mu=Mr^{2k-2}e^{2\alpha z}, \tag{3.01}$$

$$\epsilon=\epsilon_0\mu_0/\mu. \tag{3.02}$$

For fields of type C

$$dx^1=dz, \quad dx^2=dr, \quad dx^3=d\theta,$$
$$\alpha=1, \quad \beta=1, \quad \gamma=r. \tag{3.03}$$

The non-vanishing field components are

$$E_\theta=\omega/icr\cdot\varphi, \; B_z=1/r\cdot\partial\varphi/\partial r, \; B_r=-1/r\cdot\partial\varphi/\partial z. \tag{3.04}$$

The propagation equation is, from Table II,

$$\frac{\partial}{\partial r}\left\{\frac{1}{r\mu}\frac{\partial\varphi}{\partial r}\right\}+\frac{\partial}{\partial z}\left\{\frac{1}{r\mu}\frac{\partial\varphi}{\partial z}\right\}+\frac{\omega^2\epsilon}{c^2r}\cdot\varphi=0. \tag{3.05}$$

Suppose that

$$\mu=\mu_1(r)\cdot\mu_2(z), \tag{3.06}$$

$$\epsilon=\epsilon_1(r)\cdot\epsilon_2(z), \tag{3.07}$$

$$\varphi=R(r)\cdot Z(z), \tag{3.08}$$

then

$$0=\frac{r\mu_1(r)}{R}\frac{d}{dr}\left\{\frac{1}{r\mu_1(r)}\frac{dR}{dr}\right\}+\frac{\mu_2(z)}{Z}\frac{d}{dz}\left\{\frac{1}{\mu_2(z)}\frac{dZ}{dz}\right\} +\frac{\omega^2}{c^2}\mu_1(r)\epsilon_1(r)\mu_2(z)\epsilon_2(z). \tag{3.09}$$

This equation is separable if either

$$\mu_1(r)\cdot\epsilon_1(r)=k_r \;\; (k_r\text{-separability}), \tag{3.10}$$

$$\mu_2(z)\cdot\epsilon_2(z)=k_z \;\; (k_z\text{-separability}). \tag{3.11}$$

For k_r-separability

$$\frac{r\mu_1(r)}{R}\frac{d}{dr}\left\{\frac{1}{r\mu_1(r)}\frac{dR}{dr}\right\}+\lambda_1^2=0, \tag{3.12}$$

$$0=\frac{\mu_2(z)}{Z}\frac{d}{dz}\left\{\frac{1}{\mu_2(z)}\frac{dZ}{dz}\right\}-\left\{\lambda_1^2-\frac{\omega^2}{c^2}k_r\mu_2(z)\epsilon_2(z)\right\}. \tag{3.13}$$

While for k_z-separability

$$\frac{r\mu_1(r)}{R}\frac{d}{dr}\left\{\frac{1}{r\mu_1(r)}\frac{dR}{dr}\right\}+\frac{\omega^2}{c^2}k_z\mu_1(r)\epsilon_1(r)=\lambda_2^2, \tag{3.14}$$

$$\frac{\mu_2(z)}{Z}\frac{d}{dz}\left\{\frac{1}{\mu_2(z)}\frac{dZ}{dz}\right\}+\lambda_2^2=0. \tag{3.15}$$

Up to this point no use has been made of Eq. (3.01) and (3.02), and the equations might be solved by accurate or approximate values of the functions $\mu_1(r)$, $\epsilon_1(r)$ in Eq. (3.14) or arbitrary values of $\mu_2(z)$, $\epsilon_2(z)$ in (3.13). If μ and ϵ have the values given in (3.01) and (3.02), $\mu\epsilon$ is a

constant, and the equations for the factors μ_1, μ_2, ϵ_1, and ϵ_2, become

$$\mu_1 = Mr^{2k-2}, \qquad \mu_2 = e^{2az}, \tag{3.16}$$

$$\epsilon_1 = \mu_0\epsilon_0/Mr^{2k-2}, \quad \epsilon_2 = e^{-2az}. \tag{3.17}$$

Both separability conditions are met, so either (3.12), (3.13) or (3.14), (3.15) can be used. Substituting these values in (3.12) and (3.13) gives

$$\frac{Mr^{2k-1}}{R}\frac{d}{dr}\left\{\frac{1}{Mr^{2k-1}}\frac{dR}{dr}\right\}+\lambda_1^2=0 \tag{3.18}$$

and

$$\frac{e^{2az}}{Z}\frac{d}{dz}\left\{e^{-2az}\frac{dZ}{dz}\right\}-\{\lambda_1^2-\omega^2k_r/c^2\}=0$$

or

$$0=Z''-2aZ'-\{\lambda_1^2-\omega^2\mu_0\epsilon_0/c^2\}Z. \tag{3.19}$$

This is immediately solved by

$$Z=\exp pz \tag{3.20}$$

where

$$p=a\pm i(\omega^2\mu_0\epsilon_0/c^2-\lambda_1^2-a^2)^{\frac{1}{2}}. \tag{3.21}$$

Writing $R=r^kS(r)$ Eq. 3.18 becomes

$$S''+1/r\cdot S'+\{(\lambda_1)^2-k^2/r^2\}S=0. \tag{3.22}$$

Thus it is clear that the radial function is

$$R=r^k\{AJ_k(\lambda_1r)+BN_k(\lambda_1r)\} \tag{3.23}$$

and

$$\varphi=r^k\{AJ_k(\lambda_1r)+BN_k(\lambda_1r)\}e^{pz}. \tag{3.24}$$

In this problem we started with the arbitrary distribution of μ and ϵ given by (3.01) and (3.02), and showed the solution could be expressed in terms of Bessel Functions and exponentials, a generalization of the solution applying when μ and ϵ are constant, which is

$$\varphi_0=r\{AJ_1(\lambda_1r)+BN_1(\lambda_1r)\}e^{pz}. \tag{3.25}$$

The non-vanishing field components are

$$E_\theta=-i\omega/c\cdot r^{k-1}\{AJ_k(\lambda_1r)+BN_k(\lambda_1r)\}e^{pz}, \tag{3.26}$$

$$B_r=-pr^{k-1}\{AJ_k(\lambda_1(r))+BN_k(\lambda_1r)\}e^{pz}, \tag{3.27}$$

$$B_z=\lambda_1r^{k-1}\{AJ_{k-1}(\lambda_1r)+BN_{k-1}(\lambda_1r)\}e^{pz}, \tag{3.28}$$

since Bessel functions obey

$$[dZ_k/d(\lambda_1r)]=Z_{k-1}-k/\lambda_1\cdot Z_kr^{-1}.$$

The solutions agree with the classic solutions for a region where μ and ϵ are constant, as is seen on taking $k=1$, $a=0$.

This choice of the function $\mu(r, z)$ leads to an infinite value of either μ or ϵ on the axis. For this reason it is necessary to specify that the medium does not extend all the way in to the axis. An interesting case is that of a co-axial line where the space between the conductors is filled with a medium specified by Eqs. (3.01) and (3.02). If the medium fills a co-axial line, and is bounded by highly conducting metal cylinders of radii r_0 and r_1, then the condition for the vanishing of the tangential electric field is

$$J_k(\lambda_1r_0)/N_k(\lambda_1r_0)=J_k(\lambda_1r_0)/N_k(\lambda_1r_0). \tag{3.29}$$

The roots in λ_1 of this equation determine the values of the propagation constant p. This constant is complex at all angular frequencies above

$$f_c=1/2\pi\cdot c\{(\lambda_1^2+a^2)/\mu_0\epsilon_0\}^{\frac{1}{2}}.$$

Below this frequency the propagation constant is a real number.

Section 4. TM Waves of Type C

Since to each solution of the field equations representing a TE wave $\varphi_3=\varphi(\mu, \epsilon)$ there is a corresponding TM wave generated by $\psi_3=\psi(\epsilon, \mu)$, it is possible to write down immediately the TM solutions corresponding to (3.01), (3.02), and (3.24), namely

$$\epsilon=Mr^{2k-2}e^{2az}, \tag{4.01}$$

$$\mu=\mu_0\epsilon_0/\epsilon, \tag{4.02}$$

$$\psi=r^k\{CJ_k(hr)+DN_k(hr)\}e^{pz}, \tag{4.03}$$

where

$$p=a\pm i\{\omega^2\mu_0\epsilon_0/c^2-h^2-a^2\}^{\frac{1}{2}}. \tag{4.04}$$

The non-vanishing field components are

$$H_\theta=-\omega/c\cdot r^{k-1}\{CJ_k(hr)+DN_k(hr)\}e^{pz}, \tag{4.05}$$

$$D_r=-ipr^{k-1}\{CJ_k(hr)+DN_k(hr)\}e^{pz}, \tag{4.06}$$

$$D_z=ih\cdot r^{k-1}\{CJ_{k-1}(hr)+DN_{k-1}(hr)\}e^{pz}. \tag{4.07}$$

If the medium described by Eqs. (4.01) and (4.02) fills the space between two co-axial conductors of radii r_0 and r_1, the boundary conditions $D_z(r_0)=D_z(r_1)=0$ give

$$J_{k-1}(hr_0)/N_{k-1}(hr_0)=J_{k-1}(hr_1)/N_{k-1}(hr_1). \tag{4.08}$$

These results obviously reduce to the classic results for a co-axial guide when $k=1$, $a=0$.

Section 5. TEM Waves

For the case of a co-axial line filled with a medium described by (4.01) and (4.02), TEM waves can be propagated if $D_z=0$. The fields for this case are described by

$$\partial/\partial z\{1/\epsilon\cdot\partial\psi/\partial z\}+\omega^2/c^2\cdot\mu\psi=0, \tag{2.02}$$

$$D_r=-i/r\cdot\partial\psi/\partial z, \quad H_\theta=-\omega/rc\cdot\psi. \tag{2.03}$$

For this particular problem

$$\frac{d}{dz}\left\{e^{-2az}\frac{d\psi}{dz}\right\}+\frac{\omega^2}{c^2}\cdot\mu_0\epsilon_0e^{-2az}\psi=0. \tag{5.01}$$

If

$$\psi=e^{pz},$$

$$p=a\pm i\{\omega^2\mu_0\epsilon_0/c^2-a^2\}^{\frac{1}{2}}. \tag{5.02}$$

When $\omega^2<a^2c^2/\mu_0\epsilon_0$, the propagation constant p is real. If ω is very small $p=\frac{1}{2}\omega^2\mu_0\epsilon_0/ac^2$ for waves propagated

in the positive z direction. The impedance ratio becomes, from (2.04)

$$Z=iac/\omega\epsilon\mp\{\mu_0\epsilon_0/\epsilon^2-a^2c^2/\omega^2\epsilon^2\}^{\frac{1}{2}}. \quad (5.03)$$

The $\pm$ sign indicates that the impedance ratio is different for right and left traveling waves, in magnitude as well as in sign. The lower sign refers to waves traveling in the positive z direction. (The time factor is $e^{+i\omega t}$, since $\partial_4=\omega/c$.)

For waves traveling in the positive direction

$$D_r=pAe^{pz}/ir, \quad H_\theta=-\omega Ae^{pz}/cr. \quad (5.04)$$

For a co-axial line, the characteristic impedance defined as

$$Z_0=V/I=\int_{r_0}^{r_1}E_r\cdot dr\Big/\int_0^{2\pi}H\cdot ds$$

is of greater importance than the impedance ratio $Z=E_r/H_\theta$. In this case

$$Z_0=\frac{1}{2\pi M}\left\{\left[\mu_0\epsilon_0-\frac{a^2}{\omega^2c^2}\right]^{\frac{1}{2}}+\frac{ia}{\omega c}\right\}\times\left\{\frac{r_1^{2-2k}-r_0^{2-2k}}{2-2k}\right\}e^{-2az}. \quad (5.05)$$

When $k=1$, $a=0$, this reduces to

$$Z_0(1,0)=1/2\pi\cdot(\mu_0/\epsilon_0)^{\frac{1}{2}}\log_e r_1/r_0 \quad (5.06)$$

in agreement with the classic impedance of a co-axial line.

Section 6. Waves in a Region Where ϵ Varies but μ is Constant

The previous examples have dealt with cases where both μ and ϵ were functions of position. In the Type C examples, the refractive index, $(\mu\epsilon)^{\frac{1}{2}}$, was constant, although μ and ϵ varied. Another type of example, of evident practical importance, is the case where μ is constant, but ϵ is some function of position. Referring to Table III, when $dx^1=dz$, $dx^2=dr$, $dx^3=d\theta$, the propagation equation was

$$\frac{\partial}{\partial z}\left\{\frac{1}{r\epsilon}\frac{\partial\psi}{\partial z}\right\}+\frac{\partial}{\partial r}\left\{\frac{1}{r\epsilon}\frac{\partial\psi}{\partial r}\right\}+\frac{\omega^2\mu}{c^2}\frac{1}{r}\psi=0. \quad (6.01)$$

In this case μ is constant, but ϵ may be taken to be the product of two factors

$$\epsilon=\epsilon_1(r)\cdot\epsilon_2(z). \quad (6.02)$$

Factorizing ψ into $\psi=RZ$, (6.01) becomes

$$\frac{r\epsilon_1}{R}\frac{d}{dr}\left\{\frac{1}{r\epsilon_1}\frac{dR}{dr}\right\}+\frac{\epsilon_2}{Z}\frac{d}{dz}\left\{\frac{1}{\epsilon_2}\frac{dZ}{dz}\right\}+\frac{\omega^2\mu\epsilon_1\epsilon_2}{c^2}=0. \quad (6.03)$$

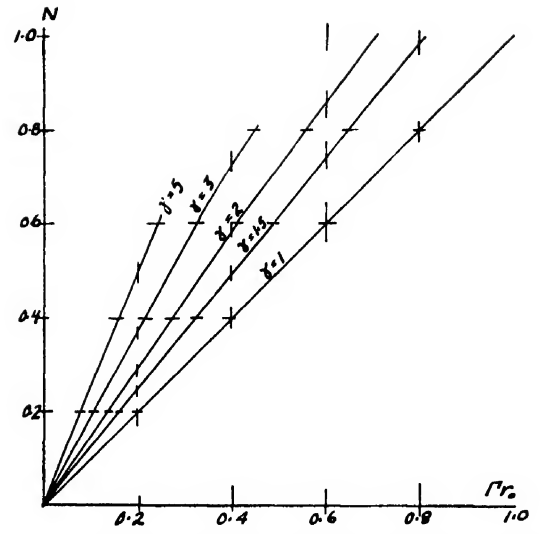

FIG. 5. Relation between the propagation constant Γ and the quantity $N=\omega r_0(\mu\epsilon_0)^{\frac{1}{2}}/c$ for a co-axial line where the ratio of outer to inner diameter is γ, filled with a medium where μ=constant, $\epsilon=\epsilon_0(r_0/r)^2$.

Applying the operator $\partial^2/\partial r\partial z$ to (6.03) gives

$$0=d\epsilon_1/dr\cdot d\epsilon_2/dz.$$

The equation is separable if ϵ is a function of r only or of z only. For co-axial line propagation, $\epsilon=\epsilon(z)$ leads to the well known results for a tapered transmission line.[5] Therefore only the case $\epsilon=\epsilon(r)$ will be considered. In this case, with $\epsilon_2=1$

$$\frac{r\epsilon(r)}{R}\frac{d}{dr}\left\{\frac{1}{r\epsilon}\frac{dR}{dr}\right\}+\left(\frac{\omega^2\mu\epsilon(r)}{c^2}+p^2\right)=0, \quad (6.04)$$

$$Z''=p^2Z. \quad (6.05)$$

The Z factor is clearly

$$Z=e^{\pm pz}. \quad (6.06)$$

The R factor depends on the chosen distribution of ϵ. For it the equation may be written

$$R''-R'\cdot d/dr\log r\epsilon+(p^2+\omega^2\mu\epsilon(r)/c^2)R=0. \quad (6.07)$$

In the particular case where $\epsilon=\epsilon_0(r_0/r)^{2}$** is chosen, the Eq. (6.07) becomes

$$R''+1/r\cdot R'+(p^2+\omega^2\mu\epsilon_0r_0^2/c^2r^2)R=0 \quad (6.08)$$

whose solution is

$$R=AJ_{i\omega r_0(\mu\epsilon_0)^{\frac{1}{2}}/c}(pr)+BN_{i\omega r_0(\mu\epsilon_0)^{\frac{1}{2}}/c}(pr). \quad (6.09)$$

This leads to a surprising exchange of role between p and $\omega^2\mu\epsilon/c^2$.

[5] Schelkunoff, *Electromagnetic Waves* (D. Van Nostrand Company, Inc. New York, 1943), p. 205.

** Again, a more general problem could be solved by taking $\omega^2\mu\epsilon/c^2=A+Br^{-2}$.

To derive an approximate expression for the relation between $\Gamma=ip$ and $N=\omega r_0/c.\ (\mu\epsilon_0)^{\frac{1}{2}}$ for low frequencies or small radii, it is necessary to use the usual positive power expansion for Bessel's functions. Since the solution contains Bessel's functions of non-integral order (order being imaginary), the solutions of the propagation equation may be rewritten as

$$\psi=\{AJ_{iN}(pr)+BJ_{-iN}(pr)\}e^{pz} \tag{6.10}$$

where

$$J_{iN}(pr)=\{\sum_0^\infty a_{2m}\cdot(pr)^{iN+2m}\}/2^{iN}\underline{|iN}, \tag{6.11}$$

$$J_{-iN}(pr)=\{\sum_0^\infty a_{2m}^*\cdot(pr)^{-iN+2m}\}/\underline{2^{-iN}|\cdot-iN} \tag{6.12}$$

and

$$a_{2m}=\underline{|Ni}/(\underline{|m|m+iN}(2i)^{2m}). \tag{6.13}$$

At the surface of a cylindrical conductor of radius r_0 the boundary condition is

$$-B/A=J_{iN}'(pr_0)/J_{-iN}'(pr_0). \tag{6.14}$$

For a co-axial line with conductors of radii r_0 and $r_1=\gamma r_0$, calling $u=pr_0$

$$J_{iN}'(u_0)/J_{-iN}'(u_0)=J_{iN}'(\gamma u_0)/J_{-iN}'(\gamma u_0). \tag{6.15}$$

Using the expansions (6.11) and (6.12) and the values of a_{2m} from (6.13) in (6.15) finally gives the boundary conditions of the co-axial line in the form

$$\sum_{s=0}^\infty u_0^{2s}A_s(N)=0 \tag{6.16}$$

with

$$A_s(N)=-i\sum_{m=0}^{s}\{a_{2m}a_{2s-2m}^*(2m+iN)\times(2s-2m-iN)\gamma^{2s-2m-iN}$$
$$-a_{2m}^*a_{2s-2m}(2m-iN)(2s-2m+iN)\gamma^{2s-2m+iN}. \tag{6.17}$$

Introducing the expression

$$\rho_{m,s}e^{i\varphi_{m,s}}=\underline{|iN|-iN}(2m+iN)\times(2s-2m-iN)/\underline{|m+iN|s-m-iN} \tag{6.18}$$

then by (6.17), (6.13), and (6.18)

$$iA_s=(-)^s2^{1-2s}\sum_{m=0}^{s}\gamma^{2s-2m}\rho_{m,s}\times\sin(\varphi_{m,s}-\sigma N)/\underline{|m|s-m} \tag{6.19}$$

with

$$\sigma=\log_e\gamma.$$

For small radii or low frequencies, we have

$$0=A_0(N)+u_0^2A_1(N) \tag{6.20}$$

leading to the approximate equation

$$-u_0^2=\Gamma^2r_0^2=4N(1+N^2)/\{(\gamma^2+1)N+(\gamma^2-1)(2+N^2)\cot\sigma N\} \tag{6.21}$$

and for extremely small values of N

$$\Gamma r_0\simeq\{2\sigma/(\gamma^2-1)\}^{\frac{1}{2}}\cdot N.$$

It is interesting to note that Γr_0 tends to the usual value for a co-axial line as $\gamma\to1$, for evidently, with $\sigma=\log\gamma$,

$$\lim\gamma\to1\ \Gamma^2r_0^2=\omega^2\mu\epsilon_0r_0^2/c^2.$$

Figure 5 shows the relation between N and Γr_0 for low frequencies.

It is hoped that these examples will serve to illustrate the application of this theory to radio and communication problems.

The author wishes to thank Hilda E. Smith for assistance with the manuscript and proof.

Hypersonic Research Facilities at the Ames Aeronautical Laboratory

VICTOR I. STEVENS
National Advisory Committee for Aeronautics, Ames Aeronautical Laboratory, Moffett Field, California
(Received June 14, 1950)

Two wind tunnels recently completed at the Ames Laboratory of the NACA— e 1 · by 14-in. supersonic wind tunnel and the supersonic free-flight wind tunnel—are capable of providing test Mach numbers well in excess of 5. Since at this time such facilities are relatively uncommon, this paper is primarily devoted to a description of these wind tunnels and their associated equipment.

The treatment of the 10- by 14-in. supersonic wind tunnel is concerned for the most part with the design and operation of the nozzle and diffuser which provides Mach numbers of 3.5 to about 8. Some mention is also made of the pressure measuring and flow visualization equipment. In the case of the supersonic free-flight wind tunnel high test Mach numbers are obtained by firing models at high speed into an oncoming supersonic air stream. Consequently the main emphasis is placed upon the launching techniques, the available range of test conditions, and the methods of obtaining data.

INTRODUCTION

ONLY a few years ago, interest in high Mach number flows was largely academic and as a result relatively little effort was directed toward solving the problems associated with generating and studying such flows. Recently, however, interest in these flows has greatly intensified and much more pressure has been brought to bear to develop research equipment which will facilitate the study of air flow at Mach numbers of 5 and above. The NACA at its Langley, Lewis, and Ames Laboratories and other research groups have been devoting increasing effort to the development of such equipment.

Perhaps the greatest obstacles to the progress of hypersonic research are the difficulties encountered in providing the high compression ratios required for the generation of high Mach number flows and in providing the instrumentation to cover the broad ranges of temperature, pressure, density, etc., that must be observed and recorded in the investigation of hypersonic flow phenomena. Two wind tunnels recently completed at the Ames Laboratory—the 10- by 14-in. supersonic wind tunnel and the supersonic free-flight wind tunnel—incorporate techniques which at least partially solve some of these problems. It is the purpose of this paper to give a brief description of these wind tunnels and their associated equipment.

10- BY 14-IN. SUPERSONIC WIND TUNNEL

The 10- by 14-in. supersonic wind tunnel has only recently been completed and is now being calibrated. It is a closed-throat, non-return, continuous-flow tunnel capable of producing any air-stream Mach number from 3.5 to something in excess of 8. The wind tunnel was designed to utilize existing compressors having a maximum exhaust pressure of only 6 atmos. absolute; consequently, it was important to keep the compression ratio required for a given Mach number as low as possible. Use of a conventional laval nozzle followed by a subsonic divergent-wall diffuser as shown in the upper half of Fig. 1 would require compression ratios of the order of 200 for a Mach number of 8. With a supply pressure of only 6 atmos. the exit pressure would have to be less than 0.03 atmos.—a value which is unacceptably low, for it would require very bulky vacuum equipment. Most of this compression ratio is required to overcome the head loss through the normal shock; therefore, use of a supersonic convergent-divergent diffuser (see lower half of Fig. 1) which decelerates the air before the normal shock, appeared advantageous to reduce this head loss and thereby reduce the compression ratio required and increase the allowable exit pressure. The limited data available at the time this design was undertaken indicated that small gains could be realized through use of this type diffuser for Mach numbers of 2 to 3, but there was little or no information available to direct the design of such a diffuser

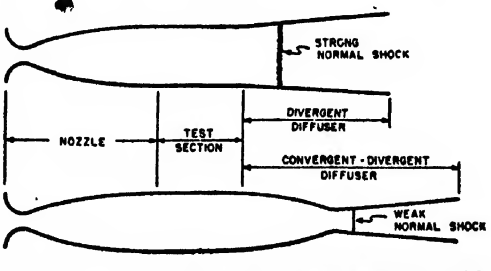

FIG. 1. Diagram of supersonic nozzles equipped with two types of diffusers.

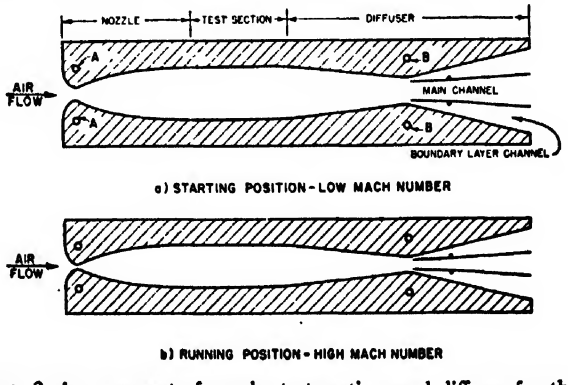

FIG. 2. Arrangement of nozzle, test section, and diffuser for the Ames 10- by 14-in. supersonic wind tunnel.

for Mach numbers as high as 8. Therefore, in 1947 an investigation of a 1- by 1-in. pilot tunnel was undertaken to develop a nozzle and diffuser for the 10- by 14-in. supersonic tunnel.

Nozzle and Diffuser

The nozzle and diffuser configuration developed is shown schematically in Fig. 2. The side walls are flat and parallel and all contour variation is in the top and bottom blocks. These blocks are rigid and are supported on pins at A and B. Jacks attached to these pins control the vertical position of the blocks and thus control the nozzle and diffuser throat openings. In a somewhat oversimplified view, opening or closing the jacks at A lowers or raises the test-section Mach number, whereas the position of jacks at B determines the location and strength of the normal shock.

Just downstream of the diffuser throat are located boundary-layer scoops. The investigations in the pilot tunnel revealed that without these scoops the normal shock boundary-layer interaction was very severe and the resulting erratic behavior of the normal shock and boundary layer made it necessary to force the normal shock far downstream of the diffuser throat in order to preserve supersonic flow ahead of the diffuser throat. The extra compression ratio required to keep the normal shock a safe distance downstream nullified, to a large extent, the gains achieved by a convergent-divergent diffuser. Removal of the boundary layer, however, stabilized the normal shock position so that supersonic flow ahead of the diffuser throat could be maintained with the shock only a short distance downstream of the scoop opening. Boundary-layer removal also greatly reduced the separation behind the normal shock and thus improved the efficiency of the subsonic diffuser.

The operation of this nozzle can probably be better understood by following through the sequence of starting supersonic flow and then changing the Mach number. The starting position is as shown in the top of Fig. 2. With the blocks open to this position, as the pressure builds up, supersonic flow at a Mach number of approximately 3.5 is established in the test section and the normal shock is pushed out of the test section through the converging section of the diffuser and into the divergent section. To establish flow with this nozzle configuration requires a compression ratio of about 6 which, as would be expected, is about the same as that required to obtain a Mach number of 3.5 in a wind tunnel with a conventional divergent diffuser. It can be shown[1] that supersonic flow in the test section will not start regardless of compression ratio available, if the second throat is not open beyond a certain minimum. For this wind tunnel the second throat is opened so that when supersonic flow is established the Mach number at the second throat is about 3. However, after flow is established the diffuser throat may be closed to give a throat Mach number of approximately 2.5. To increase the test-section Mach number, the blocks are closed as shown in the lower half of Fig. 2. With the nozzle throat closed to an opening of about 0.05 in. the test-section Mach number is 8 and the Mach number at the diffuser throat is about 3.5. The compression ratio required for this Mach number is about 30:1 which is considerably less than the estimated 200:1 required for a conventional divergent diffuser.

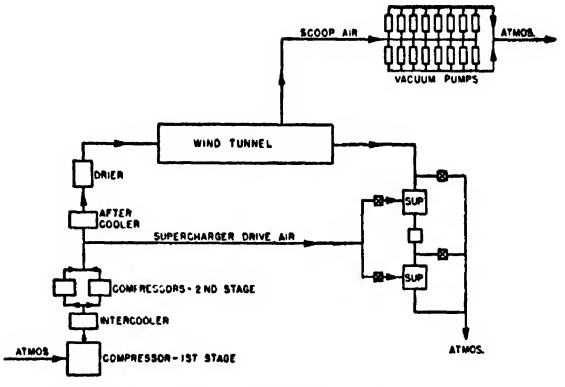

FIG. 3. Air-flow diagram for the Ames 10- by 14-in. supersonic wind tunnel.

Air Supply

The high pressure air for this wind tunnel is supplied by the equipment shown on the left side of Fig. 3. This equipment consisting of centrifugal compressors, coolers, and a silica-gel drier provides air at the nozzle entrance at a maximum total pressure of 6 atmos., a temperature of approximately 100°F and an absolute humidity of 0.0001 lb. water/lb. air. The air after passing through the nozzle and test section exhausts into either the boundary-layer scoops or the main diffuser. The low energy boundary-layer air is drawn off through the scoops by a battery of rotary vacuum pumps and discharged to the atmosphere. The air exhausting through the main diffuser is discharged directly to the atmosphere at test Mach numbers below 4.5. At Mach numbers above 4.5 this air is drawn through either one or two stages of turbine-driven superchargers to provide the required compression ratios. Since the mass flow through the tunnel decreases with increasing Mach number, it is convenient to utilize the excess air from the primary compressors to drive the turbines on the superchargers. With both superchargers operating the total compression ratio across the main passage is 55 which is more than adequate for test Mach numbers of 8.

Instrumentation

The model support and force-measuring equipment for this tunnel are very similar to that used in other supersonic wind tunnels. The models are supported

[1] A. Kantrowitz and C. du P. Donaldson, Preliminary Investigation of Supersonic Diffusers, NACA ACR L5D20 (1945).

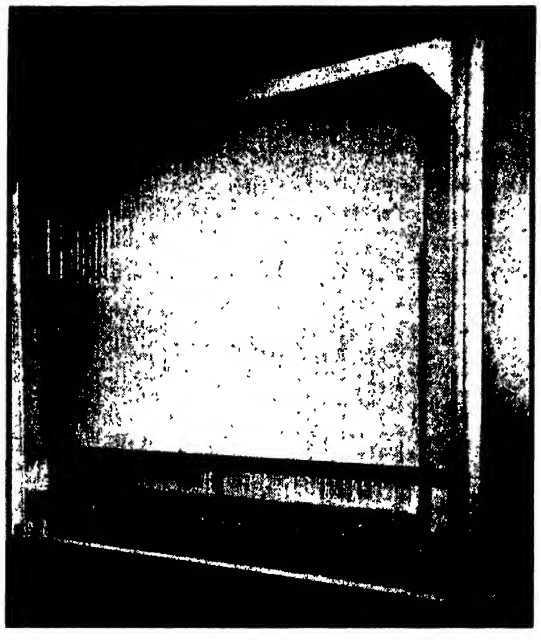

FIG. 4. Manometer board incorporating McLeod-type gauges for measuring low pressures.

from the rear on a sting which is in turn supported by a strut passing through the sidewalls. The forces and moments acting on the model are measured using a conventional strain-gauge balance system.

In contrast, the low pressures and densities existing in the wind-tunnel test section at high Mach numbers required deviations in design from the conventional pressure-measuring and flow-visualization equipment. For a given stagnation pressure the test-section static and dynamic pressures fall very rapidly with Mach number so that at a test Mach number of 8 and a stagnation pressure of 6 atmos. the static and dynamic pressures are 0.000612 and 0.0275 atmos., respectively (or 0.018 and 0.83 in. Hg). To measure pressures of this magnitude the conventional U-tube-type manometer board has been replaced by a board incorporating 40 McLeod-type gauges. This manometer board is shown in Fig. 4. Up to 40 pressures can be simultaneously recorded by photographing this board. Using these photographic records absolute pressures of 0.001 atmos. can be read to approximately one percent accuracy.

Flow about models is observed using a center-of-curvature schlieren apparatus which has much greater sensitivity to density gradients than the more common schlieren system. With the center-of-curvature schlieren the effective source and knife are located on one side of the test section at the center of curvature of the principal mirror. The mirror is located immediately adjacent to the test section on the side opposite the source and knife. Thus the light passes through the test section twice and there is no collimated light beam as in the common schlieren. The principal mirror for the 10- by 14-in. supersonic tunnel has a diameter of 1½ ft. and a radius of curvature of 50 ft. Although the schlieren system incorporating this mirror has not yet been fully checked, it is expected that the system will have adequate sensitivity over the Mach number range of this wind tunnel.

THE SUPERSONIC FREE-FLIGHT WIND TUNNEL

The supersonic free-flight wind-tunnel structure was completed early in 1949; however, the installation of the equipment required to obtain aerodynamic data was not completed until late in the fall of the same year. The major calibrations are complete and the facility is

FIG. 5. Arrangement of the Ames supersonic free-flight wind tunnel.

now being used to study the characteristics of missile-type configurations. Although the maximum test Mach number obtained to date is only slightly in excess of 8, the facility is capable of providing data for Mach numbers ranging from less than 1 to approximately 15. The necessity for high compression ratios at high test Mach numbers is obviated by generating an air-stream Mach number of only 2 or 3 in the wind-tunnel test section and providing the remainder of the total Mach number by launching the model at high velocities into the oncoming air stream. Since the air in passing through the nozzle is expanded only to a Mach number of 2 or 3, the air density and consequently the Reynolds number for a given model size are relatively high.

Data that can be obtained in this wind tunnel include the model static force characteristics which are obtained in conventional wind tunnels, as for example, lift, drag, and moment. However, the techniques for measuring these characteristics parallel those used in aeroballistic ranges.[2] The dynamic behavior of the models can also be obtained directly in this wind tunnel. The methods for obtaining these data can probably be better understood after examining the wind tunnel and related equipment.

Wind Tunnel and Launching Guns

The principal components of the wind tunnel proper are shown in Fig. 5. The wind tunnel is an intermittent-operation blow-down type with the air being supplied from the 12-ft. pressure wind tunnel at a maximum pressure of 6 atmos. The air flows from left to right as shown in Fig. 5 and passes, in turn, through the settling chamber, the nozzle, the test section, and the diffuser. After diffusion the air is ejected directly to the atmosphere. The test section is 1 ft. wide, 2 ft. deep, and 18 ft. long. The Mach number of the air flow in the test section is, of course, a function of the shape of the nozzle blocks. At present, the wind tunnel is equipped with two sets

(a) (b)

FIG. 6. Models and sabots as launched from guns. (a) Fin-stabilized. (b) Spin-stabilized.

of interchangeable blocks which give an air-stream Mach number of either 2 or 3. The models are fired from guns located in the diffuser and after passing through the test section and nozzle are stopped by the model catcher in the reservoir. The model catcher is a steel cylinder 2½ ft. in diameter and about 6 ft. long which is tightly packed with cotton waste backed up by wood and steel.

Launching of models at high velocity from guns requires techniques which in the past have been quite foreign to wind tunnels. The techniques which we use at present are closely patterned after those developed at the Naval Ordnance Laboratory, the Watertown Arsenal, and the Ballistic Research Laboratories at Aberdeen Proving Ground. While in the gun the models are supported in carriers or sabots illustrated in Fig. 6. The purpose of the sabot is to provide a gas seal and at the same time protect the model from the hot powder gases and to keep it properly aligned during launching. There are two basic types of sabots which we are using at present—one for fin-stabilized models

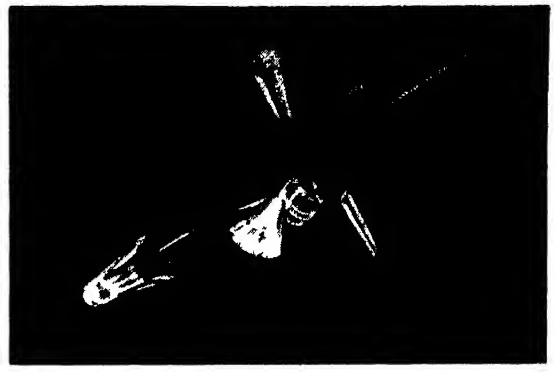

FIG. 7. Drawing showing sabot in two stages of separation from fin-stabilized model.

and one for spin-stabilized models (see Fig. 6). Both types are so constructured that when the sabot and model emerge from the gun, the sabots separate from the model and leave it free to fly on undisturbed through the wind tunnel. Sabot separation on a fin-stabilized model is illustrated in Fig. 7.

The launching guns available for use in this wind tunnel range in size from caliber .22 through .50, 20 mm, 37 mm, and 3 in. The launching velocities are varied by changing the powder charges loaded into the cartridge case—the limiting velocity being determined by the maximum pressure that the gun can withstand. In the .220 Swift, which is a sporting rifle, we have realized launching velocities of 5000 ft./sec. which, with the Mach number 2 nozzle blocks installed, gives a test Mach number of 8. It may not at first be evident how a launching velocity of 5000 ft./sec., which is a nominal sea-level Mach number of 4½, can add to the test section of 2 and yield 8. This, however, is traceable to the fact that the air in expanding through the nozzle is chilled to temperatures of about −150°F. At these low temperatures the speed of sound is of course lowered; hence, the launching velocity of 5000 ft./sec. in itself produces a Mach number of 6 which when added to the air stream Mach number of 2 gives 8. Special test barrels are being procured which should permit launching velocities of the order of 8000 ft./sec. With the Mach number 3 nozzle blocks installed in the wind tunnel this launching velocity would give a test Mach number of 15. It should be noted that a compression ratio of only 4 is required for tests at this Mach number and that to realize the same Mach number and air density in the region of the model in a conventional wind tunnel would require a stagnation pressure of more than 100,000 atmos.!

Due to the comparatively high air density in the wind-tunnel test section the test Reynolds numbers are very high for a given model size. For example, if a 6-in. model were launched in this tunnel to give a test Mach number of 7, the resulting Reynolds number would correspond to that obtained on a 50-ft. missile flying at the same Mach number at an altitude of

100,000 ft. Such a rocket is comparable in size to a V-2. In contrast, to obtain the same Reynolds number in a conventional tunnel operating at the same stagnation pressure (6 atmos.) would require a model over 10 ft. long.

Equipment and Techniques for Measuring Model Characteristics

As stated previously, the aerodynamic characteristics of the models are determined in this wind tunnel using techniques which parallel those used in aeroballistic

FIG. 8. Diagram illustrating operation of time-distance equipment.

firing ranges. To obtain drag, for example, the time-distance history of the model is recorded as the model flies through the test section and from this history the velocity, deceleration, and hence drag can be evaluated. In this wind tunnel the time-distance history is obtained using a four-station shadowgraph and a chronograph as shown in Fig. 5. As the model flies through the wind tunnel, each station in turn takes a shadowgraph of the model and a distance scale so that the distance the model travels from station to station can be measured on the shadowgraph. At the same instant each shadowgraph is taken, the chronograph records the time.

The operation of this equipment is more easily followed using Fig. 8, which isolates one of the shadowgraph stations and the principal components of the chronograph. When the model leaves the launching gun and enters the test section, it first encounters a light beam which projects through the wind tunnel and impinges on a photoelectric cell. As the model interrupts part of this light beam the output of the photoelectric cell is modified. The resulting signal is amplified and passed through a suitable time delay to allow the model to travel to the shadowgraph station. When this time delay has elapsed, the spark source is triggered and the resulting light forms a shadow image of the model on the photographic plate. Although not shown in Fig. 8, the distance scale is suspended below and along one edge of the photographic plate so that its image is also formed on the plate. When the spark is triggered, part of the light escapes from the side of the spark housing where it is picked up by a mirror and reflected along a vertical axis to a rotating prism which in turn reflects the light out to the 35-mm film on the periphery of the chronograph. Thus a latent image is formed on the chronograph film at the instant the shadowgraph is taken. As the model reaches the second, third, and fourth stations this same procedure is repeated; however, since the prism in the chronograph is rotating, the spark images are spaced approximately 90° apart on the 35-mm film. To provide a time base an H-6 mercury arc lamp is pulsed at frequencies which are regulated at any desired frequency from 10,000 to 100,000 cycles/sec. and the resulting pulsed light superimposed on the chronograph film. Since the pulse rate can be varied from 10,000 to 100,000 cycles/sec. the resulting interval between pips on the film varies from 100 to 10 μsec.

A sample of the shadowgraph and chronograph records is shown on Fig. 9. The shadowgraph was obtained on a 60° cone-cylinder model at a test Mach number of 7. The sharply defined notches of the distance scale can be seen on the upper side of the shadowgraph. At the bottom of Fig. 9 is a short segment of the chronograph record. The station marker is at the center of the section and the evenly spaced pips are the time base—each interval representing 20 μsec.

The accuracy requirements on measuring distance and time are rather stringent. For example, to restrict

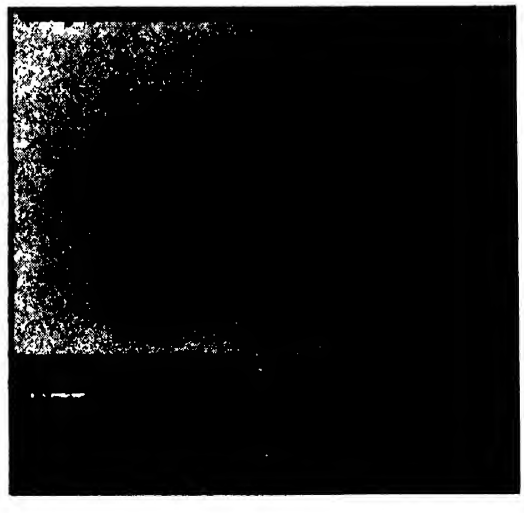

FIG. 9. Sample shadowgraph and chronograph records.

errors in drag to one percent requires in some cases distance measurements to the accuracy of 0.001 in. and time to 0.01 μsec. The requirement that time be measured to this order of accuracy becomes more significant when it is realized that in 0.01 μsec. light travels a dis-

tance of about 10 ft. It is evident, then, that in the design of equipment of this type the speed of light and light-path lengths must be considered.

Several other forms of aerodynamic data can be obtained using the time-distance record. With three lateral shadowgraph stations (omitted from Fig. 5 for clarity) and the four vertical stations already described, it is possible to define the three-dimensional flight path of the model. From this flight path, lateral and vertical accelerations, hence side force and lift, can be obtained. It is also possible to obtain base pressures using the method of characteristics to determine the conditions just ahead of the model base and using any one of the shadowgraphs to obtain the flow expansion around the base.[3] Stability parameters such as lift-curve slope, aerodynamic-center position, damping-in-roll, etc., can be evaluated by disturbing the model during the launching and observing the resulting motion. The behavior of the model during these tests can be recorded using either the shadowgraph equipment already described or by using a high speed motion-picture camera.

A sample of the data which have been obtained in this facility is given in Fig. 10 which presents the drag of a 60° cone-cylinder model as a function of Mach number. The models were launched using a .220 Swift rifle and a Lucite sabot as shown in Fig. 6. The primary purpose of the sabot for these tests was to take the rifling of the gun and thus leave the model aerodynamically smooth. As shown in Fig. 10, data were obtained for Mach numbers from 1.5 to greater than 8. Over this range the experimental data deviate from the faired curve an average of about 0.8 percent and the maximum scatter is only three percent. Since the drag of this model is relatively high, it might be expected that the scatter would be greater for better aerodynamic shapes having less drag. However, we believe that with the foreseeable improvements in equipment and measuring techniques the scatter should not be significantly increased.

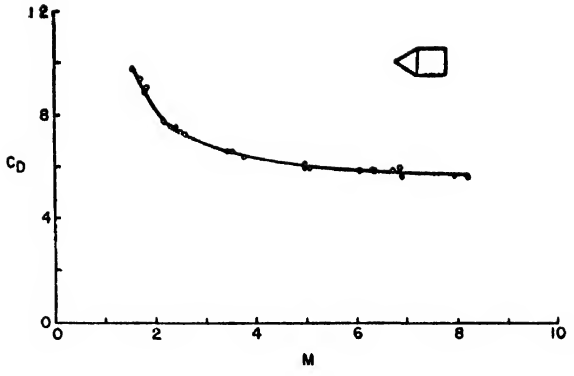

FIG. 10. Variation of drag with Mach number for 60° cone-cylinder model.

The Application of Rate-Process Theory to Glass. I. Breaking Strength*

F. B. Hodgdon†
Department of Ceramics
D. A. Stuart‡ and F. E. Bjorklund
Department of Physics
University of Utah, Salt Lake City, Utah
(Received June 5, 1950)

An equation relating the ultimate strength of glass and porcelain to time under load is derived using the rate-process theory of Eyring. The data of Preston and co-workers are used to calculate the constants in the equation. The agreement between theoretical and experimental results is excellent.

I. INTRODUCTION

RECENT work of F. W. Preston and his co-workers[1-3] has provided data on the ultimate strength of glass and porcelain as a function of the time under load over a wide range of time. Because of the nature of these data it is possible to apply to ceramic materials the rate-process theory of plastic flow, developed originally by Eyring and others for textile fibers. Minor modifications of the mathematical treatment as presented by Eyring are necessary, probably because of the inherent difference between glass and fibers. These modifications do not affect the rigor of the mathematical derivation, but the physical reasons for them are still obscure and are the basis for further study.

Tobolsky and Eyring[4] have pointed out that in all unit processes of deformation, stress produces a two-fold effect on rate of strain. There is, first of all, an elastic component for which the rate of strain varies linearly with rate of stress and, secondly, a contribution to the rate of strain by relaxation processes. The latter can be readily measured for rubber, plastics, and metals, but data on ceramic materials are meager. Stress-strain, and other relationships can be derived in many ways, but it is simplest to derive them by the use of models in which the elastic component is represented by a pure spring and the relaxation process by a spring-dashpot combination.

II. PRESENT WORK

To analyze Preston's data, a model such as that illustrated in Fig. 1 was used. In this model the element shown as a spring-dashpot combination S_2-D represents a unit of the material which moves from one equilibrium position to another under the influence of an external applied force and in which bonds broken in one position are reformed in a successive position. The element shown as a pure spring, S_1 represents a network of bonds, probably primary, which once broken do not repair. (There is evidence that these bonds may repair at elevated temperatures; in this case, the pure spring should be replaced by a spring-dashpot combination.)

The spring S_1 has a modulus g_1, the spring S_2, a modulus g_2, and the dashpot constant is $\alpha=a\lambda_2/2kT$, where a is a cross-sectional area of the flow unit normal to the direction of the flow, λ_2 is the distance between equilibrium positions of the flow unit, k is the Boltzmann constant and T is the absolute temperature. A detailed discussion of this definition of α is given elsewhere.[5] In this equation $a\lambda_2$ is the volume of the hole available for flow.

When an external force f_0 is applied to the system, let the load on S_1 be f_1 and the load on S_2 and D be f_2. Let the elongation of S_1 be l_1, that of S_2, l_2 and that of D, l_3. After the load is applied and the initial elastic deformation of the system has taken place, the rate of flow of the dashpot is given by the equation

$$dl_3/dt=K\sinh\alpha f_2, \tag{1}$$

where K is the rate constant for the dashpot.[5] If the spring S_2, after the initial force has been applied, is stressed so that the force on it is f_{20}, then the force on S_2 at any time will be $f_{20}-g_2l_3$.

From this, by substitution in Eq. (1), we obtain

$$dl_3/dt=K\sinh\alpha(f_{20}-g_2l_3). \tag{2}$$

It is important to note at this point that Eq. (1) and the equation $f_2=f_{20}-g_2l_3$ are valid whether element 2 of the model is in compression or tension. Motion of the dashpot will always be in the direction of the applied force and this motion will decrease the force on the spring S_2.

If $f_{20}-g_2l_3$ is large, we can write, as a reasonably close

[5] The derivation of this equation can be found in Glasstone, Laidler, and Eyring, *Theory of Rate Processes* (McGraw-Hill Book Company, Inc., New York, 1941). K is defined by $K=(2kT/h)\exp(-\Delta F^*/RT)$.

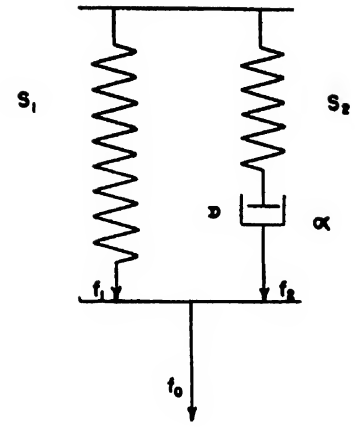

FIG. 1. Model used in derivations.

approximation

$$\frac{dl_3}{dt}=\frac{K\exp[\alpha(f_{20}-g_2l_3)]}{2}$$

which upon separation of the variables becomes

$$\frac{dl_3}{\exp[\alpha(f_{20}-g_2l_3)]}=\frac{Kdt}{2}. \tag{3}$$

Integration of Eq. (3) between the limits of $l_3=0$ when $t=0$ and $l_3=l_3$ when $t=t$ yields

$$(1/\alpha g_2)\exp[-\alpha(f_{20}-g_2l_3)]=Kt/2$$

which can be expressed in logarithmic form and arranged to give

$$f_{20}-g_2l_3=-(1/\alpha)\ln(\alpha g_2K/2)-(1/\alpha)\ln t. \tag{4}$$

Since $f_{20}-g_2l_3=f_2$ and $f_2=f_0\pm f_1$, Eq. (4) can be written

$$f_1=f_0+(1/\alpha)\ln(\alpha g_2K/2)+(1/\alpha)\ln t \text{ if } S \text{ is in tension} \tag{5a}$$

or

$$f_1=f_0-(1/\alpha)\ln(\alpha g_2K/2)-(1/\alpha)\ln t \text{ if } S \text{ is in compression.} \tag{5b}$$

This equation is equally valid with the proper sign when f_2 is a tension force and when it is a compression force. We shall consider f_2 to be a compression force and use Eq. (5b).

It has been shown by Tobolsky and Eyring[4] that with a statistical breaking of bonds, the rate of decrease of the number of primary bonds is given by the equation

$$-\frac{dN}{dt}=\frac{NkT}{h}\exp(-\Delta F^*/RT)2\sinh\frac{f_1\lambda_1}{2kTN} \tag{6}$$

where N is the number of primary bonds at time t, ΔF^* is the free energy of activation, k is the Boltzmann constant, h is Planck's constant, R is the gas constant, f_1 is the load on these bonds which causes an elongation λ_1, and T is the absolute temperature. Substitution of the value of f_1 given in Eq. (5a) in Eq. (6) gives

$$-dN/dt=(NkT/h)\times[\exp-(\Delta F_1^*/RT)]2\sinh\{[f_0-(1/\alpha)\times\ln(\alpha g_2K/2)-(1/\alpha)\ln t]\lambda_1/2kTN\}. \tag{7}$$

If the bonds do not repair after breaking, Eq. (7) may be written as an exponential:

$$-dN/dt=(NkT/h)\exp\left\{-\frac{\Delta F_1^*}{RT}+\frac{[f_0-(1/\alpha)\ln(\alpha g_2K/2)-(1/\alpha)\ln t]\lambda_1}{2kTN}\right\}. \tag{8}$$

Substituting $c=(1/\alpha)\ln(\alpha g_2K/2)$ in Eq. 8 gives

$$-dN/dt=(NkT/h)\exp(-\Delta F_1^*/RT)\times\exp[(f_0-c)\lambda_1/2kTN]t^{(-\lambda_1/2kNTa)}. \tag{9}$$

Equation (9) cannot be integrated unless further assumptions are made. In the definition $\alpha=a\lambda_2/2kT$, the numerator, $a\lambda_2$, is the average volume of the unit, the bonds of which break and repair. It is presented in the model by the dashpot. For the other bonds, those which do not repair after breaking and which are represented in the model by the pure springs, the volume is λ_1/N. As an approximation, we assume that the ratio of the volume of the non-repairable bonds to the volume of the repairable bonds is substantually constant until fracture occurs. With this assumption Eq. (9) becomes:

$$-dN/dt=(NkT/h)\exp-(\Delta F_1^*/RT)\times\exp[(f_0-e)\lambda_1/2kTN]t^{-(v_1/v_2)} \tag{10a}$$

which is equivalent to

$$\frac{dN}{(NkT/h)\exp-(\Delta F_1^*/RT)\times\exp[(f_0-c)\lambda_1/2kTN]}=-t^{-(v_1/v_2)}dt. \tag{10b}$$

When $t=0$, $N=N_0$ and when $t=t_1$, $N=0$, $v_1=\lambda_1/N_0$ and $v_2=a\lambda_2$. Equation (10b) has been integrated by Tobolsky and Eyring and gives

$$\gamma\ln t=-(f_0-c)\lambda/2kTN_0-\ln(f_0-c)\lambda/2kTN_0+(\Delta F^*-RT\ln\gamma)/RT. \tag{11}$$

III. EFFECT OF TEMPERATURE UPON BREAKING STRENGTH

If a constant load be applied to a glass specimen, it is well known that the apparent strength depends upon the temperatures. That is to say that if a constant load is applied to a specimen of glass at various temperatures the glass requires different times to fracture. Further if the time required to fracture a specimen of glass at constant load be measured and plotted *versus* the temperature, then a minimum is observed in the plotted curve.

We shall assume that v_1 and v_2 are approximately

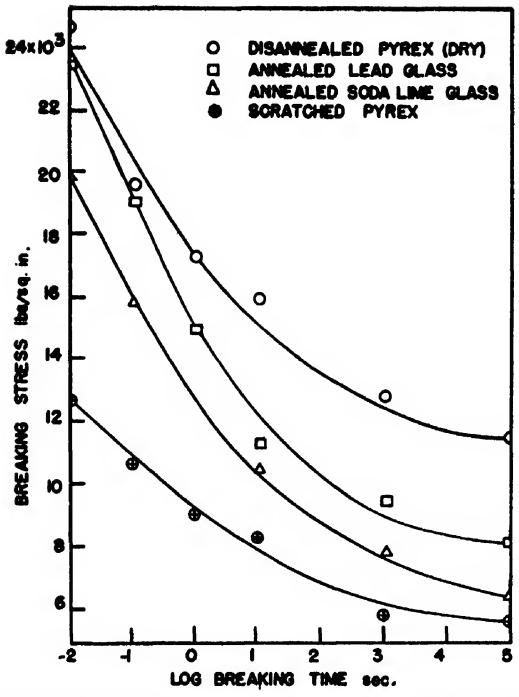

FIG. 2. Comparison of theory and experiment, breaking strength *vs.* temperature for certain glasses (after Glathart and Preston).

independent of temperature, and that $\Delta F^* = \Delta H^* - T\Delta S^*$ where ΔH^* and ΔS^* are not temperature dependant. If a minimum occurs in the time-temperature relationship, the temperature at which this minimum occurs is that temperature at which $dt/dT = 0$. Hence, differentiating Eq. (11) with respect to temperature and setting $dt/dT = 0$, we find

$$0 = \frac{\gamma}{t}\frac{dt}{dT} = \frac{(f_0 - c)v_1}{2kT}\left(\frac{1}{T} + \frac{1}{f_0 - c}\right)\frac{dc}{dt} + \frac{1}{f_0 - c}\frac{dc}{dT} - \frac{\Delta H_1^*}{RT^2} \quad (12a)$$

or

$$\frac{(f_0 - c)v_1}{2kT^2} + \left(\frac{v_1}{2kT} + \frac{1}{f_0 - c}\right)\frac{dc}{dT} - \frac{\Delta H_1^*}{RT^2} = 0 \quad (12b)$$

now

$$c = (1/\alpha)\ln(\alpha g_2 K/2)$$

or

$$c = (2kT/v_2)\ln(v_2 g_2/2h) - (2k\Delta H_2^*/Rv_2) + (2kT\Delta S_2^*/Rv_2) \quad (13)$$

and

$$dc/dT = (2k/v_2)\ln(v_2 g_2/2h) + (2k\Delta S_2^*/Rv_2). \quad (14)$$

Thus after substituting the value of dc/dT from Eq. (14) into Eq. (12a) and multiplying through by $(f_0 - c)2kT^2$ we find

$$(f_0 - c)(v_1 f_0 + (2k\Delta H_1^*\gamma/R)) + 2kT[c + (2k\Delta H_2^*/Rv_2)] = 0 \quad (15)$$

or substituting for c and rearranging

$$T^2 - \left(\frac{v_1 f_0}{2k} + \frac{2\Delta H_1^*\gamma}{R}\right)T + [(v_1 f_0/2k + \Delta H_1^*\gamma/R) \times (f_0 v_1/2k + \Delta H_2^*/R)/(\ln(v_2 g_2/2h) + \Delta S_2^*/R)] = 0.$$

Solving for T by the quadratic formula, we find,

$$T = \frac{v_1 f_0}{4k} + \frac{\Delta H_1^*\gamma}{R} \pm \left\{\left(\frac{v_1 f_0}{4k} + \frac{\Delta H_1^*\gamma}{R}\right)^2 - [(v_1 f_0/2k + \Delta H_1^*/R)(f_0 v_2/2k + \Delta H_2^*/R)/(\ln(v_2 g_2/2h) + \Delta S_2^*/R)]\right\}^{\frac{1}{2}}. \quad (16)$$

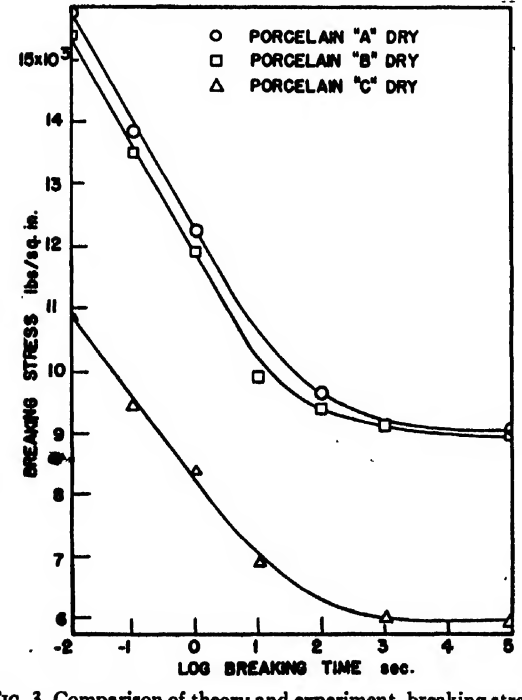

FIG. 3. Comparison of theory and experiment, breaking strength *vs.* temperature for certain porcelains (after Glathart and Preston).

It is obvious that at both the above temperatures we cannot possibly observe minima. To find at which temperature a minimum occurs, we solve for d^2t/dT^2 and substitute the above temperatures. If $d^2t/dT^2 > 0$, then at that point we observe a minimum. When this is done we find that at the lower temperature we have a minimum and at the higher a maximum.

IV. RESULTS AND DISCUSSION

The data of Preston have been used to calculate the parameters in Eq. (10a) and Figs. 2 and 3 show the results. The smooth curves are plots of the equation

TABLE I. Values of constants in the breaking strength equation.

Material	γ	ΔF_1^* kilocalories	λ_1/N_0 in^3	c psi
Disannealed Pyrex (dry)	0.272	17.1*	5.56×10^{-24}	11,000
Scratched Pyrex (wet)	0.271	17.2*	11.4×10^{-24}	5,500

Porcelain *B*	1.000	19.9	78.3×10^{-24}	8,850
Porcelain *C*	1.000	19.6	98.9×10^{-24}	8,150

* ΔF_1^* as tabulated is the apparent ΔF_1^* and should be increased by $0.5961\pi(1/\gamma)$.

when the values listed in Table I are used, and it appears that the breaking equation fits the data rather well. Further, the values obtained for the free energy of activation appear reasonable, since they are of the same order of magnitude as the strengths of alkali-oxygen and alkaline earth bond strengths in glass as determined by other methods.[6] However, as previously pointed out, a model was used in which a dashpot associated with spring S_1 has been neglected because the constant of this dashpot is such that it does affect the results at temperatures below 300°C, approximately. The simplified model presented here cannot be used in analyses of the temperature dependence of properties such as viscosity and birefringence which are now under way in these laboratories.

Data were not available with which to check reliably the breaking strength temperature results. However, calculations on a typical glass yield approximately 300°K for the minimum and 4000°K for the maximum strengths, respectively. Obviously the second temperature is so high that the maximum would never be observed.

It was assumed in our derivation that there was only an initial elongation when a load was applied, which is in accord with the known absence of "creep" in glass at ordinary temperatures; the theoretical admissability of this assumption will depend upon the slope of potential energy barrier for glass forming oxides.

The breaking equation predicts that failures in glass will be failures in tension, which is, we believe, in accord with Preston's views.

The brittle nature of glass can be explained in a qualitative manner by these results. If the strength of the alkali-oxygen and alkaline earth-oxygen bonds is of the same order of magnitude as the free energy of activation of the viscous element bond, a force sufficient to start viscous flow will also be sufficient to rupture these primary bonds. In other words, a force sufficient to cause flow, which we believe arises from the presence of "holes" in the structure is large enough to rupture bonds which do not repair. The nature of these "holes" is at present the subject of further investigation. This condition will be altered somewhat at elevated temperatures when the influence of the dashpot on spring S_1, neglected here, becomes appreciable.

ACKNOWLEDGMENT

The authors wish to express their appreciation to the staff of the School of Mines and Mineral Industries, and to H. Eyring, Dean of the Graduate School, University of Utah, for their many suggestions which were invaluable in the preparation of this paper.

The Application of Rate-Process Theory to Glass. II. Viscosity*

F. B. Hodgdon†
Department of Ceramics
D. A. Stuart‡
Department of Physics
University of Utah, Salt Lake City, Utah
(Received June 5, 1950)

In previous efforts to derive an equation for the temperature-viscosity relation of glass it has been assumed, tacitly or otherwise, that glass is a simple liquid. Since glass is not a simple liquid, it is necessary to find a model that will, in its reaction to applied stresses, have the same characteristics as a specimen of glass. By the use of Eyring's rate-process theory, such a model is proposed and several equations relating viscosity to time and to temperature are derived. The equations include an equation that relates the viscosity of any glass specimen to time, one which defines the rate of removal of internal strain, and an equation which relates the viscosity of a specimen an infinite time after beginning of a test to the temperature of the test. This final viscosity is the viscosity usually reported in the literature. It is found that the parameters in the equation reduced to infinite time can be calculated from the chemical composition of the glass and the viscosity of any given glass can be predicted at any temperature over a very wide range. Curves and tables are included to show the agreement of experiment and theoretical values.

I. INTRODUCTION

THE equation most generally used to define the viscosity-temperature relation of glass was derived by Sheppard[1] on the basis of the Maxwell-Boltzmann Distribution law. Over a limited temperature range, usually not exceeding 300°C, the deviations between observed and calculated viscosities are not large. Over extended temperature ranges, however, such as from 900°K to 1900°K, the agreement between theoretical and experimental values is not good. In fact, with some glasses the deviation is as much as tenfold, the reason for which is readily apparent. Implicit in Sheppard's derivation is the assumption that glasses are simple liquids. In view of the extensive literature indicating that glasses are not simple liquids, it is not surprising that an equation based upon the assumption that they are does not yield results in agreement with experiment.

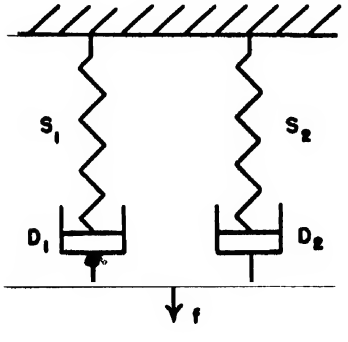

FIG. 1. Model used in derivations.

In the temperature range where the viscosity of glass is greater than 10^{10} poises, viscosities are usually measured experimentally by measuring the rate of elongation of a glass rod that is held at constant temperature and is subjected to a constant load. The quotient of the stress and the rate of elongation is, by definition, the viscosity. Data so taken can be handled readily by the type of mathematical analysis that was employed in a previous paper[2] from these laboratories to derive an equation relating time under load to the ultimate strength of glass. In that paper a model was used which consisted of pure springs and dashpots so joined that the behavior of the model under the influence of an external load represented the behavior of a glass specimen under load. It was found that a model consisting of two spring-dashpot combinations in parallel permitted the derivation of a theoretical equation for breaking strength which gave values in close agreement with experiment. The mathematical treatment of the problem was simplified by neglecting one of the dashpots; this was permissible because the characteristic of the neglected dashpot was such that it did not affect results at room temperature.

It was pointed out in that paper, however, that since the characteristic of this neglected dashpot is temperature dependent, the simplification would probably be inadmissible at higher temperatures, such as those at which the viscosity of glass is usually measured. This has been found to be the case, and in the work on viscosity, herein reported, both springs and both dashpots have been used in the mathematical derivations.

The model shown in Fig. 1 represents a glass rod subjected to a constant, external, tensile stress; since the viscosity of a given glass, as measured by a method that applies a constant tensile stress to a glass rod,

maintained at a constant temperature, does not differ from the viscosity at that temperature, as measured by other methods, the mathematical analysis applied to this model should yield results which are applicable, regardless of the experimental method employed. It has been shown by Lillie[3] and by Dale and Stanworth[4] that the viscosity of a given glass depends, among other things, on its thermal history; a satisfactory approach to the problem of viscosity should therefore consider, first of all, the manner in which a glass specimen, maintained at constant temperature, will approach an equilibrium value for viscosity with time. This is the value for viscosity, of course, most generally reported in the literature. Therefore, the viscosity-time relation at constant temperature for a specimen initially free from internal strain, will be considered first. This is, mathematically, the simplest of the time-temperature-viscosity relations. Such freedom from strain can be attained in the laboratory by maintaining the specimen for a long period of time at a temperature very near to that at which viscosity measurements are to be made, as was done by Lillie.

The second relation to be considered will be that of the rate of removal of strain initially present in a specimen. In this case, it will not be possible to verify the rate equation which will be derived by direct comparison of predicted and experimental values, as is usually done, because there is no known way to measure, quantitatively, the amount of strain present in a sample at any time. It is true that the amount of strain may be estimated by the use of polarized light but the assumption that the amount of strain is proportional to the birefringence[5] has never been established.

The third and final relation to be analyzed is the temperature dependence of viscosity under all conditions of initial internal strain. This is the most difficult, mathematically, of the time-temperature-viscosity relations and requires the equation for the rate of strain removal for its solution. It will be possible to check the validity of the assumptions which will have to be made to derive this equation in two ways. First of all, by assuming that the initial strain is zero, it should be possible to reduce the general equation to the one derived for the special case of no initial strain and as a second check, a comparison between observed and predicted values of viscosity over a wide temperature range can be made. It will be shown that equilibrium viscosities are independent of the amount or nature of initial strain present in the specimen.

It will finally be shown that it is possible to correlate the values of the parameters in the equilibrium viscosity-time equation with the chemical composition of the glass. It will be shown that it is possible, given the chemical composition of the glass as determined by analysis, to predict the equilibrium viscosity at any temperature.

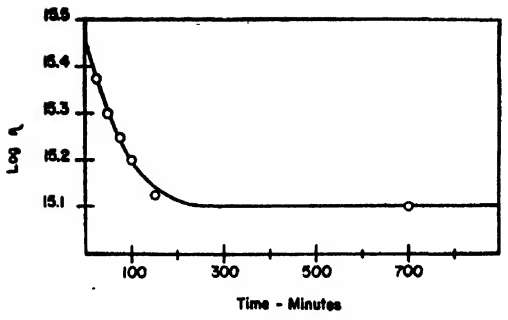

FIG. 2. Comparison of theory and experiment, log viscosity *vs.* time, for annealed glass at 486.7°C (after Lillie, see reference 3).

Two limitations are placed upon the comparison of calculated and observed values for viscosity at any temperature: the specimen must be at uniform temperature throughout its length and the viscosity determinations must be made under conditions of constant temperature. That these conditions exist is implicit in the derivations of the time-temperature-viscosity relations and represents, in any case, only those experimental conditions which would yield reproducible results.

II. NOTATION

The model used in the mathematical analyses is shown in Fig. 1. The springs represent those bonds in the glass which are stretched to their elastic limits under the influence of an external applied force and then break. They do not reform in any manner. The dashpots represent those bonds which break and then reform under the influence of the same applied force. It is not necessary that they reform in the same manner or position as that in which they originally existed; in fact, it is highly improbable that they do. No assumptions are made regarding the nature of the forces which constitute these bonds.

It is a fundamental assumption of Eyring's rate-process theory that all flow processes, of which viscous flow is one, proceed by a series of "jumps," in which discreet units of molecular dimensions move from one equilibrium position to another under the influence of an external applied force. This motion is analogous, mathematically, to the motion of a dashpot. No attempt is made to differentiate between dashpots; they differ only in that they have different temperature dependent characteristics; that is, there will be a difference in the change in their rates of flow with temperature. Both dashpots, however, obey the hyperbolic sine law; that is, their rates of flow are proportional to the hyperbolic sine of the applied force. A complete discussion of these dashpots is given elsewhere.[6]

The following symbols are used throughout this paper.

f = the total external applied force per unit area.
f_1 = the total stress on unit 1.
f_2 = the total stress on unit 2.
$f_{1,0}$ = the total stress on unit 1 at $t=0$.
$f_{2,0}$ = the total stress on unit 2 at $t=0$.
f_1' = the stress on unit 1 due to f.
f_2' = the stress on unit 2 due to f.
f'' = the total internal stress.
f_1'' = the stress on unit 1 due to f''.
f_2'' = the stress on unit 2 due to f''.
l = the total strain (elongation per unit length).
l_1 = the total elongation of spring S_1 at any time.
l_2 = the total elongation of spring S_2 at any time.
l_1' = the elongation of spring S_1 at any time caused by f_1'.
l_2' = the elongation of spring S_2 at any time caused by f_2'.
l_1'' = the elongation of spring S_1 at any time caused by f''.
l_2'' = the elongation of spring S_2 at any time caused by f''.
g_1 = the spring constant of spring S_1 so that $f_1=g_1l_1$.
g_2 = the spring constant of spring S_2 so that $f_2=g_2l_2$.
k = Boltzmann constant—1.37×10^{-16} ergs per degree.
h = Planck's constant—6.624×10^{-27} erg seconds.
R = gas constant—1.988 calories per degree.
T = temperature in degrees Kelvin.
η = viscosity in poises.
t = time in seconds.
ΔF_1^* = free energy of activation of unit 1 in calories per mole.
ΔF_2^* = free energy of activation of unit 2 in calories per mole.
ΔH_1^* = heat of activation of unit 1 in calories per mole at absolute zero.
ΔH_2^* = heat of activation of unit 2 in calories per mole at absolute zero.
ΔS_1^* = entropy of activation of unit 1 in calories per degree.
ΔS_2^* = entropy of activation of unit 2 in calories per degree.
α_1 = "constant" of dashpot 1.
α_2 = "constant" of dashpot 2.
K_1 = "characteristic" of dashpot 1.
K_2 = "characteristic" of dashpot 2.
v_1 = volume of the "hole" necessary for flow of unit 1 in cubic centimeters.
v_2 = volume of the "hole" necessary for flow of unit 2 in cubic centimeters.
λ_1 = distance in the direction of flow between equilibrium positions of unit 1 in centimeters.
λ_2 = distance in the direction of flow between equilibrium positions of unit 2 in centimeters.
a_1 = cross-sectional area of the "hole" necessary for flow of unit 1 in square centimeters.
a_2 = cross-sectional area of the "hole" necessary for flow of unit 2 in square centimeters.

The following mathematical relations exist:

$$\alpha=v/2kT,$$
$$v=a\lambda,$$

and

$$K=(2kT/h)\exp(-\Delta F^*/RT).$$

III. VISCOSITY-TIME RELATION IN THE ABSENCE OF INTERNAL STRAIN

In Fig. 1, S_1 and S_2 are pure springs, to each of which is connected, in series, a dashpot of the kind proposed by Eyring and others; that is, the dashpots are such that their rates of flow are proportional to the hyperbolic sine of the applied force:

$$dl/dt=K\sinh\alpha f.$$

At any time t the total rate of elongation will be the sum of the rate of elongation of each spring and that of its associated dashpot,

$$dl/dt=dl_1/dt+K_1\sinh\alpha_1f_1, \tag{1a}$$

$$dl/dt=dl_2/dt+K_2\sinh\alpha_2f_2. \tag{1b}$$

Since, by Hooke's law, $f_1=g_1l_1$ and $f_2=g_2l_2$, it follows that:

$$dl_1/dt=(1/g_1)(df_1/dt) \tag{2a}$$

and

$$dl_2/dt=(1/g_2)(df_2/dt). \tag{2b}$$

Since $f_1+f_2=f$, the total external applied force per unit area, which is constant:

$$df_1/dt=-df_2/dt. \tag{3}$$

Thus after elimination of f_1, l_2, and l_1, Eqs. (1a) and (1b) become:

$$dl/dt=-(1/g_1)(df_2/dt)+K_1\sinh\alpha_1(f-f_2)$$
$$=(1/g_2)(df_2/dt)+K_2\sinh\alpha_2f_2. \tag{4}$$

If $\alpha_1(f-f_2)$ and α_2f_2 are small, as a reasonably close approximation, Eq. (4) may be written:

$$dl/dt=-(1/g_1)(df_2/dt)+K_1\alpha_1(f-f_2)$$
$$=(1/g_2)(df_2/dt)+K_2\alpha_2f_2. \tag{5}$$

If

$$m=K_1\alpha_1f,$$
$$n=K_1\alpha_1+K_2\alpha_2,$$
$$p=g_1g_2/(g_1+g_2),$$

Eq. (5) becomes

$$df_2/dt=p(m-nf_2) \tag{6}$$

which has the solution

$$f_2=m/n-De^{-npt}. \tag{7}$$

In a previous work[2] it was assumed that when the external load was applied, an immediate elastic deformation occurred and that further elongation of the model was caused by movement of the dashpots. The force on the spring, before the dashpots had started to move, was called $f_{2,0}$. Using this notation we have, at $t=0$ and $f_2=f_{2,0}$

$$D=m/n-f_{2,0}=[K_1\alpha_1f/(K_1\alpha_1+K_2\alpha_2)]-f_{2,0} \tag{8}$$

by means of which the constant of integration can be evaluated. Since $dl/dt=(1/g_2)(df_2/dt)+K_2\alpha_2f_2$ [Eq. (4)], we obtain, by substitution of the value of f_2 in Eq. (7)

$$dl/dt=K_2\alpha_2m/n+D(np/g_2-K_2\alpha_2)e^{-npt}. \tag{9}$$

Substitution of the previously assigned values of m, n, and p, in Eq. (9) gives

$$dl/dt=K_1\alpha_1K_2\alpha_2f/(K_1\alpha_1+K_2\alpha_2)$$
$$+D\{[(K_1\alpha_1+K_2\alpha_2)g_1-(g_1+g_2)K_2\alpha_2]/(g_1+g_2)\}$$
$$\times\exp[-(K_1\alpha_1+K_2\alpha_2)g_1g_2t/(g_1+g_2)].$$

Since, by definition the viscosity η is $f/dl/dt$, it follows that

$$\eta=\frac{1}{K_1\alpha_1K_2\alpha_2/(K_1\alpha_1+K_2\alpha_2)+D/f[(K_1\alpha_1g_1-K_2\alpha_2g_2)/(g_1+g_2)]\exp[-(K_1\alpha_1+K_2\alpha_2)g_1g_2t/(g_1+g_2)]}. \quad (11)$$

At equilibrium, when $t=\infty$, Eq. (11) reduces to

$$\eta=(K_1\alpha_1+K_2\alpha_2)/K_1\alpha_1K_2\alpha_2. \quad (12)$$

By the use of the equations defining K, α, and v, Eq. (12) becomes

$$\eta=[(\exp(\Delta F_1^*/RT))/v_1+(\exp(\Delta F_2^*/RT))/v_2]. \quad (13)$$

In his work on viscosity, Lillie[3] held a glass at 477.8°C for 64 hours before making measurements. From his data, the following values for the parameters in Eq. (17) have been calculated

$K_1\alpha_1K_2\alpha_2/(K_1\alpha_1+K_2\alpha_2)=8\times10^{-16}$ reciprocal poises,

$(D/f)[(K_1\alpha_1g_1-K_2\alpha_2g_2)/(g_1+g_2)]=5.2\times10^{-16}$ reciprocal poises,

$[(K_1\alpha_1+K_2\alpha_2)g_1g_2/(g_1+g_2)]=1.66\times10^{-2}$ reciprocal seconds.

With these empirical values of the parameters, the viscosity-time curve which is shown in Fig. 2 was plotted. The smooth curve represents calculated values; the points represent Lillie's experimental observations.

IV. RATE OF STRAIN REMOVAL

Assume that the springs of the model shown in Fig. 1 are stressed in some way before they are connected to their respective dashpots. No assumptions are made regarding the nature of these stresses or the manner of their origin. Further, no assumption is made that the stress in each spring is the same. These stresses will, according to Hooke's law, satisfy the equations

$$f_1''=g_1l_1'' \quad (14a)$$

and

$$f_2''=g_2l_2''. \quad (14b)$$

The total rate of elongation of the system will be given by the equation:

$$dl''/dt=dl_1''/dt+K_1\sinh\alpha_1f_1''=dl_2''/dt+K_2\sinh\alpha_2f_2''. \quad (15)$$

Since $f''=f_1''+f_2''=g_1l_1''+g_2l_2''$, Eq. (15) can be written

$$df''/dt=g_1(dl_1''/dt)+g_2(dl_2''/dt)=g_1(dl''/dt)-g_1K_1\sinh\alpha_1f_1''+g_2(dl''/dt)-g_2K_2\sinh\alpha_2f_2''. \quad (16)$$

If the internal stresses are small, that is, if the glass is not badly strained, dl''/dt will be negligible; it will be true also, as a reasonably close approximation, that the hyperbolic sine is equal to its argument. With these approximations Eq. (16) becomes:

$$df''/dt=-g_1K_1\alpha_1f_1''-g_2K_2\alpha_2f_2''. \quad (17)$$

A solution of this differential equation is

$$f_1''=(\beta_1/\alpha_1)e^{-g_1K_1\alpha_1t}, \quad (18a)$$

$$f_2''=(\beta_2/\alpha_2)e^{-g_2K_2\alpha_2t} \quad (18b)$$

where β_1 and β_2 are dimensionless constants of integration. Since $f''=f_1''+f_2''$, it follows that

$$f''=(\beta_1/\alpha_1)e^{-g_1K_1\alpha_1t}+(\beta_2/\alpha_2)e^{-g_2K_2\alpha_2t}. \quad (19)$$

If the internal forces are not small, a solution of Eq. (17) is

$$f''=(g_1+g_2)l''+(2/\alpha_1)\tanh^{-1}R_1e^{-\alpha_1g_1K_1t}+(2/\alpha_2)\tanh^{-1}R_2e^{-\alpha_2g_2K_2t}+C \quad (20)$$

where R_1, R_2 and C are constants. Equation (20) will reduce to Eq. (19), when l'' is approximately zero and $e^{-\alpha_1g_1K_1t}$ and $e^{-\alpha_2g_2K_2t}$ are small.

The above solutions to Eq. (17) are not general. They are, however, valid and sufficient for the present purpose; a complete analysis of this problem and its applications to annealing will be presented in a subsequent paper.

V. VISCOSITY-TIME RELATION IN THE PRESENCE OF INTERNAL STRAIN

Assume that strain is present in the specimen when viscosity measurements are started. This condition will be realized experimentally if measurements are made on a freshly drawn fibre, as was done by Lillie[3] and by Dale and Stanworth.[4]

When internal strain is present, the total stress on each unit of the model shown in Fig. 1 is the sum of the internal stress on that unit and that part of the external load taken by the unit. That is

$$f_1=f_1'+f_1'' \quad (21a)$$

and

$$f_2=f_2'+f_2''. \quad (21b)$$

Since $f=f_1'+f_2'$, and at constant load, $df/dt=0$, it follows that

$$df_1'/dt=-df_2'/dt. \quad (22)$$

From Eqs. (1a) and (1b):

$$dl/dt=dl_1/dt+K_1\sinh\alpha_1f_1=dl_2/dt+K_2\sinh\alpha_2f_2,$$

or, as a reasonably close approximation, if the forces are small:

$$dl/dt=(1/g_1)(df_1/dt)+K_1\alpha_1f_1=(1/g_2)(df_2/dt)+K_2\alpha_2f_2.$$

Since $df_2/dt=(df''/dt)-(df_1/dt)$, it follows that

$$(df_1/dt)(1/g_1+1/g_2)+f_1(K_1\alpha_1+K_2\alpha_2)=(l/g_2)(df''/dt)+K_2\alpha_2f''+K_2\alpha_2f. \quad (23)$$

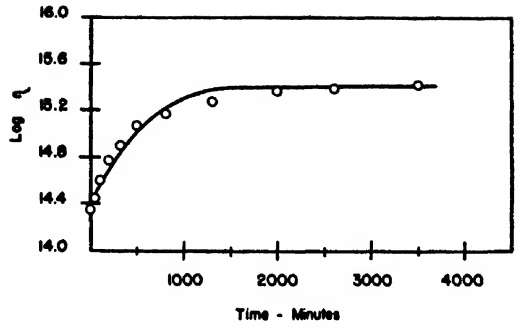

FIG. 3. Comparison of theory and experiment, log viscosity *vs.* time, for freshly drawn glass at 477.8°C (after Lillie, see reference 3).

It was shown in Eq. (19) that

$$f''=(\beta_1/\alpha_1)e^{-\alpha_1 g_1 K_1 t}+(\beta_2/\alpha_2)e^{-\alpha_2 g_2 K_2 t}.$$

Hence

$$df''/dt=-\alpha_1 g_1 K_1 f_1''-\alpha_2 g_2 K_2 f_2''$$

from which it follows that

$$df_1/dt+f_1 g_1 g_2(K_1\alpha_1+K_2\alpha_2)/(g_1+g_2)$$
$$=K_2\alpha_2 g_1 g_2 f/(g_1+g_2)+[g_1 g_2/(g_1+g_2)]$$
$$\times(K_2\alpha_2-(g_1/g_2)K_1\alpha_1)(\beta_1/\alpha_1)e^{-\alpha_1 g_1 K_1 t}. \quad (24)$$

If

$$m=(K_1\alpha_1+K_2\alpha_2)g_1 g_2/(g_1+g_2),$$
$$n=K_2\alpha_2 g_1 g_2 f/(g_1+g_2),$$
$$p=[g_1 g_2/(g_1+g_2)][K_2\alpha_2-(g_1/g_2)K_1\alpha_1](\beta_1/\alpha_1),$$

Eq. (24) can be written

$$df_1/dt+mf_1=n+pe^{-\alpha_1 g_1 K_1 t}. \quad (25)$$

For which a solution is

$$f_1=n/m+[p/(m-\alpha_1 K_1 g_1)]e^{-\alpha_1 g_1 K_1 t}+Ce^{-mt}. \quad (26)$$

When $t=0$, $f_1=f_{1,0}$ and $f_2=f_{2,0}$, where $f_{1,0}$ and $f_{2,0}$ have the meanings previously given. By means of these boundary conditions it is possible to evaluate the constant of integration in Eq. (26):

$$C=f_{1,0}-\frac{K_2\alpha_2 f}{(K_1\alpha_1+K_2\alpha_2)}-[(g_2K_2\alpha_2+g_1K_1\alpha_1)\beta_1/$$
$$(K_2\alpha_2 g_2 f-K_1\alpha_1 g_1-K_1\alpha_1 g_2)\alpha_1]. \quad (27)$$

Differentiation of Eq. (26) with respect to time gives

$$df_1/dt=-[p\alpha_1 K_1 g_1/(m-\alpha_1 K_1 g_1)]$$
$$\times e^{-\alpha_1 g_1 K_1 t}-mCe^{-mt}. \quad (28)$$

Since $dl/dt=+(1/g_1)(df_1/dt)+K_1\alpha_1 f_1$, [Eq. (5)], Eq. (28) can be written in the form:

$$dl/dt=pe^{-\alpha_1 g_1 K_1 t}$$
$$\cdot[(K_1\alpha_1-\alpha_1 g_1 K_1/g_1)/(m-\alpha_1 K_1 g_1)]$$
$$+e^{-mt}(-mC/g_1+K_1\alpha_1 C)+K_1\alpha_1 n/m. \quad (29)$$

Substitution of the values of m, n, and p, previously assigned, in Eq. (29) and simplifying gives

$$dl/dt=\frac{K_1\alpha_1 K_2\alpha_2 f}{(K_1\alpha_1+K_2\alpha_2)}+\left[\frac{C(K_1\alpha_1 g_1+K_2\alpha_2 g_2)}{(g_1+g_2)}\right]$$
$$\times\exp\left[\frac{-(K_1\alpha_1+K_2\alpha_2)g_1 g_2 t}{(g_1+g_2)}\right]. \quad (30)$$

A comparison of Eq. (30) with Eq. (10) shows that it differs only in the constant C: If the initial strain is zero, $\beta_1=0$ and

$$C=f_{1,0}-K_2\alpha_2 f/(K_1\alpha_1+K_2\alpha_2).$$

Since $f_{1,0}=f-f_{2,0}$, we can write

$$C=K_1\alpha_1 f/(K_1\alpha_1+K_2\alpha_2)-f_{2,0}$$

which is identical with the value of D in Eq. (8). At infinite time, Eq. (30) will reduce to Eq. (13).

$$\eta=h[\exp(\Delta F_1^*/RT)/v_1+\exp(\Delta F_1^*/RT)/v_2].$$

The values of the parameters in Eq. (30) for glasses having internal strain have been calculated from the data of Lillie[3] and of Dale and Stanworth.[4] With these values which are listed in Table IV, the viscosity-time relation of the glasses used have been calculated. The results are shown in Figs. 3 to 5 inclusive. The smooth curves represent theoretical values; the points are observed values.

VI. RELATION OF VISCOSITY TO COMPOSITION

An examination of the general viscosity equation [Eq. (19)] shows that it contains four temperature dependent parameters ΔF_1^*, ΔF_2^*, v_1, and v_2. In order to correlate viscosity and composition, it was necessary to establish the form of the function for each of these parameters. This cannot be done in an exact mathematical manner in the present state of the knowledge of glass structure, and it was therefore necessary to rely upon purely empirical relations. The relations which were finally adopted probably do not have any real significance; the best justification for them is that their use permits the calculation of the viscosity of a glass to a high degree of accuracy over an extended temperature range.

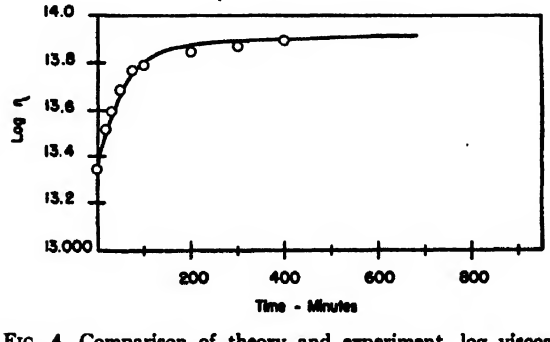

FIG. 4. Comparison of theory and experiment, log viscosity *vs.* time, for freshly drawn glass at 505.5°C (after Lillie, see reference 3).

It was first assumed that the free energies of activation were defined by the equations:

$$\Delta F_1^* = \Delta H_1^* - T\Delta S_1^*,$$
$$\Delta F_2^* = \Delta H_2^* - T\Delta S_2^*$$

and that ΔH_1^* and ΔH_2^* were independent of the temperature. In other words, it was assumed that the free energies of activation were linear functions of temperature and that the changes in them with temperature could be considered entropy changes.

A satisfactory form of the function for v_1 and v_2 was more difficult, but repeated trials finally led to the definitions:

$$v_1 = b_1 \exp(-d_1T + m_1T^2),$$
$$v_2 = b_2 \exp(-d_2T + m_2T^2)$$

where b_1, b_2 d_1, d_2, m_1, and m_2 are constants. However, it was found that unless the temperature T was very high the T^2 terms can be neglected. It was found that m_1 was of the order of magnitude of -2×10^{-8}.

Substitution of the above empirical functions in the viscosity equation, neglecting the terms in T^2, gives

$$\eta = h[\exp(\Delta H_1^*/RT - \Delta S_1^*/R + d_1T - \ln b_1) + \exp(\Delta H_2^*/RT - \Delta S_2^*/R + d_2T - \ln b_2)]$$

from which it follows, after factoring out $(\exp\Delta F_1^*/RT)/v_1$, that

$$\log\eta = (\Delta H_1^* - \Delta S_1^*T)/2.3RT + d_1T/2.3 + \log h/b_1 + \log\{1+\exp[(\Delta H_2^* - \Delta H_1^* + (\Delta S_1^* - \Delta S_2^*)T)/RT + (d_2-d_1)T + \ln b_1/b_2]\}. \quad (31)$$

If

$$M = \exp\{[\Delta H_2^* - \Delta H_1^* + (\Delta S_1^* - \Delta S_2^*)T]/RT + (d_2-d_1)T + \ln b_1/b_2\}$$

the viscosity equation can be written:

$$\log\eta = \log h + \Delta H_1^*/2.3RT - (\Delta S_1^*/2.3R + \log b_1) + d_1T/2.3 + \log(M+1) \quad (32)$$

where M has the meaning given above.

At temperatures where ΔF_1^* is much greater than ΔF_2^*, M becomes negligible and the viscosity equation reduces to

$$\log\eta = \log h + \Delta H_1^*/2.3RT - (\Delta S_1^*/2.3R + \log b_1) + d_1T/2.3. \quad (33)$$

TABLE I. Values of parameters in viscosity-time equation.

Glass designation	Temperature °C	$K_{1\alpha1}K_{1\alpha2}$ / $K_{1\alpha1}+K_{1\alpha2}$ poises^{-1}	$C(K_{1\alpha1}g_1 - K_{1\alpha2}g_2)$ / $f(g_1+g_2)$ poises^{-1}	$(K_{1\alpha1}-K_{1\alpha2})g_1g_2$ / g_1+g_2 minutes^{-1}
H. R. Lillie	447.8	1.26×10^{-14}	3.10×10^{-14}	2.41×10^{-3}
	505.5	3.80×10^{-16}	31.4×10^{-16}	3.27×10^{-3}
Dale and Stanworth	C_9 595	5.623×10^{-13}	193.9×10^{-13}	2.04×10^{-3}

	C_{40} 585	3.162×10^{-13}	174.6×10^{-13}	1.24×10^{-3}

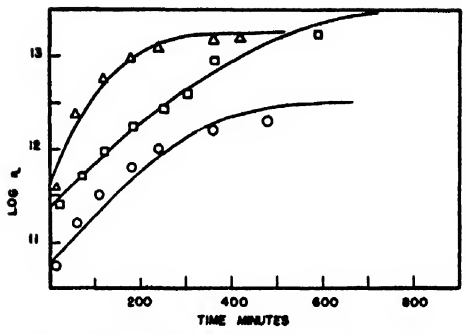

FIG. 5. Comparison of theory and experiment, log viscosity *vs.* time, for glass at different temperatures (after Dale and Stanworth, see reference 4). △ temperature 505°C, Glass No. *C* 40; □ temperature 550°C, Glass No. *C* 40; ○ temperature 595°C, Glass No. *C* 9.

This is the form of the equation which should be used when a calculation of parameters shows that ΔF_2^* is much greater than ΔF_1^*. With ordinary commercial glasses, this condition will hold when the temperature is in excess of approximately 1000°C.

An examination of the reduced viscosity equation, Eq. (33), reveals that it contains two constants, b_1 and ΔS_1^*, which are not separable. While a separation is desirable from the standpoint of an elucidation of the structure of glass, it is fortunately unnecessary if viscosities only are to be calculated. The same condition applies to the constants b_2 and ΔS_2^* in the general equation [Eq. (31)]. It is probable that this difficulty will arise, regardless of the manner in which the general viscosity equation [Eq. (19)] is expanded. For example, another expansion of that equation can be made in this manner:

$$\eta = h[(\exp(\Delta F_1^*/RT)/v_1) + (\exp(\Delta F_2^*/RT)/v_2)]$$

which can be written

$$\eta = e^{ax} + e^{by}$$

which is equivalent to

$$\eta = 2e^{(ax+by)/2}\cosh[(ax-by)/2].$$

We can then write

$$\eta = 2(h/b_1b_2)^{\frac{1}{2}}\exp\tfrac{1}{2}[(\Delta F_1^* + \Delta F_2^*)/RT + d_1T + d_2T] \times\cosh\tfrac{1}{2}[(\Delta F_1^* + \Delta F_2^*)/RT + \ln b_1/b_2 + d_1T - d_2T]$$

from which it can readily be seen that the same combinations of constants will appear.

The final assumption necessary to relate composition to viscosity is concerned with the manner in which each constituent oxide of the glass contributes to the value of each of the four parameters in the viscosity equation. It was found that the contribution of each oxide to the parameters with subscript 1 in Eqs. (31) and (33) was linearly proportional to the mole fraction of that oxide present. This is also true of the parameters with subscript 2 when alumina is not present. When it is present, it is necessary to assume that a compound with the

TABLE II. Composition of glasses used for the calculation of viscosity.

Na_2O	30,000	−26.0	−0.00400	34,000	−8.72	−0.00090
SO_3	25,000	−20.0	0.00160	—	—	—

formula $3Na_2O \cdot Al_2O_3$ is formed in order to evaluate the parameters with subscript 2, and to recalculate mole fractions after making adjustment in composition which this assumption requires. The proportionality constants for the oxides are listed in Table IV. The product of this constant and the mole fraction of the corresponding oxide present will give the contribution of each oxide to each parameter.

The viscosities of a large number of glasses have been calculated by means of the above equations. The results of these calculations, together with the compositions of the glasses, expressed as mole percent, are shown in Tables II and III.

VII. DISCUSSION OF RESULTS

The agreement between observed and calculated logarithms of viscosity (Table III) is, in general, good. There are several possible reasons for the deviations which occur. An error of 0.1 percent in the chemical analysis for silica will introduce an error of almost three percent in the calculated logarithm of viscosity. It is unfortunate that this condition exists but it is probably impossible to obtain a viscosity-temperature equation which does not contain several terms, dependent upon temperature, that combine in such a way that analysis errors are greatly magnified. This condition, therefore, points to the need for extreme care in analysis if viscosities are to be calculated and indicates that analyses cannot be calculated from batch weights, as is so frequently done, if accuracy in predicting viscosities is desired.

There are other possible sources of error: it may be that the forms of the temperature dependent functions of the parameters in the viscosity equation are not correct. As has been pointed out, these forms are purely empirical and were used only because they yielded reasonable results. Further, only in the case of soda and alumina was any assumption made regarding the formation of compounds; other compounds may exist which exert an influence on the values of the parameters. It cannot be emphasized too strongly that the factors for the oxides, herein presented, are tentative values, based on the best available data on viscosity, but subject to change when better data become available or our knowledge of glass structure increases. A third possible source of error is the tacit assumption that no phase changes occur in the temperature ranges considered. If such changes do occur, it will be necessary to apply corrections to the entropy terms. It is also possible that a separation of the entropy and volume terms, ΔS and b, might allow a better calculation of viscosity values.

It should also be pointed out that by reason of the form of the model used to derive the various equations, a one-to-one ratio of units designated by the subscript 1 and the subscript 2, appears to exist. It is unlikely that this is so. The determination of the correct ratio, however, involves the derivation of the viscosity-time-temperature equations on a purely statistical basis. When work on such a derivation can be completed, it may serve to explain the discrepancies between the values of ΔF_1^*, found in this paper and the values found from breaking strength data and by other methods.

VIII. ACKNOWLEDGMENTS

Many individuals have contributed to this work. The authors wish to thank Dean H. Eyring and the staff of the Naval Research Project at the University of Utah for advice and criticism. Special appreciation is due Dr. Dan McLachlan, Department of Metallurgy, University of Utah, for his advice and encouragement and to Dr. O. G. Burch, Dr. E. F. Poncelet, Mr. Stephen Barber and others of the research staff of the Owens-Illinois Glass Company. The authors are indebted to Messrs. F. J. Bjorklund and O. L. Anderson, Department of Physics, University of Utah, for their assistance in the laborious task of calculating and checking factors for the oxides, and to Mr. James P. Poole, Pennsylvania State College, for supplying invaluable data on viscosity.

Circuit Analysis of Linear Varying-Parameter Networks

LOTFI A. ZADEH
Columbia University, New York, New York
(Received May 8, 1950)

This paper describes a theory of linear varying-parameter networks which is essentially a generalization of the familiar frequency domain theory of fixed linear networks. Such basic concepts as impedance, admittance, gain, etc., are extended to linear varying-parameter networks and their important properties are outlined. Extensions are given also of the general mesh and node equations, Thevenin's theorem, dualization, and some other relations that hold in the case of fixed networks. On the whole it is shown that many theorems, properties, and relations that hold in the case of fixed networks may be extended with proper modifications to linear varying-parameter networks.

I. INTRODUCTION

A LINEAR varying-parameter network is essentially a linear system in which one or more parameter-values are functions of time. Familiar examples of such networks are the various types of amplitude and phase modulators, variable bandwidth amplifiers, variable delay networks, etc. One may also add to this list the ordinary fixed linear networks, for these are simply a degenerate form of linear varying-parameter networks.

In mathematical terms, the behavior of a linear varying-parameter network is governed by a system of linear differential equations with time-dependent coefficients. These equations interrelate the voltages and currents in various parts of the network. A typical relation of this kind involving only two variables $u(t)$ and $v(t)$, each representing a voltage or a current, may be written in the following form:

$$[a_n(t)p^n+\cdots+a_1(t)p+a_0(t)]v(t) = [b_m(t)p^m+\cdots+b_1(t)p+b_0(t)]u(t), \quad (1)$$

where $p=d/dt$ and the a's and b's are known functions of time. The variable on the right, $u(t)$, is usually referred to as the input while the variable on the left, $v(t)$, is referred to as the output or the response to $u(t)$. The standard problem in connection with Eq. (1) is to find the response $v(t)$ to a given input $u(t)$ on the assumption that the network is unexcited prior to application of $u(t)$. The latter condition means, more precisely, that if $u(t)$ is zero for, say, $t<0$, then $v(t)$ must also be zero for $t<0$.

Most of the papers[1-7] having direct or indirect bearing on the subject of linear varying-parameter networks are concerned with various methods and techniques for obtaining approximate solutions to the problem stated above. In the present paper, however, a different aspect of the theory of linear varying-parameter networks will be considered. Specifically, the purpose is to extend to such networks the concepts, principles, procedures and, more generally, the techniques commonly used in the circuit analysis of fixed linear networks in the frequency domain. The basis for such an extension has been established in reference 6. Thus, by using the frequency analysis approach described in reference 6 it is possible to introduce into the theory of linear varying-parameter networks such familiar and useful notions as impedance, admittance, gain, phase, poles, zeros, etc.—all of these becoming time-varying quantities. It is also possible to extend to linear varying-parameter networks such well-known theorems as the superposition theorem, compensation theorem, Thevenin's theorem, etc., with practically no modifications. In addition it is possible to extend to linear varying-parameter networks the familiar and powerful techniques of dualization, impedance and frequency transformation,[8] spectrum analysis,[9] network expansion, vector representation in the complex plane, pole and zero analysis, etc.

The above list is by no means exhaustive, but is sufficient to indicate that many if not most of the concepts and techniques used in the circuit analysis of fixed networks may be extended to linear varying-parameter networks. Our objective in this paper is limited to that of extending only the more basic of such concepts and techniques. It appears that the exploration of the behavior and properties of linear varying-parameter networks from the frequency domain point of view offers a fruitful field for further study and investigations.

II. GENERAL THEORY

In order to simplify the terminology, the term "variable network" will frequently be used hereinafter in the same sense as "linear varying-parameter network."

As a preliminary to the extension of the basic frequency domain concepts such as impedance, admittance, etc., to linear varying-parameter networks, it will be necessary to introduce the notion of the so-called *system*

function[10] of a variable network. Briefly, the system function of a variable network N is defined by the relation

$$H(j\omega;t)=\left.\frac{v(t)}{u(t)}\right]_{u(t)=e^{j\omega t}}. \tag{2}$$

In other words, the system function of N is a function $H(j\omega;t)$ such that $H(j\omega;t)e^{j\omega t}$ represents the response of N to $u(t)=e^{j\omega t}$. It is evident that for a fixed network $H(j\omega;t)$ reduces to $H(j\omega)$ and the above definition of $H(j\omega;t)$ reduces to the conventional definition of the system function of a fixed network.

The salient characteristic of the system function is that $H(j\omega;t)$ connects the output and input of a variable network in much the same manner as $H(j\omega)$ connects the output and input of a fixed network. Specifically, it may readily be shown that the output $v(t)$ of a variable network is given by the following relation:

$$v(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}H(j\omega;t)U(j\omega)e^{j\omega t}d\omega, \tag{3}$$

where $U(j\omega)$ is the Fourier transform of $u(t)$. It is seen that Eq. (3) is similar in form to the relation connecting the output and input of a fixed network:

$$v(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}H(j\omega)U(j\omega)e^{j\omega t}d\omega. \tag{4}$$

In view of this similarity and also of the fact that in Eq. (3) the variable t in $H(j\omega;t)$ plays the role of a parameter, it follows that the output of a variable network may be expressed in the same forms as the output of a fixed network. The more important of these forms are as follows:

(a) Fourier Transform Form

The Fourier transform equivalent of Eq. (3) is:

$$v(t)=\mathfrak{F}^{-1}\{H(j\omega;t)U(j\omega)\}, \tag{5}$$

where $\mathfrak{F}^{-1}$ represents the operation of inverse Fourier transformation, and the variable t in $H(j\omega;t)$ should be treated as if it were a constant parameter. It should be noted that while $v(t)$ is the inverse Fourier transform of $H(j\omega;t)U(j\omega)$, the latter quantity is not the Fourier transform of $v(t)$. In fact, it may readily be shown[6] that the Fourier transform of $v(t)$ is given by the relation

$$V(j\omega)=\int_{-\infty}^{\infty}\Gamma(j\omega';j\omega)U(j\omega')d\omega', \tag{6}$$

where the so-called *bi-frequency system function* $\Gamma(j\omega';j\omega)$ is the Fourier transform of $H(j\omega';t)e^{j\omega' t}$.

[10] The properties of this function are discussed in detail in reference 6.

(b) Laplace Transform Form

The Laplace transform equivalent of Eq. (3) is

$$v(t)=\mathfrak{L}^{-1}\{H(s;t)U(s)\} \tag{7}$$

where s is the complex frequency ($s=\sigma+j\omega$), $U(s)$ is the Laplace transform of $u(t)$, $\mathfrak{L}^{-1}$ represents the operation of inverse Laplace transformation, and the variable t in $H(s;t)$ should be treated as a constant parameter. For example, assume that the input is a unit impulse function (Dirac's δ-function) $\delta(t)$, i.e.,

$$u(t)=\delta(t), \tag{8}$$

and that $H(s;t)$ is of the form

$$H(s;t)=1/[s+\alpha(t)], \tag{9}$$

where $\alpha(t)$ is a given function of time. Since the Laplace transform of $\delta(t)$ is unity, it follows from Eq. (7) that

$$v(t)=\mathfrak{L}^{-1}\{1/[s+\alpha(t)]\} \tag{10}$$

and hence

$$v(t)=e^{-t\alpha(t)}, \tag{11}$$

which thus represents the response of the network to a unit impulse applied at $t=0$.

(c) Operational Form

The operational equivalent of Eq. (3) is:

$$v(t)=H(p;t)u(t), \tag{12}$$

where p is the usual differential operator. As in (a) and (b), in the process of operating by $H(p;t)$ on $u(t)$, the variable t in $H(p;t)$ should be treated as if it were a constant parameter.

From the above discussion it is seen that the system function of a variable network, particularly in its operational form, provides a very convenient means for describing the behavior of the network. Thus through use of the notion of the system function the behavior of a given variable network becomes identified with that of a linear time-dependent operator $H(p;t)$ which operates on the input to the network, $u(t)$, in accordance with the standard rules of operational calculus and thus yields the output $v(t)$. A significant advantage of the system function over other means for describing the behavior of a variable network is that once $H(j\omega;t)$ has been obtained, the response to a given input may be determined in most cases by using only a table of Laplace or Fourier transforms.

The problem of the determination of the system function of a variable network may be approached in several different ways. The most straightforward approach is to start with Eq. (1), which represents the relation between the output and input of the network. For convenience of the discussion, this relation will be rewritten in a compact form

$$L(p;t)v(t)=K(p;t)u(t), \tag{13}$$

where $L(p;t)$ and $K(p;t)$ stand respectively for the left-hand and right-hand operators in Eq. (1). Applying this relation to the case where $u(t)=e^{j\omega t}$, and making use of the fact that for this case the output is equal to $H(j\omega;t)e^{j\omega t}$, Eq. (13) gives,

$$L(p;t)\{H(j\omega;t)e^{j\omega t}\}=K(p;t)e^{j\omega t}. \tag{14}$$

By use of the identities

$$K(p;t)e^{j\omega t}\equiv e^{j\omega t}K(j\omega;t) \tag{15}$$

and

$$L(p;t)\{H(j\omega;t)e^{j\omega t}\}\equiv e^{j\omega t}L(p+j\omega;t)H(j\omega;t), \tag{16}$$

Eq. (14) reduces to the following relation:

$$L(p+j\omega;t)H(j\omega;t)=K(j\omega;t). \tag{17}$$

This relation is in effect a linear differential equation in which t is the independent variable, $j\omega$ is a fixed parameter, $K(j\omega;t)$ is the forcing function, and $H(j\omega;t)$ is the dependent variable. The problem of solving this equation for $H(j\omega;t)$ is considered in reference 6. Insofar as the purposes of the present analysis are concerned, it will be sufficient to assume that Eq. (17) can be solved for $H(j\omega;t)$ and thus yield an explicit expression for the system function of the network.

An indirect and frequently more convenient approach to the problem is provided by the techniques described in the present paper. In principle, the approach consists in expressing the system function of a given network in terms of the system functions of its constituent elements. This process is quite similar in form to the conventional circuit analysis of fixed networks and for this reason will be referred to by the same name. It should be emphasized, however, that the primary objective of this paper is not that of developing a method of obtaining an explicit expression for the system function of a variable network; rather, it is that of extending the conventional circuit analysis techniques to variable networks and, in particular, of establishing rules of combining the system functions of various basic combinations of networks.

An important rule of combination of system functions —one which will be found very useful later—concerns the manner in which successive operations by two or more system functions on a given input may be replaced by a single operation with a so-called *product* system function on the same input.

Consider two system functions $H_1(s;t)$ and $H_2(s;t)$ and let

$$v(t)=H_1(p;t)u(t) \tag{18}$$

and

$$w(t)=H_2(p;t)v(t). \tag{19}$$

These two relations may be combined into the one relation

$$w(t)=H_2(p;t)[H_1(p;t)u(t)], \tag{20}$$

which means that $w(t)$ is the result of successive operation by $H_1(p;t)$ and $H_2(p;t)$ on $u(t)$.

Now let it be assumed that Eq. (20) may be replaced by

$$w(t)=H_3(p;t)u(t) \tag{21}$$

where $H_3(p;t)$ is an as yet unknown system function such that the result of operation by $H_3(p;t)$ on $u(t)$ is identical with the result of successive operation by $H_1(p;t)$ and $H_2(p;t)$ on $u(t)$. $H_3(p;t)$ will be referred to as the *product system function* of $H_1(p;t)$ and $H_2(p;t)$.

To obtain the expression for $H_3(s;t)$ in terms of $H_1(s;t)$ and $H_2(s;t)$, let $u(t)=e^{st}$ in Eq. (20). Then from Eq. (20) the corresponding $w(t)$ is found to be

$$w(t)=H_2(p;t)[H_1(s;t)e^{st}] \tag{22}$$

or, equivalently

$$w(t)=e^{st}H_2(p+s;t)H_1(s;t). \tag{23}$$

On the other hand, substituting $u(t)=e^{st}$ into Eq. (21) we obtain

$$w(t)=H_3(s;t)e^{st}. \tag{24}$$

From comparison of Eqs. (23) and (24) it follows that the product system function of $H_1(s;t)$ and $H_2(s;t)$ is given by the operational relation

$$H_3(s;t)=H_2(p+s;t)H_1(s;t). \tag{25}$$

In this relation the variable t in $H_2(p+s;t)$ should be treated as a constant parameter and $H_1(s;t)$ should be treated as a function of time involving s as a parameter. It is evident that $H_2(p+s;t)$ should be interpreted as a *bilateral* operator, since in general $H_1(s;t)$ would not vanish for negative t.

Equation (25) may be written in a symbolic form

$$H_3=H_2*H_1 \tag{25a}$$

where the operation $*$ is distributive, associative and, in general, non-commutative. As should be expected, for the particular case of fixed networks Eq. (25) reduces to the familiar relation

$$H_3(s)=H_2(s)H_1(s). \tag{26}$$

The relation given by Eq. (25) expresses essentially the group property of system functions under multiplication. In connection with this property it is convenient to introduce at this point the notion of *inverse system functions*. Thus we shall say that two system functions $H_1(s;t)$ and $H_2(s;t)$ are the inverses of each other if and only if the associated product system function is equal to unity. The inverse of a system function $H(s;t)$ will be denoted as $H^{-1}(s;t)$ or $[H(s;t)]^{-1}$. With this notation the relation between a system function and its inverse assumes the following form:

$$H(p+s;t)H^{-1}(s;t)=H^{-1}(p+s;t)H(s;t)=1 \tag{27}$$

or, more simply,

$$H*H^{-1}=H^{-1}*H=1. \tag{27a}$$

This relation represents a generalization of the corre-

sponding relation in fixed networks, namely,

$$H(s)H^{-1}(s)=H^{-1}(s)H(s)=1. \tag{28}$$

Specific applications of the relations given above to the circuit analysis of linear varying-parameter networks will be made later. At this point it will suffice to note that the concept of the system function provides the necessary basis for the extension to variable networks of the frequency domain techniques commonly used in the analysis of fixed linear networks. In what follows we shall consider first such basic network functions as impedance, admittance, etc., and then will extend to variable networks some of the more important properties and relations that hold in the case of fixed networks.

III. BASIC NETWORK FUNCTIONS AND THEIR PROPERTIES

(a) Impedance

Consider a two-terminal variable network N. Let $v(t)$ be the voltage across the terminals of N and let $i(t)$ be the current flowing through N. The *instantaneous input impedance* of N or simply, the input impedance of N, is defined as a function $Z(j\omega;t)$ such that $Z(j\omega;t)e^{j\omega t}$ represents the output voltage $v(t)$ when the input current $i(t)$ is a complex exponential $i(t)=e^{j\omega t}$. In other words,

$$Z(j\omega;t)=\frac{v(t)}{i(t)}\Bigg]_{i(t)=e^{j\omega t}}. \tag{29}$$

It is seen that $Z(j\omega;t)$ is essentially the system function connecting $v(t)$ and $i(t)$. From this it follows immediately that the voltage $v(t)$ corresponding to a given input current $i(t)$ may be expressed in the four equivalent forms represented by Eqs. (3), (5), (7), and (12). For example, in operational form,

$$v(t)=Z(p;t)i(t), \tag{30}$$

where, as usual, the variable t in $Z(p;t)$ should be treated as if it were a constant parameter.

From the general relation represented by Eq. (17) it follows that if $v(t)$ and $i(t)$ are connected to each other by a differential equation such as Eq. (13), then $Z(s;t)$ satisfies the following differential equation

$$L(p+s;t)Z(s;t)=K(s;t). \tag{31}$$

A useful interpretation of $Z(j\omega;t)$ may be obtained by using the usual vector representation of voltages, currents, impedances, etc., in the complex plane. In such a plane $Z(j\omega;t)$ may be represented as a time-varying vector whose magnitude is $|Z(j\omega;t)|$ and whose argument is the phase of $Z(j\omega;t)$. This vector may be interpreted as the instantaneous amplitude of the output voltage $v(t)$ resulting from an input current of the form $i(t)=e^{j\omega t}$.

A very basic and quite obvious property of $Z(s;t)$ is related to the manner in which any number of impedances in series may be combined into a single impedance. Thus consider n variable networks N_1, N_2, $\cdots$, N_n in series with each other, and let the input impedances of these networks be respectively $Z_1(s;t)$, $Z_2(s;t)$, $\cdots$, $Z_n(s;t)$. Because of the linear character of system functions it follows immediately that the input impedance of the over-all network is given by:

$$Z(s;t)=Z_1(s;t)+Z_2(s;t)+\cdots+Z_n(s;t). \tag{32}$$

As a simple illustration of this relation consider a network consisting of a series connection of a variable resistance $R=R(t)$, a variable inductance $L=L(t)$, and a variable capacitance $C=C(t)$. The impedances of these elements are respectively $R(t)$, $L(t)s+\dot{L}(t)$, and $1/C(t)s$,[11] where the dot represents differentiation with respect to time. From Eq. (32) it follows that the input impedance in question is:

$$Z(s;t)=R(t)+L(t)s+\dot{L}(t)+1/[C(t)s]. \tag{33}$$

The input impedance of a variable network has many other properties in addition to those discussed above. Only a few of these will be considered in the following sections. The consideration of other properties is outside the scope of the present paper.

(b) Admittance

The notions of admittance and impedance of a two-terminal variable network are duals of each other. Thus, the input admittance of a network N is defined as a function $Y(j\omega;t)$ such that $Y(j\omega;t)e^{j\omega t}$ represents the current flowing through N when a voltage of the form $v(t)=e^{j\omega t}$ is applied across the input terminals of N. In other words,

$$Y(j\omega;t)=\frac{i(t)}{v(t)}\Bigg]_{v(t)=e^{j\omega t}}. \tag{34}$$

It is seen that $Y(j\omega;t)$ is the system function connecting $i(t)$ and $v(t)$. The dual of Eq. (30) is

$$i(t)=Y(p;t)v(t). \tag{35}$$

Also, the dual of Eq. (31) is

$$K(p+s;t)Y(s;t)=L(s;t). \tag{36}$$

Corresponding to the property of series addition of impedances there is the property of shunt addition of admittances. Thus, let $Y(s;t)$ be the admittance of a network consisting of a parallel connection of N_1, N_2, $\cdots$, N_n, the admittances of these networks being $Y_1(s;t)$, $Y_2(s;t)$, $\cdots$, $Y_n(s;t)$, respectively. It is evident that $Y(s;t)$ is given by

$$Y(s;t)=Y_1(s;t)+Y_2(s;t)+\cdots+Y_n(s;t) \tag{37}$$

which is the dual of Eq. (32).

An important mutual property of the input impedance

[11] These expressions follow from the relations $i=d(cv)/dt$ and $v=d(Li)/dt$.

and admittance of a variable network is that $Z(s;t)$ and $Y(s;t)$ are inverse system functions in the sense defined in section II. This fact follows immediately from the relations

$$v(t)=Z(p;t)i(t) \tag{30}$$

and

$$i(t)=Y(p;t)v(t). \tag{35}$$

Application of Eq. (27) to $Z(s;t)$ and $Y(s;t)$ yields the following relation between the impedance and admittance of a variable network

$$Z(p+s;t)Y(s;t)=Y(p+s;t)Z(s;t)=1 \tag{38}$$

or

$$Z*Y=Y*Z=1. \tag{39}$$

This relation represents a generalization of the familiar relation

$$Z(s)Y(s)=Y(s)Z(s)=1. \tag{39a}$$

Equation (38) may be used for determining the admittance of a network from the knowledge of its impedance and *vice-versa*. For example, consider a variable capacitor the capacitance of which is a function of time, $C=C(t)$. The impedance of such a capacitor is

$$Z(s;t)=1/[C(t)s]. \tag{40}$$

From Eq. (38) it follows that the admittance of this capacitor satisfies the operational relation

$$\frac{1}{C(t)(p+s)}\{Y(s;t)\}=1. \tag{41}$$

Multiplying both sides of Eq. (41) first by $C(t)$ and then by $(p+s)$ we obtain

$$Y(s;t)=(p+s)C(t) \tag{42}$$

or

$$Y(s;t)=C(t)s+C(t), \tag{43}$$

which thus represents the admittance of a variable capacitor.

In general, the determination of the impedance of a variable network from knowledge of its admittance, or *vice-versa*, is not an easy problem. For the purposes of the present analysis it will suffice to note that in most cases the solution of this problem reduces to the solution of an integral equation which results from the application of Eq. (3) to Eq. (38). In many practical cases it is not difficult to obtain an adequate approximation to $Z(s;t)$ when $Y(s,t)$ is given, or *vice-versa*, either directly from Eq. (38) or by using an approximate method of solution of the integral equation referred to above.

(c) Gain (Transfer Function)

Let $e_1(t)$ and $e_2(t)$ denote respectively the input and output of a four-terminal variable network N. By analogy with the definitions of impedance and admittance, the *gain* or *transfer function* of N is defined as a function $G(j\omega;t)$ such that $G(j\omega;t)e^{j\omega t}$ represents the output voltage $e_2(t)$ when the input voltage $e_1(t)$ is of the form $e_1(t)=e^{j\omega t}$. In other words,

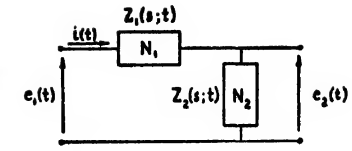

FIG. 1. Calculation of the gain of a variable network.

$$G(j\omega;t)=\left.\frac{e_2(t)}{e_1(t)}\right]_{e_1(t)=e^{j\omega t}}. \tag{44}$$

It is seen that $G(j\omega;t)$ is the system function connecting $e_2(t)$ and $e_1(t)$. As in the case of $Z(j\omega;t)$ and $Y(j\omega;t)$, we may write

$$e_2(t)=G(p;t)e_1(t). \tag{45}$$

Formally, the expression for the gain of a variable network may be obtained in much the same manner as in the case of a fixed network. Consider for example the network shown in Fig. 1 in which N_1 and N_2 are two variable networks whose impedances are respectively, $Z_1(s;t)$ and $Z_2(s;t)$; $e_1(t)$ and $e_2(t)$ represent respectively the input and output voltages, and the problem is to find an expression for the gain $G(s;t)$ in terms of the component impedances of the network.

The input admittance of the network under consideration may be written as:

$$Y(p;t)=[Z_1(p;t)+Z_2(p;t)]^{-1} \tag{46}$$

and hence the input current $i(t)$ may be expressed as

$$i(t)=[Z_1(p;t)+Z_2(p;t)]^{-1}e_1(t). \tag{47}$$

The output voltage $e_2(t)$ is related to $i(t)$ through

$$e_2(t)=Z_2(p;t)i(t). \tag{48}$$

By combining Eqs. (48) and (47), and making use of the multiplication rule of system functions (Eq. (25)) it follows that the expression for the gain is:

$$G(s;t)=Z_2(p+s;t)[Z_1(s;t)+Z_2(s;t)]^{-1} \tag{49}$$

or

$$G=Z_2*(Z_1+Z_2)^{-1}. \tag{49a}$$

The corresponding expression for a fixed network reads:

$$G(s)=Z_2(s)[Z_1(s)+Z_2(s)]^{-1}. \tag{50}$$

A network configuration frequently used in practice consists of two or more four-terminal networks which are connected in tandem. Consider two such networks N_1 and N_2 (Fig. 2) and let their gains be respectively $G_1(s;t)$ and $G_2(s;t)$. From Eq. (25) it follows immediately that the overall gain $G(s;t)$ is given by the relation

$$G(s;t)=G_2(p+s;t)G_1(s;t). \tag{51}$$

In this relation the variable t in $G_2(p+s;t)$ should be treated as if it were a constant parameter and $G_1(s;t)$

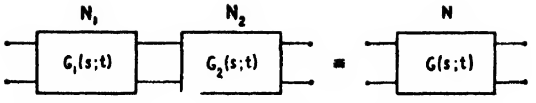

FIG. 2. Tandem connection of two variable networks.

should be treated as a function of time involving s as a parameter. It will be noticed that for the particular case of fixed networks Eq. (51) reduces to the familiar relation

$$G(s)=G_2(s)G_1(s). \tag{52}$$

As an application of Eq. (51) consider the case where N_1 is an amplitude modulator whose gain is

$$G_1(s;t)=A(t) \tag{53}$$

and N_2 is a phase modulator whose gain is expressed by

$$G_2(s;t)=e^{-s\alpha\cos\beta t} \tag{54}$$

where α and β are constants and $A(t)$ is a specified function of time.

From Eq. (51) the gain of the over-all system is found to be

$$G(s;t)=e^{-(p+s)\alpha\cos\beta t}\{A(t)\} \tag{55}$$

or

$$G(s;t)=e^{-s\alpha\cos\beta t}A(t-\alpha\cos\beta t). \tag{56}$$

It will be noted that in general an expression of the form

$$G(s;t)=G_2(s;t)G_1(t) \tag{57}$$

represents a composite network consisting of a variable network whose gain is $G_2(s;t)$ *followed* by an amplitude modulator whose gain is $G_1(t)$. Thus, Eq. (57) shows that an amplitude modulator *followed* by a phase modulator (the order of N_1 and N_2 in Fig. 2) is equivalent to the same phase modulator *followed* by an amplitude modulator whose gain is the same as that of the original modulator except for a delay in time. The same conclusion could be reached, of course, by purely physical considerations.

IV. BASIC NETWORK PROPERTIES

As was stated in the introduction, many if not most of the theorems, properties, relations, etc., that hold in the case of fixed networks, may be extended to linear varying-parameter networks. In what follows only a few such theorems, properties, relations, etc., will be considered. The topics discussed below have been chosen primarily because of their simplicity, basic importance and illustrative value.

(a) General Mesh and Node Equations of a Variable Network

The mesh and node equations of a variable network have the same form as those of a fixed network, the only difference being that all impedances and admittances in the former type of network are time-dependent quantities. Thus, for example, using operational notation the mesh equations of a variable network may be written in the following form:

$$\begin{aligned}
e_1&=Z_{11}(p;t)i_1+Z_{12}(p;t)i_2+\cdots+Z_{1n}(p;t)i_n\\
e_2&=Z_{21}(p;t)i_1+Z_{22}(p;t)i_2+\cdots+Z_{2n}(p;t)i_n\\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\\
e_n&=Z_{n1}(p;t)i_1+Z_{n2}(p;t)i_2+\cdots+Z_{nn}(p;t)i_n.
\end{aligned} \tag{58}$$

In these equations $i_1, i_2, \cdots, i_n$ represent the mesh currents; $e_1, e_2, \cdots, e_n$ represent the loop voltages; and $Z_{11}(p;t)$, $Z_{12}(p;t)$, etc., represent the self and mutual loop impedances.

It is important to note that the principle of reciprocity does hold in the case of linear varying-parameter networks. Thus, in Eq. (58) $Z_{rs}(p;t)$ is equal to $Z_{sr}(p;t)$.

(b) Thevenin's Theorem

Thevenin's theorem may be extended to variable networks with practically no modifications in its standard form. Thus let aa' be the terminals of a variable network N (Fig. 3) and let $Z_L(s;t)$ be an impedance connected across aa'. *Then, insofar as $Z_L(s;t)$ is concerned, the network N may be replaced by a voltage source $e(t)$ in series with an impedance $Z(s;t)$, where $e(t)$ is the open-circuit voltage across aa' and $Z(s;t)$ is the impedance looking into aa' when all sources of voltage inside N are short-circuited.*

To prove the above statement we shall assume for simplicity that there is only one voltage source $e_s(t)$ inside N. Let $v(t)$ and $i(t)$ denote respectively the voltage across aa' and the current through these terminals. Because of the linearity of the system we can write

$$i(t)=Y(p;t)v(t)+Y'(p;t)e_s(t), \tag{59}$$

where $Y(p;t)$ and $Y'(p;t)$ are some as yet unspecified admittances. To obtain the physical significance of $Y(p;t)$ and $Y'(p;t)$ we proceed as follows:

First, let the voltage source $e_s(t)$ be short-circuited, i.e., $e_s(t)=0$. Then, Eq. (59) gives

$$i(t)=Y(p;t)v(t) \tag{60}$$

which shows that $Y(p;t)$ is the admittance looking into aa' when $e_s(t)$ is short-circuited.

Next, let the terminals aa' be open-circuited, i.e., $i(t)=0$, and let the voltage appearing across aa' under these conditions be denoted by $e(t)$. For this case Eq. (59) gives

$$0=Y(p;t)e(t)+Y'(p;t)e_s(t). \tag{61}$$

Combining Eqs. (59) and (61) we find

$$i(t)=Y(p;t)[v(t)-e(t)] \tag{62}$$

or, equivalently

$$v(t)-e(t)=Z(p;t)i(t) \tag{63}$$

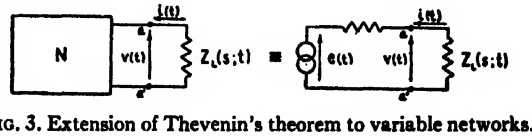

FIG. 3. Extension of Thevenin's theorem to variable networks.

where in view of Eq. (60) $Z(p;t)$ represents the impedance looking into aa' when all voltage sources in N are short-circuited. Equation (63) constitutes essentially a proof of the stated extension of Thevenin's theorem to linear varying-parameter networks.

(c) Dualization

A widely used technique in both the analysis and synthesis of fixed networks is that of dualization. This technique may also be used in variable networks in much the same manner as in the case of fixed networks. In fact, the only new aspect of dualization in the case of variable networks is that the relations between dual circuit-elements assume the following form:

Dual of a capacitance $C=f(t)$ is an inductance $L=f(t)$ and vice-versa.

Dual of resistance $R=h(t)$ is a conductance $G=h(t)$ and vice-versa.

It will be noticed that for the particular case of fixed networks the above relations reduce to the standard form. It should be emphasized that all dual properties and relations that apply to fixed networks, apply also to linear varying-parameter networks. For example, if the input impedance of a network N is $Z(p;t)$, then the input impedance of the dual of N is the inverse of $Z(p;t)$.

V. CONCLUDING REMARKS

The results obtained in the preceding sections show that the basic notion of the system function and the derived notions of impedance, admittance, gain, etc., provide the necessary basis for the extension of the conventional "fixed network" techniques of circuit analysis to linear varying-parameter networks. Much further work along these lines remains to be done, particularly in connection with the difficult problem of finding the inverse of a given system function. Nevertheless, even at its present stage of development, the circuit analysis approach outlined in this paper not only enhances understanding of the behavior of variable networks but may also be used with advantage in the solution of many problems arising in connection with the analysis and synthesis of linear varying-parameter systems.

Convection Currents in Porous Media. III. Extended Theory of the Critical Gradient

F. T. Rogers, Jr.
U. S. Naval Ordnance Test Station, Inyokern, California*

AND

H. L. Morrison
North Carolina State College of Engineering, Raleigh, North Carolina

(Received April 19, 1950)

The theory of the critical gradient for onset of thermal convection in a fluid entrapped in a porous medium is extended to allow for the exponential dependence of viscosity upon temperature and for non-linear vertical temperature-distributions which characterize transients in heat flow. Although there are approximations in the mathematical treatment, the extended theory agrees rather well with experimental data, as the simple theory does not in certain instances. New experimental data are reported for the critical gradient, obtained largely with silicone fluids in unconsolidated sands.

An earlier paper[1] under this same general title developed from basic considerations the expression

$$\beta_c=4\pi^2h^2\mu/kg\rho_0\alpha D^2, \tag{1}$$

for the (negative) mean thermal gradient which must obtain in a fluid entrapped in a porous medium in order for convection to occur. Here h^2 represents the thermal diffusivity of fluid and medium *in situ*, k the flow-permeability of the medium, μ and ρ_0 the viscosity and bottom density of the fluid, α the coefficient of cubical thermal expansion of fluid relative to medium, and g the acceleration of gravity. In the development μ was for simplicity taken to be everywhere constant, and the temperature was taken to be essentially linear in the distance above the bottom of fluid and medium.

A subsequent paper[2] reported the results of experiments designed to test the validity of Eq. (1). It was clear from these experiments that Eq. (1) is substantially correct, except for its prediction of excessive[1] β_c-values, but that its applicability is severely limited by the underlying assumptions. In the experiments μ was of necessity not constant, and in most of them convection began before a linear (i.e., steady-state) condition of heat flow could be established. The viscosity depended upon temperature according to

$$\mu\cong\mu_0\exp[-\nu(\Theta-\Theta_0)], \tag{2}$$

[2] H. L. Morrison, F. T. Rogers, Jr., and C. W. Horton, J. App. Phys. 20, 1027 (1949).

where ν is a constant for a given fluid and μ_0 is the viscosity at temperature Θ_0, whereas data such as are shown in Fig. 1 imply departures of vertical temperature-distribution from linearity given by

$$\theta \cong \theta_1 \sin(\pi z/D) + \theta_2 \sin(2\pi z/D), \tag{3}$$

θ_1 and θ_2 being constants, z being distance above bottom, and D being bottom-to-top distance through the convective fluid. That the experimental results could be represented by the empirical equation,

$$\beta_{c,\,\mathrm{obs}} \cong \frac{4\pi^2 h^2 \mu_M}{kg\rho_0 D^2}\left(\frac{k\rho_0}{h^2 \mu_M K}\right)^{0.51}, \tag{4}$$

where $K = 10^{-3}$ sec.^{2}/cm^2 deg. C for c.g.s. units, bears out both points made at the beginning of this paragraph; here μ_M is the viscosity corresponding to the average temperature in the convective fluid.

THE EXTENDED THEORY

The object of extending the simple theory for β_c is to obtain an improved form of Eq. (1), which accounts for experimentally observed critical gradients as well as does Eq. (4), and perhaps to find a physical basis for Eq. (4). The process of extension is merely to allow for the sense of Eqs. (2) and (3) in a repetition of the calculations in reference 1. Thus Eq. (14) of reference 1 now appears as

$$\frac{\partial^2 w}{\partial z^2} - \nu\beta\frac{\partial w}{\partial z} - Aw + A\lambda\theta \exp[\nu(\beta z + \theta)] = 0, \tag{5}$$

where $A = l^2 + m^2$ and $\lambda = kg\rho_0\alpha/\mu_0$, μ_0 being identified as the bottom viscosity. Likewise, Eq. (15) of reference 1 is now

$$n\theta + w\beta + w\frac{\partial \theta}{\partial z} = h^2\left(\frac{\partial^2}{\partial^2 z} - l^2 - m^2\right)\theta = 0, \tag{6}$$

reflecting the fact that θ-derivatives may be comparable to β itself. Since the precision of available data does not seem sufficient to warrant retention of the second term in Eq. (3), the sense of Eq. (3) is, approximately, that $\theta = \theta_m \sin sz$; use of this in Eq. (6) leads, for small w and for $n = 0$ to

$$\theta = -\frac{w(\beta + s\theta_m)}{h^2\sigma}, \tag{7}$$

where $\sigma = s^2 + l^2 + m^2$. Then substitution of Eq. (7) into Eq. (5) yields ($\beta = -\beta_c$)

$$\frac{\partial^2 w}{\partial z^2} + \nu\beta_c\frac{\partial w}{\partial z} - Aw + \frac{A}{B}(\beta_c - s\theta_m)e^{-\nu\beta_c z}w = 0, \tag{8}$$

where $B = h^2\sigma/\lambda$, which must be solved for β_c under the boundary conditions $w(0) = w(D) = 0$.

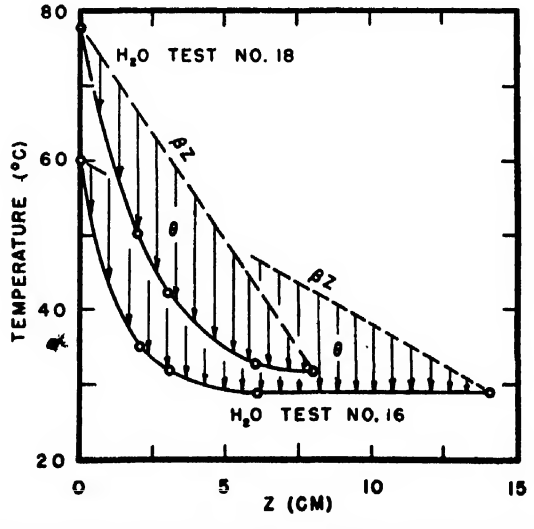

FIG. 1. Resolution of two typical non-linear vertical distributions of temperature, into linear and non-linear portions; see Eq. (3). These are the same distributions as are shown in Fig. 1 of reference 1. (Note: the axis of abscissae in Fig. 1 of reference 1 should have been labelled $D-z$ rather than z.)

Case I: $\nu = 0$

If the viscosity were actually constant, as was assumed in reference 1, but if the vertical temperature distribution were not linear, then the first derivative and the exponential in Eq. (8) would be missing. In this event Eq. (8) would have as its solution a linear combination of sine and cosine with the argument $z(A/B)^{\frac{1}{2}} \times (\beta_c - s\theta_m - B)^{\frac{1}{2}}$, and in order that boundary conditions be satisfied, this argument would equal π for $z = D$. Hence, since $A = \pi/D$ and $\sigma = 2A$ by arguments advanced in reference 1,

$$\beta_c = \frac{4\pi^2 h^2 \mu_0}{kg\rho_0\alpha D^2} + \frac{\pi\theta_m}{D}, \quad \nu = 0. \tag{9}$$

Equation (9) clearly shows how, as reference 2 reported, a negative non-linearity, θ_m, can lead to drastically smaller critical gradients than Eq. (1) would predict.

Case II: νBD small

For $\nu > 0$ but νBD small, Eq. (8) has the series solution

$$w = \sum_{j=1}^{\infty} a_j z^j,$$

where

$$\left.\begin{aligned} a_j &= \left[\frac{Q^{\frac{1}{2}(j-1)}}{(j-2)!} - \cdots\right]\frac{a_1}{j(j-1)!}, \quad j \text{ odd}, \\ a_j &= \left[\frac{Q^{\frac{1}{2}(j-2)}}{(j-2)!} - \cdots\right]\frac{\nu\beta a_1}{j(j-1)!}, \quad j \text{ even}, \end{aligned}\right\}$$

and

$$Q = A + A(s\theta_m - \beta_c)/B,$$

to the first order in νBD. By suitable manipulation, this can be rearranged, so that the boundary condition $w(D)=0$ leads to

$$\pi[(\beta_c/B)-(s\theta_m/B)-1]^{\frac{1}{2}}\sin\pi[(\beta_c/B)-(s\theta_m/B)-1]^{\frac{1}{2}} -\nu\beta_c D\cos\pi[(\beta_c/B)-(s\theta_m/B)-1]^{\frac{1}{2}} +\text{higher-order terms in } \nu BD=0. \quad (10)$$

The first two terms in Eq. (10) suffice to determine β_c for the present case; since $\beta_c/B-s\theta_m/B$ must be close to 2, some reduction yields

$$\beta_c=\frac{\dfrac{4\pi^2h^2\mu_0}{kg\rho_0\alpha D^2}+\dfrac{\pi\theta_m}{D}}{1+\dfrac{2\nu D}{\pi^2}\dfrac{4\pi^2h^2\mu_0}{kg\rho_0\alpha D^2}}, \quad \nu BD \text{ small.} \quad (11)$$

The outstanding feature of Eq. (11) is its insistence that a non-constant viscosity should reduce the critical gradient.

Case III: νBD large

Equation (8) can be put into the form of Bessel's equation[3] by the transformations $\eta=w\exp(\nu\beta_c z)$ and $\zeta=[4A(\beta_c/B-s\theta_m/B)/\nu^2\beta_c^2]^{\frac{1}{2}}\exp(-\frac{1}{2}\nu\beta_c z)$,

$$\eta''+\frac{\eta'}{\zeta^2}+\left[1-\frac{1+(4A/\nu^2\beta_c^2)}{\zeta^2}\right]=0, \quad (12)$$

and this is well suited to the study of less simple convective environments. In terms of

$$q=(1+4A/\nu^2\beta_c^2)^{\frac{1}{2}},\quad \zeta_0=2\pi(\beta_c/B-s\theta_m/B)^{\frac{1}{2}}/\nu\beta_c D,\quad \text{and}\quad \zeta_D=\zeta_0\exp(-\tfrac{1}{2}\nu\beta_c D),$$

its solution, a linear combination of Bessel functions of

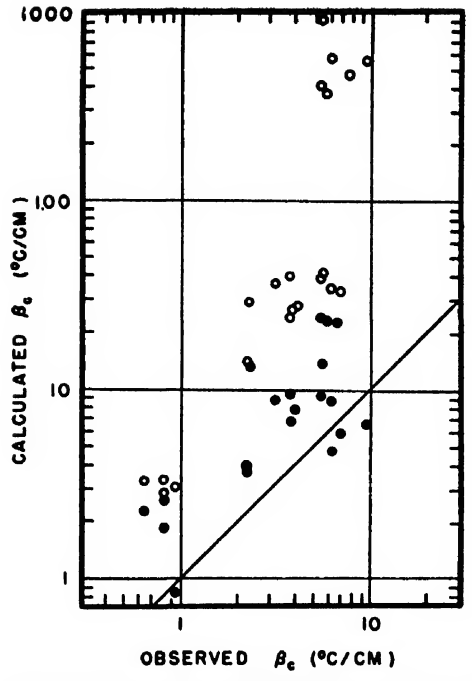

FIG. 2. Comparison of the simple theory, Eq. (1) (open circles), and the extended theory, Eqs. (11) and (14) (filled circles), with observational data. Points on the straight line would represent perfect agreement. The general tendency of points to lie above the line was anticipated in reference 1, and is attributable in part to a choice of boundary conditions differing somewhat from those which obtained in the experiments.

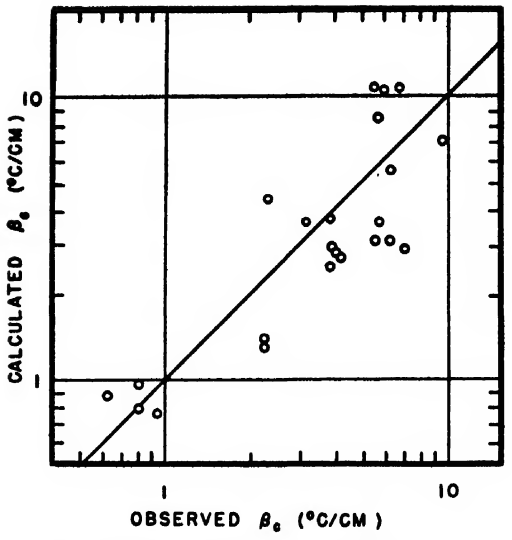

FIG. 3. Comparison of the improved empirical formula, Eq. (15), with observational data. Points on the straight line represent perfect agreement. Although Eq. (15) predicts critical gradients which depart in some instances by a factor of three from observed values, it is perhaps the best formula available at the present time.

the first and second kinds of order q, can be written as

$$J_q(\zeta_0)J_{-q}(\zeta_D)-J_q(\zeta_D)J_{-q}(\zeta_0)=0, \qquad (13)$$

and in this form satisfies the condition $w(D)=0$. Since the domain of large $\nu\beta_c D$-values is not of great interest at present, it suffices to indicate what Eq. (13) predicts for the typical value $\nu\beta_c D=5.62$ (i.e., $q=\frac{3}{2}$); in this instance Eq. (13) reduces to

$$\zeta_0\cong 2^{\frac{1}{2}}\pi,$$

whence for θ_m sufficiently negative

$$\beta_c|_{\theta_m\ll 0}\cong\frac{1}{\nu D}\left(\frac{-4\pi\theta_m/D}{4\pi^2h^2\mu_0/kg\rho_0\alpha D^2}\right)^{\frac{1}{3}}, \quad \nu\beta_c D=5.62. \qquad (14)$$

Computational experience suggests that Eq. (14) holds as a solution of Eq. (13), in an approximate sense for $3<\nu\beta_c D<9$.

COMPARISON WITH EXPERIMENT

For the purpose of providing a larger body of data against which to compare the above extended theory, additional experiments have been carried out by the technique reported in reference 2. In most of these experiments silicone fluids were used, each being identified by type (Dow-Corning DC-200) and (by a suitable prefix) by its nominal kinematic viscosity in centistokes at 25°C. Ciba oil red C Y dye was employed[4] in the silicone experiments as a visible indicator of the state of fluid motion, and an unidentified blue dye in the few glycerol experiments. Table I exhibits typical data obtained from these new experiments.

Table II contains the observed mean critical gradients for all tests reported in reference 2 as well as for those in Table I, together with gradients calculated by the various formulas of theory.

It is obvious by inspection of Table II that the extended theory as embodied in Eqs. (11) and (14), is in far better accord with the observational data than is the original simple theory summarized by Eq. (1). Figure 2 illustrates this, and at the same time demonstrates the quasi-statistical character of the accordance. For the present it does not seem worth while to expend much effort on mathematical refinements of the extended theory, because many components of experimental technique deserve prior improvement.[5]

While the entries in Table II show that the empirical Eq. (4) is in about as good agreement with observation as are Eqs. (11) and (14), a brief search has been made for a better empirical law. It has been found, as Fig. 3 shows graphically, that a more precise relation is

$$\beta_{c(\text{empir})}=0.415(\beta_{c(\text{Eq. (4)})}+0.455\beta_{c(\text{Eqs. (11), (14)})}), \qquad (15)$$

the notation here being self-explanatory. Equation (15) predicts critical gradients differing from the observed ones by not more than a factor of three, and so is probably the most accurate formula available at the present time.

[4] The authors are indebted to the Ciba Company, Inc., New York, New York, for the gift of oil red C Y dye used in these experiments.

Theory of Axially Slitted Circular and Elliptic Cylinder Antennas

D. R. RHODES
Department of Electrical Engineering, The Ohio State University Research Foundation, Columbus, Ohio
(Received April 20, 1950)

A method proposed by Sommerfeld for solving boundary value problems involving discontinous surfaces has been applied to the general case of a plane electromagnetic wave of arbitrary direction of incidence and polarization diffracting about one or more sections of perfecting conducting circular and elliptic cylinders of infinite length. The solution is in series form, where the series coefficients are independent for the special case of slots of infinitesimal width (slits). Radiation from the slitted cylinder is restricted to discrete right circular cones about the cylinder axis, each cone corresponding to an ordinary wave-guide mode in the cylinder, while slots of finite width radiate over a continuous range of conical angles. For slots of small but finite width, the relative pattern in the cone $\alpha=\alpha_0$ about a circular cylinder of radius a is the same as in a plane normal to the axis of a cylinder of radius $a\sin\alpha_0$; patterns of the slotted elliptic cylinder are similarly related, where the analog of radius is distance between foci. Conical patterns are shown for the principal *TE* and *TM* wave-guide modes in circular cylinders containing one and two diametrically opposed axial slits.

A NUMBER of papers have appeared in the past ten years in which controllable radiation from long axial slots cut in the walls of rectangular wave guide has been reported. In connection with an experimental investigation of radiation from slotted cylinder traveling wave antennas conducted at The Ohio State University[1] it was apparent that a theoretical analysis of this type of antenna would be desirable. A rigorous boundary-value solution involving no assumptions that limit the validity of the solution for a long slot in a rectangular wave guide is, in general, a difficult problem. A slotted cylindrical wave guide whose surface is defined by a single constant coordinate, however, can be treated as a diffraction problem using a method proposed by Sommerfeld[2] in connection with scattering by a cylindrical mirror. Although Sommerfeld applied the method only to two-dimensional scalar fields incident normally on a section of a circular cylinder, the method is easily extended to include the general vector field incident at any angle on elliptic as well as circular cylinders of one or more sections. The solution involves rather lengthy numerical computations in general, but a very simple solution results when the slots are assumed to be narrow. It is the special case of slots of infinite length and vanishing width, or "slits" as they shall be referred to,[3] in a perfectly conducting circular and elliptic cylindrical shell of zero wall thickness which is treated in this paper.

1. DIFFRACTION AROUND SECTIONS OF CIRCULAR CYLINDRICAL SHELLS

The coordinate system of the slotted cylinder is shown in Fig. 1. The fields diffracted about the cylinder by a plane wave incident at an arbitrary angle with respect to the cylinder axis can be obtained by expressing the electric and magnetic fields in terms of two independent single component Hertzian vectors directed along the z axis.[4] Each of the two scalar functions are then solutions of the ordinary scalar wave equation. The required solution is that linear combination of characteristic functions whose coefficients are such that the boundary conditions at the cylindrical surface and at infinity are satisfied.

A single section and two equal diametrically opposed sections of a circular cylinder are shown in cross section

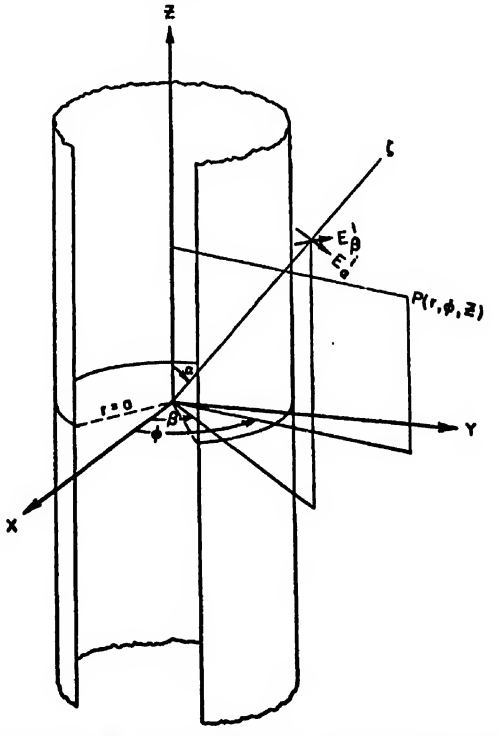

FIG. 1. Coordinate system defining the spherical angles of arrival α and β of the incident plane wave along the ζ-axis and the cylindrical coordinates r, φ, z of an arbitrary point in space.

[3] The term "slit" carries the connotation of narrowness to a greater degree than the term "slot" and hence shall be used to specify a slot in this more restrictive sense.
[4] J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill Book Company, Inc., New York, 1941), pp. 349–51.

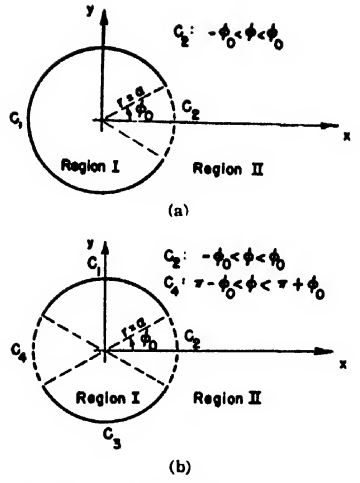

FIG. 2. Cross section of an infinitely long circular cylinder of radius a with (a) a single conducting section, and (b) two equal diametrically opposed conducting sections.

in Fig. 2. These two cases only will be considered. Boundary conditions at the cylindrical surface require that the tangential components of electric field and the normal components of magnetic field vanish over the conducting sections, and that all components of electric and magnetic field match over the aperture separating the interior and exterior regions of the cylinder. The requirement that the scattered radiation consist of outward traveling waves at infinity is satisfied by choosing Hankel functions of the second kind as the radial function in the scattered waves.

For any arbitrary polarization of the incident plane wave it is necessary to use both Hertz vectors. However, if the incident wave is resolved into two orthogonal components, one in and one normal to the plane of incidence, the diffracted field produced by each component can be independently determined using only one Hertz vector. The total field is obtained by superposing the two at every point in space. Elliptically as well as linearly polarized incident waves can be used by including the appropriate time phase between the two orthogonal components.

The incident electric field will, in general, have components $E_\alpha{}^i$ and $E_\beta{}^i$. Each of these components is of the form[5]

$$E^i = E_0 e^{ikz\cos\alpha+i\omega t}\sum_{-\infty}^{\infty} i^n J_n(kr\sin\alpha)e^{in(\varphi-\beta)}. \quad (1)$$

Considering first the component $E_\alpha{}^i$, the fields are derivable from a transverse magnetic Hertzian potential Π_z proportional to E_z. Resolving $E_\alpha{}^i$ into its cylindrical components, the incident potential $\Pi_z{}^i$ is found from $E_z{}^i$ to be

$$\Pi_z{}^i = K\sum_{n=-\infty}^{\infty} i^n J_n(kr\sin\alpha)e^{in(\varphi-\beta)}, \quad (2)$$

where

$$K = -\frac{E_{0\alpha}}{k^2\sin\alpha}e^{ikz\cos\alpha+i\omega t}. \quad (3)$$

Designating the potential inside the cylinder by $\Pi_z{}^{\mathrm{I}}$ and the potential outside the cylinder by $\Pi_z{}^{\mathrm{II}}$, the latter of which can be written as the sum of the incident and scattered potentials

$$\Pi_z{}^{\mathrm{II}} = \Pi_z{}^{\mathrm{I}} + \Pi_z{}^s, \quad (4)$$

the potentials can be written in the following form:

$$\Pi_z{}^{\mathrm{I}} = K\sum_{n=-N}^{N} a_n J_n(kr\sin\alpha)e^{in(\varphi-\beta)}, \quad (5)$$

$$\Pi_z{}^{\mathrm{II}} = K\sum_{n=-N}^{N}[i^n J_n(kr\sin\alpha) + c_n H_n{}^{(2)}(kr\sin\alpha)]e^{in(\varphi-\beta)}, \quad (6)$$

where the summations are limited to a finite number of terms. The exact solution can be approximated as closely as desired by series containing $2N+1$ terms if the arbitrary positive integer N is chosen sufficiently large.

The boundary conditions at $r=a$ must determine the unknown coefficients a_n and c_n uniquely. Three necessary and sufficient independent boundary conditions on the potentials are the following:

$$(\Pi_z{}^{\mathrm{I}} = \Pi_z{}^{\mathrm{II}})c_1 + c_2, \quad (7a)$$

$$(\Pi_z{}^{\mathrm{I}} = \Pi_z{}^{\mathrm{II}} = 0)c_1, \quad (7b)$$

$$\left(\frac{\partial\Pi_z{}^{\mathrm{I}}}{\partial r} = \frac{\partial\Pi_z{}^{\mathrm{II}}}{\partial r}\right)_{c_2}. \quad (7c)$$

Since the potentials in the two regions must match over the periodic orthogonal interval $0\leq\varphi\leq 2\pi$, by Eq. (7a), the coefficients may be equated termwise:[6]

$$a_n J_n = i^n J_n + c_n H_n{}^{(2)}. \quad (8)$$

Boundary condition Eq. (7b) requires that

$$\left(\sum_{n=-N}^{N} a_n J_n e^{in(\varphi-\beta)} = 0\right)c_1, \quad (9)$$

and boundary condition Eq. (7c) together with Eq. (8) relating a_n and c_n requires that

$$\left(\sum_{n=-N}^{N}\frac{a_n - i^n}{H_n{}^{(2)}}e^{in(\varphi-\beta)} = 0\right)_{c_2}. \quad (10)$$

Equations (9) and (10) relate the coefficients a_n over the two subintervals C_1 and C_2. The solution for the coefficients is referred to by Sommerfeld[3] as a "non-final determination of coefficients," that is, each coefficient depends upon every other coefficient in the series because of the non-orthogonal subintervals. This is a very

[5] Reference 4, p. 371–2. The notation used is essentially that of Stratton with the exception that the time convention has been chosen to be $e^{i\omega t}$ rather than $e^{-i\omega t}$.

[6] The convention will be adopted that all solutions of Bessel's differential equation evaluated at $r=a$ will be written without the argument.

essential distinction from the problem of diffraction around a completely closed conducting surface in which each coefficient is uniquely determined independently of the others. The method of solution proposed by Sommerfeld is that of minimizing the total mean square error incurred over the two subintervals, thereby obtaining the best approximation possible for the finite number of terms used in the series. Since it is required that each summation in Eqs. (9) and (10) is to approximate the null function, the total mean square error over C_1 and C_2 is given by

$$M=\int_{C_1}\left[\sum_{n=-N}^{N} a_n J_n e^{in(\varphi-\beta)}\right]^2 d\varphi + \int_{C_2}\left[\sum_{n=-N}^{N}\frac{a_n-i^n}{H_n^{(2)}} e^{in(\varphi-\beta)}\right]^2 d\varphi. \quad (11)$$

Differentiating M with respect to each unknown coefficient results in the following set of $2N+1$ equations, which must be satisfied simultaneously for the $2N+1$ unknown a_n's:

$$2\pi a_p J_p^2 e^{-ip\beta} - \sum_{n=-N}^{N}\left[J_n J_p - \frac{1}{H_n^{(2)}H_p^{(2)}}\right]\mathfrak{a}_{np} e^{-in\beta} a_n = \sum_{n=-N}^{N}\frac{i^n e^{-in\beta}}{H_n^{(2)}H_p^{(2)}}\mathfrak{a}_{np}, \quad |p|\leq N, \quad (12)$$

where δ_{np} is Kronecker's delta and where the integral of products of angular functions over C_2 is given by

$$\mathfrak{a}_{np}=\frac{2\sin(n-p)\varphi_0}{n-p}, \quad (13)$$

$\mathfrak{a}_{pp}$ being defined as the limit when $n\to p$.

The analysis for transverse electric fields excited by the other component E_β^i of the incident plane wave is exactly analogous to the preceding analysis for transverse magnetic fields, where K is replaced by

$$K^*=-\frac{E_{0\beta}}{\eta k^2\sin\alpha} e^{ikx\cos\alpha+i\omega t},$$

where $\eta=(\mu/\epsilon)^{\frac{1}{2}}$. The equations relating coefficients a_n^* and c_n^* correspond to those relating a_n and c_n in Eqs. (8) and (12) when the radial functions are replaced by their derivatives.

The fields diffracted around a multiple section cylindrical shell by an incident plane wave are treated in the same manner as the single section cylinder. As with the single-section cylinder the boundary conditions must be satisfied over each of the conducting sections and apertures between sections. Minimizing the total mean square error over the cylinder again gives the best approximation in the sense of least squares. Although the method is applied here only to the case of two equal diametrically opposed sections, it can be easily extended to include more than two sections.

For the transverse magnetic component E_α^i of a plane wave incident on the cylinder shown in cross section in Fig. 2b, boundary conditions again require that a_n and c_n be related by Eq. (8) and that Eqs. (9) and (10) must hold over the subintervals C_1, C_3 and C_2, C_4, respectively. The resulting relationship between coefficients a_n then reduces to the following set of equations:

$$\pi a_p J_p^2 e^{-ip\beta} - \sum_{n=-N}^{N}{}'\left[J_n J_p - \frac{1}{H_n^{(2)}H_p^{(2)}}\right]\mathfrak{a}_{np} e^{-in\beta} a_n = \sum_{n=-N}^{N}{}'\frac{i^n e^{-in\beta}}{H_n^{(2)}H_p^{(2)}}\mathfrak{a}_{np}, \quad |p|\leq N, \quad (14)$$

where the primed summation is on even values of n when p is even and odd values of n when p is odd. The set of equations relating coefficients a_n^* for the transverse electric component E_β^i correspond to Eqs. (14) when the radial functions are replaced by their derivatives.

It can be seen from Eq. (12) that the coefficients a_n are functions of the angles α and β of the incoming plane wave. This is a severe limitation when solving for the pattern of the scattered field or of a detecting probe near the conducting surface, since it is necessary to repeat the solution of the system of equations for each angle of incidence. The limitation vanishes, however, for the special case of a vanishingly narrow slot in a cylinder.

2. SERIES COEFFICIENTS FOR NARROW SLOTS

As the slot width vanishes, the set of Eqs. (12) relating coefficients a_n reduces to a set of independent equations, each equation involving only a single coefficient, since C_1 approaches the interval of orthogonality of the angular functions. When the angular slot width $2\varphi_0$ is small, the integrals over C_1 are essentially independent of n and p, reducing to

$$\mathfrak{a}_{np}\approx 2\varphi_0. \quad (15)$$

Consider first the transverse magnetic component of the plane wave incident on the cylinder. When the argument $ka\sin\alpha$ is not a zero of J_q, then by choosing φ_0 vanishingly small all of the terms in the summation on a_n become vanishingly small with respect to the unsummed term containing a_p, Eqs. (12) then becoming

$$2\pi a_p J_p^2 e^{-ip\beta}=\frac{2\varphi_0}{H_p^{(2)}}F_c(\alpha,\beta), \quad |p|\leq N, \quad (16)$$

where

$$F_c(\alpha,\beta)=\sum_{n=-N}^{N}\frac{i^n e^{-in\beta}}{H_n^{(2)}}. \quad (17)$$

When $ka\sin\alpha$ is a zero of J_q, then for $p\neq q$ the set of Eqs. (12) reduce as before to Eq. (16). For $p=q$, however, the unsummed term containing a_q is zero and all

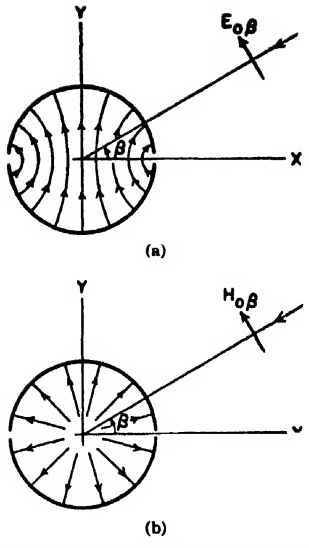

FIG. 3. Electric field distribution in the xy-plane within a slitted cylinder excited by a plane wave incident at (a) α_{11}', and (b) α_{01}.

of the a_n's in the summation are vanishingly small except the one containing a_q; hence at $p=q$ the set of Eqs. (12) reduces to

$$a_q e^{-iq\beta} = -iN_q F_c(\alpha, \beta), \quad |q| \leq N, \tag{18}$$

which determines each coefficient a_q explicitly. The coefficients a_n^* for transverse electric excitation correspond as before when the radial functions are replaced by their derivatives. A similar solution follows immediately from Eq. (14) for the double section cylinder.

The scattered radiation reduces to that of a completely closed cylinder in the limit as φ_0 vanishes, since a_n vanishes everywhere except at the zeros of J_q. For a_n to vanish everywhere including the zeros of J_q it is only necessary to let φ_0 vanish before J_q passes through its zeros. The coefficients for the scattered radiation are then obtained directly from Eq. (8).

3. MODES IN THE SLITTED CIRCULAR CYLINDER

a. Existence of Wave-Guide Modes at Certain Critical Incident Angles

The electric and magnetic fields everywhere inside a cylinder containing one or more slits have vanishingly small amplitudes due to the factor φ_0, except when the incident plane wave arrives at such an angle that

$$J_q(ka \sin\alpha_{qm}) = 0, \tag{19a}$$

or

$$J_q'(ka \sin\alpha_{qm}') = 0, \tag{19b}$$

where α_{qm} and α_{qm}' denote the incident angles for which the mth zeros of J_q and J_q' occur, respectively. The series representing each field component then reduces to two terms, namely, those for which $n=\pm q$. At α_{qm} the components of electric field in a cylinder containing a single slit reduce to the following:

$$E_r^{(1)} = -\epsilon_q E_{0\alpha}[\cos\alpha_{qm} J_q'(kr \sin\alpha_{qm}) \times \cos q\varphi] N_q F_c(\alpha, \beta), \tag{20a}$$

$$E_\varphi^{(1)} = \epsilon_q E_{0\alpha}\left[\cos\alpha_{qm} \frac{q}{kr \sin\alpha_{qm}} \times J_q(kr \sin\alpha_{qm}) \sin q\varphi\right] N_q F_c(\alpha, \beta). \tag{20b}$$

$$E_z^{(1)} = i\epsilon_q E_{0\alpha}[\sin\alpha_{qm} J_q(kr \sin\alpha_{qm}) \times \sin q\varphi] N_q F_c(\alpha, \beta), \tag{20c}$$

where ϵ_q is Newman's number; the common factor $\exp(ikz \cos\alpha_{qm} + i\omega t)$ has been omitted. Equations (20) are precisely the expressions given by Stratton[7] for the electric field components of the TM_{qm} mode in a hollow circular cylinder wave guide if Stratton's coefficients a_{qm} are chosen to be

$$a_{qm} = i\epsilon_q E_{0\alpha}(\lambda/\lambda_{qm}) N_q F_c(\alpha, \beta),$$

and if the critical angle α_{qm} is related to the cut-off wave-length λ_{qm} of the TM_{qm} circular wave-guide mode in such a way that

$$\sin\alpha_{qm} = \lambda/\lambda_{qm} = u_{qm}/ka, \tag{21}$$

where u_{qm} is the mth zero of J_q. Similarly, it can be shown that a plane wave incident at $\alpha=\alpha_{qm}'$ excites the TE_{qm} mode in a slitted circular cylinder, where α_{qm}' is related to the wave-length of the exciting plane wave and to its cut-off wave-length by Eq. (21). The field distribution of the lowest order TE and TM modes excited in a slitted cylinder are shown in Fig. 3.

An interesting philosophical but physically useless observation is the fact that a non-vanishing energy bearing field can exist in the cylinder in the ideal case of a plane wave incident at the critical conical angles on a perfectly conducting cylindrical shell, even when the shell is completely closed. These fields are physically unobtainable, since they must collapse if any energy is withdrawn from the system.

b. Modes Dependent on Slit Width

At all angles of incidence other than those in the cones α_{qm} and α_{qm}' the coefficients of the series for the fields in the cylinder are proportional to the slit width. Even at the critical angles defined by these cones all but one pair of coefficients are proportional to slit width, the fields associated with this pair being identified with ordinary wave-guide modes in the cylinder. As a consequence, for incidence at angles other than the critical angles all fields in the cylinder vanish with slit width. Since there has been some interest expressed by various

[7] Reference 4, p. 541, Eqs. (75). A typographical error is apparent in the angular function in the expression for E_z.

authors[8-10] in one special case in which these vanishing modes are excited, namely, the case of a plane wave incident normally on a slitted cylinder of arbitrary radius, these modes will be briefly considered.

For a single slit in a cylinder, the axial component of electric field for TM waves and the angular component of electric field for TE waves, for incidence at angles other than α_{qm} and α_{qm}', are given by the following:

$$E_z^{(1)} = -\frac{\varphi_0}{\pi} E_{0\alpha} \sum_{p=0}^{N} \frac{\epsilon_p}{J_p^2 H_p^{(2)}} \times [\sin\alpha J_p(kr\sin\alpha)\cos p\varphi] F_c(\alpha, \beta), \quad (22a)$$

$$E_\varphi^{(2)} = -i\frac{\varphi_0}{\pi} E_{0\beta} \sum_{p=0}^{N} \frac{\epsilon_p}{J_p'^2 H_p^{(2)\prime}} \times [J_p'(kr\sin\alpha)\cos p\varphi] F_c'(\alpha, \beta), \quad (22b)$$

where $F_c'(\alpha, \beta)$ corresponds to $F_c(\alpha, \beta)$ when the radial functions are replaced by their derivatives. For a cylinder containing two diametrically opposed slits the conical pattern factors $F_c(\alpha, \beta)$ and $F_c'(\alpha, \beta)$ are each summed over even values of n when p is even and odd values of n when p is odd. Individual terms in the summation on p in Eqs. (22) do not represent ordinary wave-guide modes, since no relation such as that given by Eq. (21) can exist for arbitrary values of α.

At normal incidence, Eqs. (22) contain the same conical pattern factors which Sinclair[8] obtained in a plane normal to the cylinder axis for a very narrow axial slot in a cylinder when considered as a transmitting antenna. Sinclair resolved an assumed uniformly distributed tangential electric field at $r=a$ into a Fourier series and equated this series termwise to a second series representing the total electric field for $r \geq a$. Using Sinclair's method, Papas and King[9] computed the current distribution on the surface of a circular cylinder excited by an electric field across an axial slit. Sinclair has also shown[10] that the pattern, in a plane normal to the cylinder axis, of arrays of axial slits on the surface of conducting circular cylinders can be calculated by superposing the fields caused by each slit. The patterns of two diametrically opposed slits obtained by using Sinclair's method of arraying slits are the same as given here.

4. OPERATION AS A TRAVELING WAVE ANTENNA

Operation of the slitted cylinder as a receiving antenna is readily apparent. As the conical angle α is continuously varied, the fields in the cylinder abruptly change at α_{qm} and α_{qm}' from fields having vanishingly small amplitudes (proportional to the slit width) into a single TM or TE wave-guide mode whose amplitude is independent of the slit width. Since the zeros of J_q and J_q' are distinct, no two wave-guide modes are excited at the same angle of incidence and hence each mode is distinct (exceptions are the TE_{0m} and TM_{1m} modes, which are excited at the same incident angle since $J_0' = -J_1$). A receiving probe placed in the cylinder has an open-circuit voltage induced in it proportional to the field at the probe. A slotted cylinder antenna should exhibit directional characteristics dependent on slot width, approaching infinite directivity as the slot width vanishes.

The critical conical angles were determined several years ago by Hansen[11] by considering axially slitted wave guides as transmitting traveling wave antennas. Maximum radiation occurs at those angles for which radiation from every infinitesimal element of the slit aperture interferes constructively. Referring to Fig. 4, maximum constructive interference occurs when α_{qm} or α_{qm}' is related to the excitation wave-length and to the guide wave-length by

$$\cos\alpha_{qm} = \lambda/\lambda_g. \quad (23)$$

Equation (23), obtained from simple interference considerations, is equivalent to Eq. (21) obtained by rigorous solution of the boundary value problem.

The critical cones associated with each wave-guide mode are distinguished by the roots u_{qm} and u_{qm}'. For any given wave-guide mode these cones are related to the electrical radius of the cylinder by Eq. (21). The angles α_{qm} and α_{qm}' are plotted in Fig. 5 as a function of the electrical radius a/λ for cylinders not exceeding a radius of one wave-length. The critical cones asymptoti-

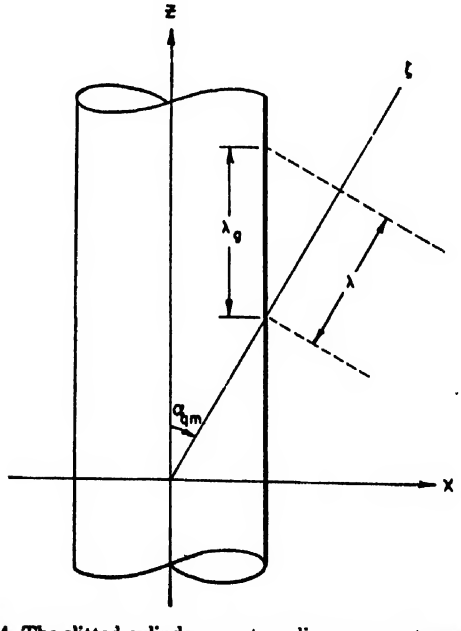

FIG. 4. The slitted cylinder as a traveling wave antenna. Maximum constructive interference occurs in cones defined by $\cos\alpha_{qm} = \lambda/\lambda_g$, where λ is free space wave-length and λ_g is guide wave-length.

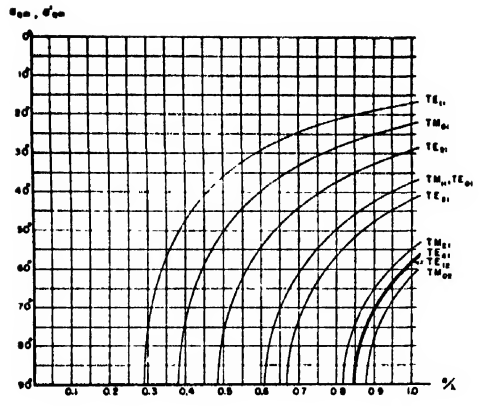

FIG. 5. Critical conical angles α_{qm} and α_{qm}' as a function of electrical radius of the slitted circular cylinder.

cally approach the cylinder axis as the excitation frequency is increased. In contrast to the unbounded upper frequency limit, each mode has a sharply defined low frequency limit. The low frequency limit occurs when maximum radiation is in the plane normal to the cylinder axis, and corresponds to the condition of cut-off in the cylindrical wave guide. For all frequencies below the low frequency limit the wave guide is operating below its cut-off frequency, and the energy propagating inside the cylinder is rapidly attenuated.

The slitted cylinder antenna is fundamentally linearly polarized, the electric field radiated by TM modes being E_α and that by TE modes being E_β.

The theory of the slitted cylinder can be used to predict the conical pattern and critical cones of wave-guide-fed slits in cylinders. The critical cones are determined by the phase velocity of waves traveling in the slit, which is determined entirely by the wave-guide cross-section; the conical pattern depends on the cross sections of both wave guide and cylinder. For the case of a circular wave guide feeding a slotted circular cylinder as shown in Fig. 6a, the argument of the radial functions in the conical pattern factor $F_c(\alpha_{qm}, \beta)$ for the TM_{qm} mode in the wave-guide is

$$kb \sin\alpha_{qm} = (b/a)u_{qm}. \tag{24}$$

Two or more wave-guide-fed slits in a cylinder, as suggested in Fig. 6b, may be independently excited and the radiation pattern calculated by Sinclair's method of superposing fields.

5. RADIATION PATTERNS

The relative conical radiation patterns of the slitted cylinder are plots of the conical pattern factors $F_c(\alpha, \beta)$ and $F_c'(\alpha, \beta)$. The pattern factors are complex functions of β from which the amplitude and phase patterns can be obtained. The conical pattern is fixed for any given wave-guide mode in a slitted cylinder regardless of the cylinder radius or critical conical angle. In Fig. 7 is shown the conical amplitude patterns characteristic of the lowest order TE and TM modes in a circular cylinder containing one or two diametrically opposed slits. An example of the three dimensional pattern of a slitted cylinder is shown in Fig. 8 for a $\frac{3}{8}\lambda$ diameter cylinder containing one or two diametrically opposed slits. The patterns in the critical cones are those shown in Fig. 7 when plotted on an absolute scale. The critical cones for the cylinder diameter chosen are $\alpha_{11}' = 42°$ and $\alpha_{01} = 61°$.

Since the incident angle α appears in the pattern factor only in the product $ka \sin\alpha$, it follows that the relative pattern in any cone $\alpha = \alpha_0$ about a cylinder of radius $r = a$ is the same as the relative pattern in a plane normal to the axis of a cylinder of radius $r = a \sin\alpha_0$.

6. SLITTED ELLIPTIC CYLINDER

The preceding method outlined for the slitted circular cylinder can be applied equally well to the slitted elliptic cylinder, the only other closed cylindrical surface defined by a single coordinate for which the scalar wave equation is separable. Elliptic cylinder coordinates (u, v, z) are related to cartesian coordinates (x, y, z) by the transformation

$$x = c_0 \cosh u \cos v, \quad y = c_0 \sinh u \sin v;$$

the metric coefficients are given by $h_u = h_v = c_0(\cosh^2 u - \cos^2 v)^{\frac{1}{2}}$. The coordinate system in Fig. 9 shows a conducting elliptic cylinder defined by $u = u_0$ with a slot of angular width $2v_1$, located at $v = v_0$. The coordinates u and v are radial and angular coordinates corresponding to r and φ of the circular cylinder.

The wave functions resulting from separation of the wave equation consist of products of radial and angular Mathieu functions. Using the series expansion of a plane wave in terms of even and odd elliptic wave functions as given by Stratton,[12] the transverse magnetic potentials inside and outside the cylinder $u = u_0$ can be written as follows:

$$\Pi_e^I = (8\pi)^{\frac{1}{2}} K \sum_{n=0}^{N} [(a_n^e/N_n^e) Je_n(c, \cosh u) \times Se_n(c, \cos v) Se_n(c, \cos\beta) + (a_n^o/N_n^o) Jo_n(c, \cosh u) \times So_n(c, \cos v) So_n(c, \cos\beta)]. \tag{25a}$$

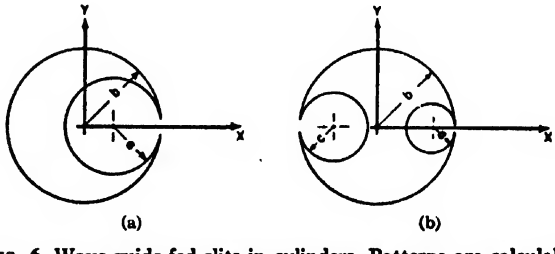

FIG. 6. Wave-guide-fed slits in cylinders. Patterns are calculable from slitted cylinder theory.

[12] Reference 4, p. 386, Eq. (84).

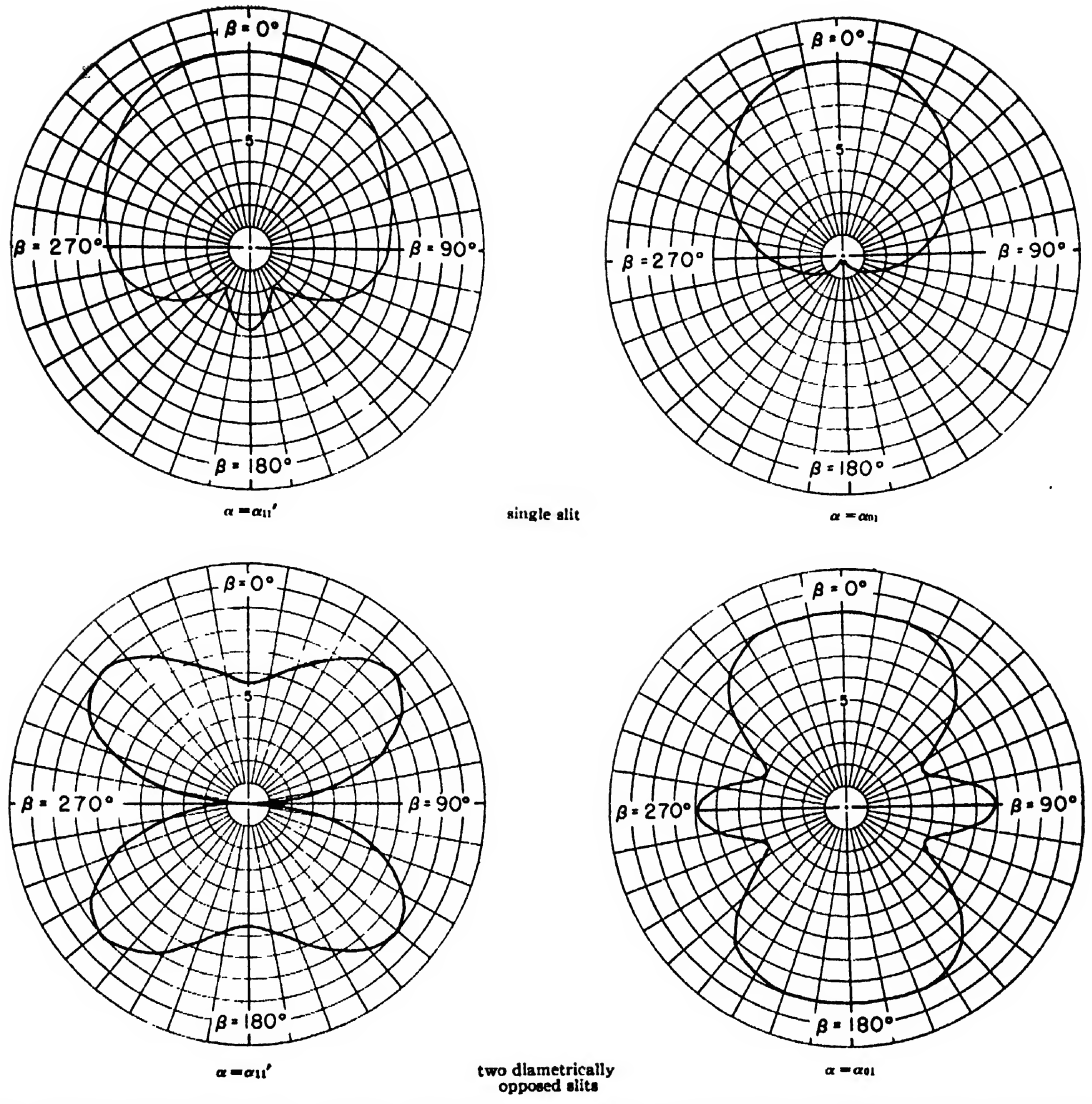

FIG. 7. Relative conical patterns of a circular cylinder containing one or two diametrically opposed slits when the cylinder is excited in the TE_{11} or TM_{01} circular wave-guide mode.

$$\Pi_z^{II} = (8\pi)^{\frac{1}{2}} K \sum_{n=0}^{N} \Big[\frac{1}{N_n^e} \{ i^n Je_n(c, \cosh u) + c_n^e He_n^{(2)}(c, \cosh u) \} \times Se_n(c, \cos v) Se_n(c, \cos\beta) + (1/N_n^o) \{ i^n Jo_n(c, \cosh u) + c_n^o Ho_n^{(2)}(c, \cosh u) \} \times So_n(c, \cos v) So_n(c, \cos\beta) \Big]. \quad (25b)$$

The boundary conditions require that Π_z match over the interval $0 \leq v \leq 2\pi$ and vanish over C_1, and that $\partial\Pi_z/\partial u$ match over C_2. The condition that Π_z must match over the interval of orthogonality of the angular functions requires that

$$a_n^e Je_n = i^n Je_n + c_n^e He_n^{(2)}, \quad (26a)$$

$$a_n^o Jo_n = i^n Jo_n + c_n^o Ho_n^{(2)}, \quad (26b)$$

where the radial functions are evaluated at $u = u_0$. The other two boundary conditions relate the coefficients over the non-orthogonal subintervals C_1 and C_2. Minimizing the total mean square error and letting v_1 vanish again results in a set of independent equations for the unknown coefficients a_n. When

$$Je_{a_e}(c, \cosh u_0) = 0, \quad (27a)$$

or

$$Jo_{a_o}(c, \cosh u_0) = 0, \quad (27b)$$

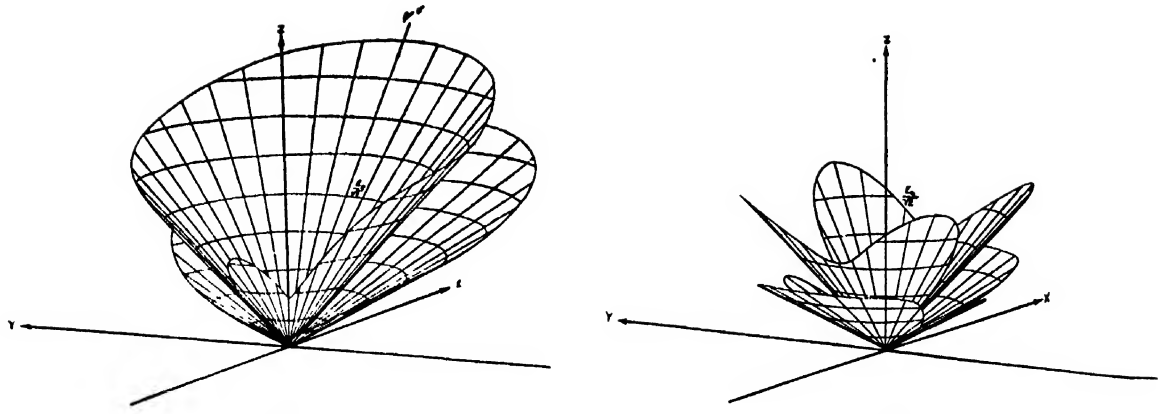

FIG. 8. Three-dimensional pattern of a radial electric probe located at $\varphi=(\pi/2)$ in a $\frac{1}{2}\lambda$ diameter cylinder containing (a) a single slit located at $\varphi=0$, and (b) two diametrically opposed slits located at $\varphi=0$ and $\varphi=\pi$. The incident wave is polarized such that $E_{0\alpha}=E_{0\beta}=(\sqrt{2}/2)E_0$. The patterns in the critical cones are taken from Fig. 7. Patterns at $\alpha=\alpha_{01}$ are shown multiplied by a factor of two.

the coefficients for $p\neq q$ are given by

$$a_p^{e}Je_p^{2}Se_p^{\beta}=\frac{2v_1Se_p^{v_0}}{He_p^{(2)}}F_e(c, v_0, \beta), \quad p\leq N, \quad (28a)$$

$$a_p^{o}Jo_p^{2}So_p^{\beta}=\frac{2v_1So_p^{v_0}}{Ho_p^{(2)}}F_e(c, v_0, \beta), \quad p\leq N, \quad (28b)$$

while that for $p=q_e$ is given by

$$a_{q_e}^{e}\frac{Se_{q_e}^{\beta}}{N_{q_e}^{e}}=-i\frac{Ne_{q_e}}{Se_{q_e}^{v_0}}F_e(c, v_0, \beta), \quad q_e\leq N, \quad (29a)$$

and that for $p=q_o$ is given by

$$a_{q_o}^{o}\frac{So_{q_o}^{\beta}}{N_{q_o}^{o}}=-i\frac{No_{q_o}}{So_{q_o}^{v_0}}F_e(c, v_0, \beta), \quad q_o\leq N, \quad (29b)$$

where $Se_{q_e}^{\beta}$ represents $Se_{q_e}(c, \cos\beta)$, $Se_{q_e}^{v_0}$ represents $Se_{q_e}(c, \cos v_0)$, etc., and where the elliptic conical pattern factor is given by

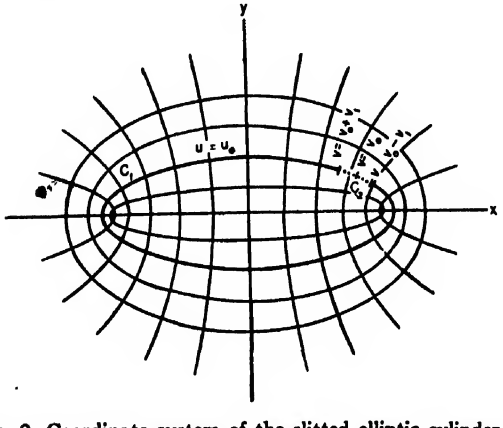

FIG. 9. Coordinate system of the slitted elliptic cylinder. The cylinder is defined by $u=u_0$ with distance between foci $2c_0$. A single slit is located at $v=v_0$ with angular width $2v_1$.

$$F_e(c, v_0, \beta)=\sum_{n=0}^{N} i^n\left(\frac{Se_n^{\beta}Se_n^{v_0}}{N_n^{e}He_n^{(2)}}+\frac{So_n^{\beta}So_n^{v_0}}{N_n^{o}Ho_n^{(2)}}\right). \quad (30)$$

The coefficients a_n^{e*} and a_n^{o*} for TE modes are obtained from those for TM modes by replacing the radial functions by their derivatives in Eqs. (28) to (30).

The fields in the cylinder at the critical angles ${}_e\alpha_{qm}$ and ${}_o\alpha_{qm}$ are the ordinary wave-guide modes in the elliptic wave guide.[13] At all angles other than the critical angles the fields vanish according to Eq. (28). The elliptic conical pattern factor in a plane normal to the axis is the same as that derived by Sinclair[14] and Carter[15] for the two-dimensional TE case. Since the incident angle α appears in the pattern factor only in the product $c=kc_0\sin\alpha$, the pattern in any cone $\alpha=\alpha_0$ about a cylinder $u=u_0$ whose distance between foci is $2c_0$ is the same as the pattern in a plane normal to the axis of a cylinder $u=u_0$ whose distance between foci is $2c_0\sin\alpha_0$.

The transition to the circular case follows as the limit when $c_0\to 0$ and $u\to\infty$, for then $c_0\cosh u\to r$. The solution for the elliptic cylinder then goes over to that for the circular cylinder.

Frequency Factor and Activation Energy for the Volume Diffusion of Metals*

G. J. DIENES
Atomic Energy Research Department, North American Aviation, Inc., Los Angeles, California
(Received May 12, 1950)

The theoretical equations proposed for calculating D_0 of the diffusion-constant-temperature relation

$$D=D_0e^{-E/RT}$$

are critically discussed in the light of presently available data. It is concluded that none of the relations gives satisfactory agreement with experiment.

Empirical analysis of experimental data covering a wide range of D_0 and E values showed that the quantity E/T_m, where T_m is the melting point in °K, is the main factor in determining the value of D_0, and that D_0 depends approximately exponentially on E/T_m. In addition to many other diffusion constants, it is shown that the anisotropic diffusion of zinc and the widely differing diffusion constants for self-diffusion in α- and γ-iron are included in the proposed empirical correlation.

A possible theoretical basis for the empirical correlation is described based on the idea of local melting or disordering. The quantity E/T_m is identified with the entropy of activation.

I. INTRODUCTION

IT is well known that the temperature dependence of diffusion can be well described by the simple exponential relation

$$D=D_0e^{-E/RT}, \tag{1}$$

where D=diffusion constant; D_0=constant, same dimensions as D; E=activation energy; R=gas constant; T=temperature in °K. Many attempts have been made to derive theoretical or semi-empirical expression for D_0, the so-called frequency factor. Recently, sufficient data on volume diffusion have become available to judge critically the validity of these equations.[1]

It may be pointed out that investigations over the last ten years or so have shown very clearly that the diffusion constant as well as the activation energy is a function of the concentration in most intermetallic systems. The importance of proper thermodynamic treatment has been emphasized (use of activities in place of concentrations). A review by A. D. Le Claire[2] summarizes well our present state of knowledge, and it is clear that the corresponding D_0 of such systems is not yet amenable to theoretical analysis. Any relation proposed for D_0, therefore, should be tested by comparison with self-diffusion data and with intermetallic diffusion data obtained at very low concentrations and far below the solubility limits so that concentration dependence is negligible. Since grain boundary and surface diffusion present special problems, the present discussion will be limited to volume diffusion.

It should also be remarked that evaluation of D_0 should not be tested by comparing experimental and calculated values of the activation energy, E. Such a calculation is found to be quite insensitive to the value of D_0 chosen because of the masking effect of the exponential factor in Eq. (1). D_0 values now known cover a sufficiently wide range for proper comparison of any proposed relation with experiment.

Table I is a summary of proposed theoretical and semi-empirical relations. (For notation, see headings of Table II.) In the third column the implied linear functional relations are also indicated. Leichter[3] has pointed out that only the Langmuir-Dushman[4] equation and the relation proposed by him predict the right order of magnitude for D_0. This conclusion is based on a few self-diffusion studies.[5] It is probably far more important, however, that none of the relations listed in Table I predict the correct functional dependence. Sufficient data are given in Table II for systems of known self-diffusion to verify this statement by simply plotting the data according to column three of Table I. Among others, glaring examples of deviations may be found in the anisotropy of Zn and in the self-diffusion of iron in the α- and γ-phase.[5]

Bradley's[6] relation comes closest to showing a correlation provided the relation between D_0 and Evd^2/T_M (where T_M is the mean temperature of the experiment) is taken to be an exponential rather than a linear one. It will become clear from later discussion in this paper that the above is to be expected for the simple reason that T_M is usually not too far removed from the melting point.

II. EMPIRICAL CORRELATION

The discussion given so far indicates that no suitable expression exists (theoretical or empirical) for relating D_0 to, and for calculating it from, other physical quantities. An analysis of presently available experimental data was undertaken in order to find out whether it is possible to abstract from the data themselves the physically significant quantities which determine D_0. Guided by the often proposed idea of melting, or disorder, as an important factor in diffusion, it was empirically discovered that the physically important quantity is

$$E/T_m,$$

where E=activation energy; T_m=melting point in °K. This conclusion is based on the data given in Tables II and III. An attempt was made to include all reliable diffusion data within the restrictions discussed in the introduction. In cases where several different values are available, Smithell's judgment has been accepted in most cases as to reliability (as given in his tables).[1] It was found that good correlation is obtained over a wide range of D_0 values by plotting $\log(D_0/\nu d^2)$ or $\log(D_0/\nu\lambda^2)$ against E/T_m. The best correlation appears to be given by $\log(D_0/\nu\lambda^2)$ *vs.* E/T_m. The possibility of a close relation between E and T_m for self-diffusion has been discussed by many workers.[7] It is to be emphasized that the present discussion is concerned with the relation between D_0 and the above quantities, rather than the possible interrelation of E and T_m.

The results are shown in Fig. 1, where $\log(D_0/\nu\lambda^2)$ is plotted against $E/2.303RT_m$ for all the items of Table II and III. Several values are available for Cu with three typical ones given in Table II. All of these fall along the correlation curve and furnish no judgment as to the best values for this material. This is probably due to compensating errors in E and D_0 in the various experimental data. In Table III all physical constants refer to the solvent atoms. This is obviously incorrect in the immediate neighborhood of a solute atom but no data are available for more accurate analysis. These variations must be minor, however, relative to the exponential influence of E/T_m. Within the experimental reliability of D_0 values the correlation is seen to be a very good one and covers a D_0 range from about 10^{-9} to 10^{+4} and activation energies from 8 to 140 kcal./mole. This curve clearly establishes E/T_m as the main factor which determines the value of D_0. However, since the influence of this factor is approximately an exponential

one, more subtle differences, specifically the relation of D_0 to lattice parameters, are extremely difficult to determine until a large amount of considerably more accurate experimental information is available.

The correlation is seen to be non-linear, except perhaps over the middle range, where a line of slope 1, indicated by the broken line, may be drawn. Over the linear range D_0 may be expressed as

$$D_0 = \nu\lambda^2 K e^{E/RT_m} \qquad (2)$$

with $K = 10^{-6}$. Since the linear form is valid only over a limited range, no physical significance can be assigned to the value of K.

It is to be noted that the anisotropy of Zn is properly taken care of in this correlation.* Furthermore, self-diffusion in α- and γ-iron also fits into this scheme provided the transition point between the two phases is accepted as the melting point of α-iron. This choice is not unreasonable in view of the fact that such a transition involves a great loosening of the lattice over the transition range of temperatures. Bismuth, which also shows anisotropic diffusion,[8] has been left out of Table II and Fig. 1. Available data on Bi are very approximate.[8] In the direction perpendicular to the C axis, a tremendously high D_0 was obtained ($\sim10^{47}$), which can be fitted in approximately with the present correlation. In the parallel direction a low D_0 is obtained ($\sim10^{-3}$) and the corresponding activation energy appears to be much too high. This point would fit very poorly on Fig. 1; but, because of the large scatter in the

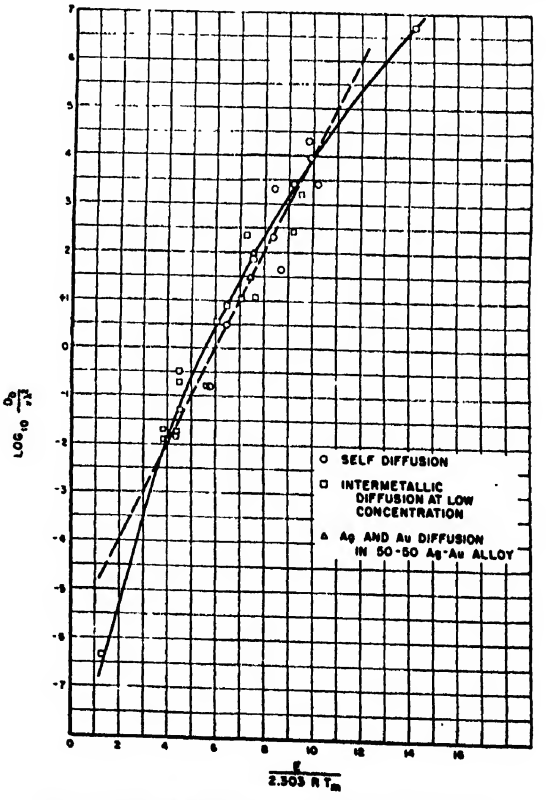

FIG. 1. Correlation of frequency factor with E/T_m.

* The Debye temperature given in Table II for Zn is an average value and, in the absence of better information, the same value was used for both directions. The characteristic temperature is unlikely to deviate by more than 30–40 percent from the average owing to anisotropy. This would have a negligible influence on the results since the frequency factors differ by more than a factor of 10.[3]

[8] W. Seith, Zeits. f. Elektrochemie 39, 538 (1933). See also R. F. Mehl, Trans. A.I.M.E. 122, 11 (1936).

data, it cannot be concluded that Bi is an exception to the correlation presented here. More experimental data on diffusion anisotropy as well as on the influence of phase changes (analogous to iron) would be very helpful.

It may be of interest also to note that Johnson's[9] values for the self-diffusion of silver and gold in a 50:50 AgAu alloy fall along the correlation curve.

III. THEORETICAL CONSIDERATIONS

It has been shown in the preceding sections that, empirically, the frequency factor, D_0, depends roughly exponentially on a definite fraction of the activation energy determined by the melting point. It is natural to look, therefore, for local melting, or disordering, as the elementary activation step. Such a proposal has been made by Mott[10] recently in connection with creep at low stresses. It appears that a similar picture may be applicable to diffusion. Let us assume that the elementary activation step is the disordering or melting of a small group of atoms by thermal fluctuations at a temperature T, which is below the melting point T_m, and let us assume that this small group of atoms may be treated thermodynamically. The free energy per atom necessary to produce this local melting, or disordering, may be written

$$\Delta F' = \Delta H' - T\Delta S' \tag{3}$$

with $\Delta F'$ equal to zero, at the melting point, T_m. Then

$$\Delta S' = \Delta H'/T_m. \tag{4}$$

The free energy of activation may be assumed to be proportional to $\Delta F'$ (the proportionality constant depending on the number of atoms involved),[10] i.e.,

$$F = \alpha\Delta F' = \alpha\Delta H' - T\alpha\Delta H'/T_m \tag{5}$$

or in the usual notation

$$F = E - TE/T_m, \tag{6}$$

where E/T_m represents the entropy of activation. Following reaction rate theory,[11] the expression for the diffusion constant D may be written

$$D = D_0 e^{-E/RT} = \beta e^{E/RT_m} e^{-E/RT} \tag{7}$$

which is of the same form as the empirical equation valid over the linear range of Fig. 1. D_0 is identified with

$$\beta e^{E/RT_m},$$

where $\beta = K\nu\lambda^2$.

Thus, it is possible to lend some theoretical support to the empirical analysis presented in this paper.

It may be added that Eq. (7) has no physical meaning for $T > T_m$. At $T = T_m$

$$D = D_m = K \cdot \nu\lambda^2. \tag{8}$$

The analysis presented here states, therefore, that melting temperatures represent equivalent states for comparison of diffusion processes. Physically, it is far more reasonable to compare diffusion constants, and to relate them to lattice parameters, at the melting point rather than at $T = \infty$ as implied by the use of D_0. It would be desirable, of course to know accurately the lattice parameters at the melting point.

Another feature of the picture presented here may be pointed out qualitatively. Experimental results up to date indicate[2] that the activation energy for the diffusion of any metal A in dilute solution in another metal B is always less than the activation energy for self-diffusion in B. Johnson[9] has pointed out that the hole mechanism of diffusion is apparently unable to account for this trend and proposed that diffusion takes place via the motion of substituted atom-hole complexes. This suggestion has been criticized by Frenkel[12] as being improbable.

The picture of diffusion presented here can explain the above phenomenon qualitatively. The free energy of activation in Eq. (5) may be lowered either by decreasing α, i.e., the size of the region to be melted, or by decreasing the heat of fusion, $\Delta H'$. It seems unlikely that α would be changed appreciably. The heat of fusion, however, may be lowered considerably even in a dilute solution of A in B, since it is precisely around an atom of A that local melting must occur, and the concentration of A in the small group of B atoms may be quite high. Some change in the melting point is also to be expected modifying somewhat at the correlation of Fig. 1. The wide applicability of this correlation shows, however, that the important change must be in the activation energy. No quantitative results can be given at this time.

With the importance of melting characteristics, as related to diffusion, empirically established, it seems likely that considerable further theoretical progress may be made by a careful investigation of melting and local disorder phenomena. Modern theories of melting and fluctuation phenomena should form a convenient starting point.

Note added in proof: Since this paper was written, the author's attention has been called to a recent paper by C. F. Birchenall and R. F. Mehl, Trans. A.I.M.E., 188, 144 (1950), in which new data are given for self-diffusion in α- and γ-iron which supersede entirely their previous results (Reference 5). These new data fit into the correlation scheme presented here and do not change the conclusions given in the text. As a matter of fact, since the activation energies for the two phases are now practically identical, the explanation in terms of melting points may acquire added significance.

Letters to the Editor

Thorium Sulfide as a Thermionic Emitter

T. E. HANLEY
Naval Research Laboratory, Washington, D. C.
June 28, 1950

IN a recently declassified AEC report[1] it is stated that sulfides of thorium, particularly ThS, have high resistance to thermal shock and are "more resistant toward metals than the oxides." In addition, ThS has an electrical conductivity of $10^{-1}\Omega$ cm and "is as non-volatile as the most refractory oxides." In view of these characteristics it was of interest to investigate the possibility of using ThS as a thermionic emitter.

A sample of this material was obtained through the AEC. A coating bath was set up in order to obtain uniform coatings. The bath was prepared by ball-milling (Pyrex balls in Pyrex container) 5 g of ThS with a mixture of 50 ml of methanol and 50 ml of acetone. This combination when used as a coating bath with a nickel anode would put a 0.001-in. coating on a 0.0005-in. wire in 10 sec. at 50 v and an initial current density of 40 ma/cm^2.

The temperature scale for ThS was obtained by heating a ThS-coated 0.002-in. molybdenum cylinder (o.d. = 0.125 in., $L = 3.5$ in.) in vacuum. The brightness temperature was measured on the outer coated surface, while the true temperature was obtained by sighting the optical pyrometer on a 0.30-in. hole in the cylinder. The measurements give a spectral emissivity of 0.4 for ThS.

The thermionic emission data were taken using coated 0.005-in. tungsten wires in a guard ring diode structure. The Richardson constants of the material are approximately $\Phi = 3.4$ ev and $A = 100$ amp./cm^2/deg.^{2}. In the vicinity of 1500°C Br the emission from ThS is only one-fourth as great as that from thoria (ThO_2).

Some measurements were also made to determine the rate of evaporation of this material by measuring the loss of weight from a uniformly coated tungsten strip which was held at a known temperature for a given length of time in vacuum. These measurements indicate a vapor pressure of 10^{-3} mm Hg at 1870°C Br whereas the previously mentioned report[1] gives the vapor pressure as less than 10^{-3} mm Hg at 2200°C. Perhaps comparison of these data is not in order, since the conditions of the measurements for the values given in the AEC report are not stated.

On the Fredrickson-Eyring Theory of the Mechanical Behavior of Metals*

J. FLEERMAN† AND G. J. DIENES
Atomic Energy Research Department, North American Aviation, Inc., Downey, California
August 28, 1950

IT is generally felt that a unified theory of the mechanical behavior of metals must be based upon a dynamical theory since it is well known that the results of a stress-strain experiment depend markedly upon the time scale of the experiment. The first serious attempt to formulate a dynamical theory of the behavior of metals is due to Fredrickson and Eyring.[1] We shall refer to this paper as FE. It is the object of this letter to discuss some of the implications of their theory.

FE have used the method of the statistical rate theory of processes to formulate a theory of the mechanical behavior of metals. The behavior of the fundamental unit of dashpot and spring is determined by the differential equation

$$d\epsilon/dt = (1/g_i)(d\sigma/dt) + k_i \sinh\alpha_i\sigma, \qquad (1)$$

where σ and ϵ are the stress and strain, respectively, g_i is the spring constant of the ith element and, k_i and α_i are the viscosity parameters determined by way of a quantity β_i. The first term on the right-hand side of the equation describes the elastic properties of metals according to Hooke's law; the last term describes the flow properties according to the Eyring theory of viscosity. As a model used to interpret a stress-strain curve, FE use the combination of springs g_1, g_2, and g_3 and dashpot elements β_1 and β_2 in the form of Maxwell elements coupled in parallel. The spring g_1 and dashpot β_1 combine to form unit one, unit two consists of the spring g_2 and dashpot β_2, unit three is the spring element g_3 alone. FE have applied the results of their analysis to determine the equation for a loading curve obtained with a constant rate of straining.

To test the generality of this dynamical theory we have used Eq. (1) to calculate an unloading curve and (what turns out to be more interesting) a reloading curve calculated from the assumption that the material is reloaded immediately after unloading. The problem of strain relaxation, or recovery, at zero load is discussed separately under several simplifying assumptions.

With the test material loaded to a stress $\sigma_0^{(1)}$ at a strain $\epsilon_0^{(1)}$ under the conditions of a constant strain rate $\dot{\epsilon}$ the unloading curve can be evaluated by solving Eq. (1) subject to the initial condition $\sigma^{(1)} = \sigma_0^{(1)}$ at $t = 0$. We get

$$\sigma^{(1)} = \sigma_0^{(1)} - \frac{1}{\alpha}\ln\left\{\frac{1+\left[1+\dfrac{\exp(\alpha\sigma_0^{(1)})}{\beta}\right]\tanh\left[\dfrac{\alpha g}{2}(\epsilon_0^{(1)}-\epsilon)\right]}{1-\tanh(\alpha g/2)(\epsilon_0^{(1)}-\epsilon)}\right\}. \qquad (2)$$

The unloading curve for each unit of the Maxwell representation is calculated from Eq. (2) to a value of zero stress for the entire model. It turns out that after unloading the first unit is in a state of compression while the second and third units are in extension.

Similarly, the reloading curve can be determined from Eq. (1) using the initial condition that at $t = 0$, $\sigma = \sigma_0^{(2)}$, where $\sigma_0^{(2)}$ can be positive or negative depending upon whether it refers to unit one or two. We get

$$\sigma^{(2)} = \sigma_0^{(2)} + \frac{1}{\alpha}\ln\left\{\frac{1+\left[1+\dfrac{\exp(-\alpha\sigma_0^{(2)})}{\beta}\right]\tanh\left[\dfrac{\alpha g}{2}(\epsilon-\epsilon_0^{(2)})\right]}{1-\left[1-\dfrac{\exp(\alpha\sigma_0^{(2)})}{\beta}\right]\tanh\left[\dfrac{\alpha g}{2}(\epsilon-\epsilon_0^{(2)})\right]}\right\}. \qquad (3)$$

We have calculated the unloading and reloading stress-strain curves for SAE 1020 steel according to Eqs. (2) and (3), respectively,

1. at $T = -70$°C and a strain rate of 5×10^{-5} sec.$^{-1}$,
2. at $T = -70$°C and a strain rate of 500×10^{-5} sec.$^{-1}$,
3. at $T = 100$°C and a strain rate of 5×10^{-5} sec.$^{-1}$,

where we have assumed the material has been loaded to a value of true strain equal to 0.5 and then unloaded.

The results of these calculations are shown in Fig. 1. It will be noted that in all cases the reloading curve rises appreciably above the initial loading curve for equivalent values of strain. It appears that the model predicts too much strain hardening.[2]

It is important to determine the magnitude and rate of strain recovery to be expected from the FE theory. Such a calculation is to be carried out via Voigt-type of mechanical model representation. However, as a result of the non-linear character of Eq. (1), the equations which arise in the transformation of a Maxwell representation to a Voigt representation are too complex to interpret in a simple manner. In order to make an estimate of the relaxation time we have replaced the non-linear viscous element in the Maxwell representation by an equivalent Newtonian viscous element η. If we choose the viscosity η to be given by the equation

$$\eta = 1/\alpha k, \qquad (4)$$

then the relaxation time which is calculated will always be a time that is greater than any relaxation time obtained from the FE theory. Furthermore, it can be shown that another simplification which may be made, without appreciably influencing the results is the following: letting $g_1 = 0$ in the Maxwell representation renders the equivalent Voigt representation, consisting of springs

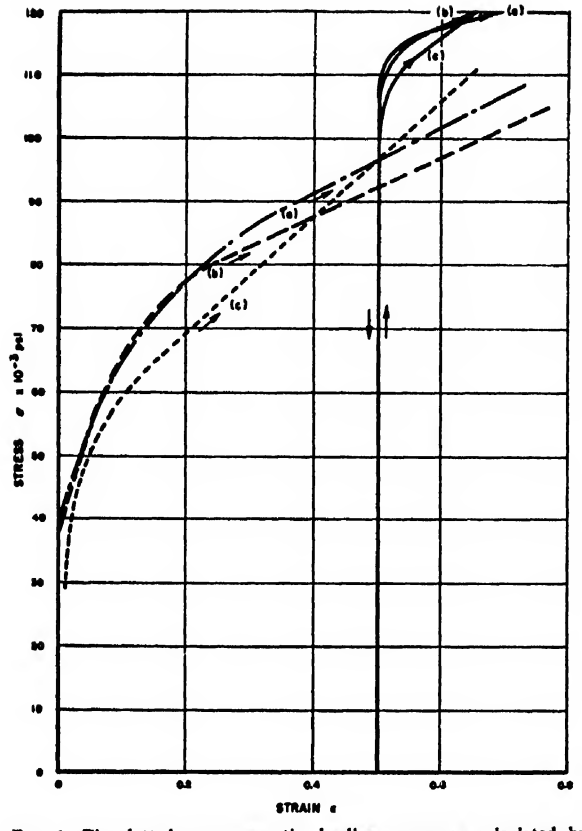

FIG. 1. The dotted curves are the loading curves as calculated by Fredrickson and Eyring. Curve (a) computed for $T=-70°C$ and $\dot{\epsilon}=500\times10^{-6}$ sec.$^{-1}$, curve (b) computed for $T=-70°C$ and $\dot{\epsilon}=5\times10^{-6}$ sec.$^{-1}$, curve (c) computed for $T=100°C$ and $\dot{\epsilon}=5\times10^{-6}$ sec.$^{-1}$. The solid curves are the unloading and reloading curves computed from a strain $\epsilon=0.5$ as discussed in the text.

g_1' and g_2' and Newtonian viscous elements η_1' and η_2' easily manageable.

Using the method outlined, we have calculated the maximum relaxation time for SAE 1020 steel at $T=-70°C$ and $\dot{\epsilon}=5\times10^{-5}$ sec.$^{-1}$ to be 2.6 days and 2.2 hours for the two units which appear in the Voigt representation. It is evident that strain relaxation is going to take place at a rate far greater than experimentally expected for steel in a temperature range where plastic deformation should be essentially permanent.[3]

Thus, upon the basis of calculations presented here, we conclude that the FE dynamical theory of the mechanical behavior of metals has inherent within it the following characteristics:

1. It predicts too much strain hardening.
2. It predicts a relaxation time for deformation recovery which is much too small and consequently it fails to account for the permanent deformation in steel in the temperature range $-70°C$ to $100°C$.

Base-Metal Effects in Thoria-Coated Filaments

HERBERT NELSON
Tube Department, Radio Corporation of America, Harrison, New Jersey
August 11, 1950

THE thoria-coated filament has shown promise of meeting the demands for a thermionic source supplying long-life emission at high current densities and voltages better than does either the barium-strontium oxide-coated cathode or the thoriated tungsten filament. Investigation of the properties of this new type filament has therefore appeared fruitful and has been carried out in various laboratories of the RCA organization. The purpose of the present communication is to summarize briefly some of the results obtained in the part of this investigation which has had to do with base-metal effects. Adherence of the thoria to the metal base, ease of thermionic activation, and level of thermionic emission reached have been studied as a function of base material.

With regard to adherence, a problem is created as a result of the rather large difference in thermal expansion between thoria and the refractory metals suitable for base material. The coefficient of thermal expansion for thoria[1] is 11.3×10^{-6}, while for W, Mo, Ta, and Pt, the values are 4.2, 4.9, 7.0, and 9.0×10^{-6}, respectively. On the basis of these figures it is to be expected that adherence is best with Pt and poorest with W. Experimental work has shown the foregoing to be true. Adherence was found poor with W, fair with Mo, good with Ta, and excellent with Pt. With Ta, layers of thoria as thick as 3 mils (45 mg/cm^2) were found to adhere to the end of 3000-to-4000-hour life tests conducted in diodes. With W, on the other hand, even very thin layers (8 mg/cm^2) did tend to chip off at the very beginning of life tests. With Mo, chipping difficulties were also encountered though filaments with as much as 20 mg/cm^2 of thoria were operated successfully on life for as long as 2000 to 3000 hours.

Though, as suggested above, the better match in thermal expansion may account for the superior adherence to Pt and Ta, it is also possible that the relatively high ductility of these metals at operating temperatures may be a contributing factor.

Since it seems reasonable to expect that for low work function, thoria, like BaSrO, depends upon a stoichiometric excess of metal in the crystal lattice, tests were made to determine whether the base metal, as a reducing agent, has an effect upon the ease of activation of thoria-coated filaments. For this purpose four tubes were constructed identical in all respects except that two were made with a base material of Ta while the other two were made with Pt. The tubes were exhausted and processed in identical fashion, the electron emission being determined as a function of the filament temperature during the initial glowing. The results obtained are shown in Fig. 1, curves *A* and *B* expressing the temperature-electron emission relation for thoria on Ta and Pt, respectively. The fact that high thermionic activity is reached at

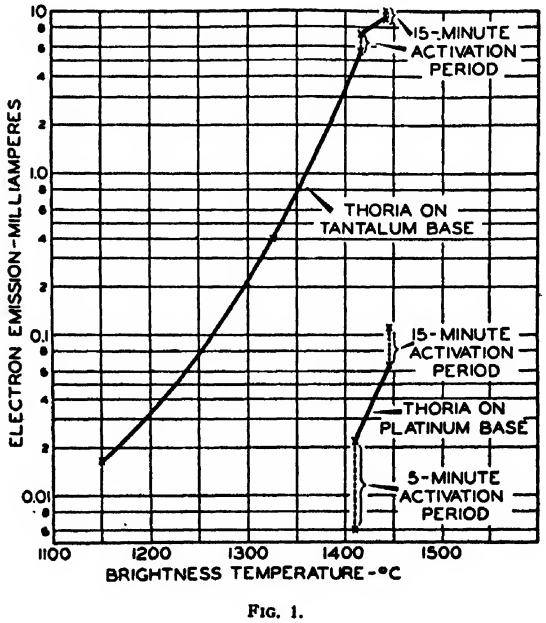

FIG. 1.

a greatly lower temperature with Ta, a good reducing agent, than with Pt, a poor reducing agent, is consistent with the view that a low work function of thoria is associated with a stoichiometric excess of metal in the crystal lattice.

When Mo, W, or Ta is used as base material, roughly the same maximum space-charge-limited emission, about 5 amp./cm², is obtained at 1900°K B.T. At lower temperatures, however, higher values are invariably obtained with Mo than with Ta. At 1800°K B.T., for instance, the average emission with Mo was found to be equal to 3.1 amp./cm², while the average with Ta was found to be 2.0 amp./cm². No explanation has as yet been found for this superiority of Mo at low temperatures.

Acknowledgment is made to the following members of the RCA organization who have made fundamental contributions to the development of the thoria-coated filament: Dr. Lloyd Garner, Dr. Philip Smith, and Mr. M. N. Fredenburgh

Erratum: The Mechanical Properties of Glass

[J. App. Phys. 13, 623–634 (1942)]

F. W. Preston
The Preston Laboratories, Butler, Pennsylvania

On p. 631 there is an error in the caption for Fig. 5. The limiting velocity of the propagation of cracks should be 5080 ft./sec., rather than 3 miles/sec. as stated.

A similar error occurs on p. 624, in which the velocity of sound in glass should be approximately 1 mile/sec., instead of 3 miles/sec.

Scheme for Analyzing Capillary Measurements on Non-Newtonian Liquids

Orrin H. Clark and M. L. Deutsch
Socony-Vacuum Laboratories, Research and Development Department, Paulsboro, New Jersey

August 11, 1950

It has kindly been pointed out by Mr. A. B. Bestul that the formulas for analyzing non-Newtonian capillary flow given in our recent paper, "Scheme for analyzing capillary measurements on non-Newtonian liquids,"[1] were developed by B. Rabinowitsch, "Über die Viskosität und Elastizität von Solen,"[2] and have since been referred to in various other journals. The absence of these useful equations from such a book as Green's *Industrial Rheology and Rheological Structures* is surprising and led to the regrettable submission by us of their derivation as original material.

[2] B. Rabinowitsch, Zeits. f. physik. Chemie A145, 1–26 (1929).

Original Authorship of Formulas Given in Clark and Deutsch's Paper

M. Reiner
Institute of Technology, Haifa, Israel
and
G. W. Scott Blair
National Institute for Research in Dairying, University of Reading, England

September 14, 1950

The fact that the paper by Clark and Deutsch in the July issue of your Journal (p. 713) was passed by your referee as describing "a powerful new scheme" shows that rheological literature is not as widely known as it should be. May we, therefore, as authors of textbooks on rheology in which the relevant papers are quoted (Scott Blair, 1938; Reiner, 1949) be permitted to point out that this method is due to Weissenberg and was first applied by B. Rabinowitsch (1929) for the case of the capillary viscometer, followed by Mooney (1931), who adapted it to the rotating cylinder instrument? Hersey (1932) named it the "differentiation method" because it applies differentiation to the observed consistency curve in order to find the rheological equation of the material, in contradistinction to the "integration method," where a rheological equation is assumed and the consistency curve derived by integration.

We do not doubt that Messrs. Clark and Deutsch derived their Eq. (12) independently, but it will be seen that it is identical with Eq. (9) of Hersey's paper.

Application of Liouville's Approximation to the Blind Navigation Problem

J. J. Gilvarry and S. H. Browne*
The Rand Corporation, Inc., Santa Monica, California

September 8, 1950

In a recent paper[1] in this journal, it has been shown that the problem of determining a vehicle's position vector $\mathbf{r}$ from the reading $\mathbf{b}(t)$ of an accelerometer as a function of time t is equivalent to solving the differential equation

$$(d^2\mathbf{r}/dt^2)+\omega_0^2(R_0/R)^3(R_0\mathbf{k}+\mathbf{r})=\mathbf{b}(t), \tag{1}$$

where R (with initial value R_0) is the vehicle's radial distance from the earth's center, $\mathbf{k}$ is a radial unit vector at the origin, and $\omega_0=(g_0/R_0)^{\frac{1}{2}}$ if g_0 is the gravitational acceleration at the initial point of motion. A case not treated in that discussion presents itself when the vehicle's altitude $h=R-R_0$ relative to the earth is available as a function $h(t)$ of time from continuous measurements made by an altimeter (of radar or atmospheric-pressure type). The quantity $h(t)$ is then an independently measured integral of the motion (thus the problem of determining position coordinates is actually overdetermined). In this case, Eq. (1) becomes

$$(d^2\mathbf{r}/dt^2)+\omega_0^2\Gamma(t)\mathbf{r}=\mathbf{b}(t)-g_0\Gamma(t)\mathbf{k}, \tag{2}$$

where

$$\Gamma(t)=[1+h(t)/R_0]^{-2}\sim 1-3h(t)/R_0, \tag{3}$$

and the approximation indicated in (3) is valid for $h\ll R_0$. Equation (2) is linear in the coordinates and, from the standpoint of computer design, presents definite advantages over the nonlinear Eq. (1).

Any numerical method of solving a linear differential equation of second order will serve as a computational method to determine $\mathbf{r}(t)$ from a given $\mathbf{b}(t)$ and $h(t)$, or, when suitably mechanized, will serve as the basis of a computer design. For numerical computation, however, the majority of such methods are not well adapted to equations of the type (2), where one term (the $\mathbf{g}$-term) is a slowly varying function, but another term (the $\mathbf{b}$-term) may show rapid variations in time. When applicable, though, Liouville's approximation[2] is well suited to problems of this kind, and this letter indicates briefly its application to (2). The approximation in question is known as the Wentzel-Kramers-Brillouin-Jeffries approximation in its application as an asymptotic approximation in quantum mechanics; more generally, it appears in connection with transformations and asymptotic developments of Sturm-Liouville systems.[3] It is ascribed to Liouville by Schelkunoff.[4]

The quantity Γ (which is always positive for $|h|<R_0$) is approximately unity except for the perturbing parameter $h(t)$. Under the transformation

$$t'=\int_0^t \Gamma^{1/2}(\sigma)d\sigma, \quad \mathbf{r}'=\mathbf{r}\Gamma^{1/4}(t), \tag{4}$$

Eq. (2) yields the approximation

$$(d^2\mathbf{r}'/dt'^2)+\omega_0^2\mathbf{r}'=\Gamma^{-3/4}(t)\mathbf{b}(t)-g_0\Gamma^{1/4}(t)\mathbf{k}, \tag{5}$$

provided the first and second derivatives of $h(t)$ are sufficiently small so that

$$\Gamma^{-3/4}(d^2\Gamma^{-1/4}/dt^2)\ll\omega_0^2, \tag{6}$$

and hence the term $\Gamma^{-3/4}(d^2\Gamma^{-1/4}/dt^2)\mathbf{r}'$ can be neglected in (5). When the right-hand side of Eq. (5) is considered a function $\mathbf{b}'$

of t', the equation is linear with constant coefficients in the reduced variables t', r'. The explicit solution for r then follows directly as

$$r=(v_0/\omega_0\Gamma^{1/4})\sin\left[\omega_0\int_0^t\Gamma^{1/2}(\sigma)d\sigma\right]+\frac{1}{\omega_0\Gamma^{1/4}}$$
$$\times\int_0^t\left[\frac{b(\tau)}{\Gamma^{1/4}(\tau)}-g_0\Gamma^{3/4}(\tau)k\right]\sin\left[\omega_0\left(\int_0^t\Gamma^{1/2}(\sigma)d\sigma-\tau\right)\right]d\tau, \quad (7)$$

under the initial conditions $r_0=0$ and $(dr/dt)_0=v_0$. In actual application, Γ in (7) can usually be replaced by the approximation indicated in (3).

Equation (7) yields a convenient solution for numerical computation, since the solution is reduced to quadratures which can be carried out by the trapezoid or Simpson's rule (the sine function under the integral sign must be expanded by the addition theorem). To apply the method over an extended interval (over which the effect of the neglected term in Eq. (5) may be significant), one can use (7) as the step solution in the method of "linear continuation" described in the previous paper.[1] Alternatively, Schelkunoff's "wave perturbation" method[4,5] (with a slight modification for the presence of a forcing function) may be used; this method is based on Liouville's approximation, but defines the final solution as the limit of an iterative process over the over-all interval.

Natural Crystal Greenockite (Cadmium Sulfide) as an X-Ray Detector

E. L. Criscuolo and D. T. O'Connor
U. S. Naval Ordnance Laboratory, Silver Spring, Maryland
September 8, 1950

RECENTLY,[1] artificially produced cadmium sulfide crystals have been described as sensitive x-ray detectors. Previous work described in the literature[2] refers to artificial cadmium sulfide crystals.

Natural greenockite crystal fragments of the order of 1 mm³ have been observed to pass direct currents up to 1×10^{-8} amp. in a 100-kv x-ray beam of an intensity of 4 roentgens per minute. This rough measurement was made using a micro-ammeter and a collecting battery voltage of 22 volts. Four samples gave similar results; they were light-sensitive and non-luminescent.

The mineral specimen was obtained from the Smithsonian Institute through the courtesy of Dr. W. F. Foshag, Chief of the Division of Mineralogy and Petrology, and Dr. R. Kellogg, Director.

Measurements on the Diffusion of Interstitial Atoms in B.C.C. Lattices*

C. A. Wert
Institute for the Study of Metals, University of Chicago, Chicago, Illinois
August 14, 1950

THE alloys of interstitial dissolved atoms in the b.c.c. lattices offer the possibility that one can make extremely accurate measurements of the rate of diffusion of the solute atoms. This is so because the high temperature bulk diffusion measured by standard metallurgical methods can be extended to lower temperatures by measurements made on an atomistic scale by use of relaxation measurements. The diffusion of C in α-Fe offers an example of this technique. Stanley[1] measured the rate of diffusion in the range 500°C to 700°C. The author[2] measured diffusion in the range −35°C to +200°C. Together the data extend the knowledge of the diffusion coefficient over some 14 cycles of 10; this range is somewhat higher than has been done for any other system.

In an effort to extend this type of measurement to other systems, the author has made measurements of diffusion of C in Ta and Cb and of N in α-Fe. These measurements were made by two manifestations of the anelastic relaxation effects; the internal friction and the elastic aftereffect. The methods used are those described earlier.[2] The data are shown in Fig. 1. Here the diffusion

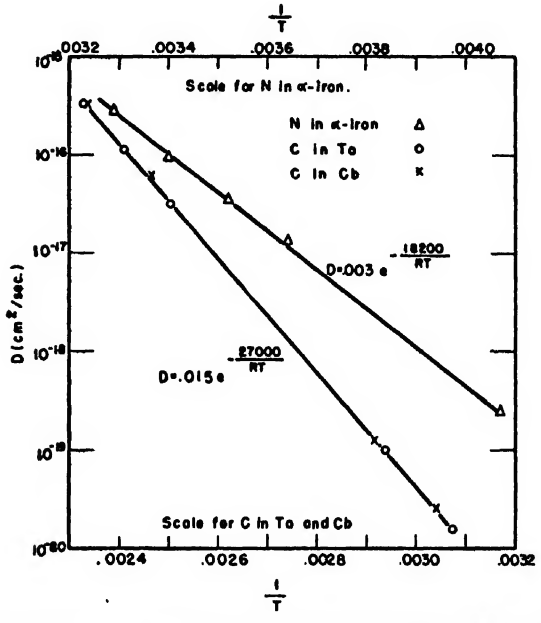

FIG. 1. Diffusion coefficient for C in Ta and Cb and N in α-Fe *vs.* $1/T$.

of N in α-iron and of C in Ta and Cb are seen to satisfy the well-known relation $D=D_0\exp(-H/RT)$. These data, of course, do not have the range quoted above for C in α-Fe; further measurements at much higher temperatures are needed for really accurate determination of D_0 and H.

An attempt to examine the various factors which make up D_0 has been made by Wert and Zener.[3] They expressed D_0 as

$$D_0=n\alpha a^2\nu e^{\Delta S/R}, \quad (1)$$

where n, α, and a^2 are geometrical constants for a given lattice, ν is the frequency of oscillation of a solute atom in an interstitial site, and ΔS an "entropy of activation." They found that if all of the activation energy for diffusion went into straining the lattice, then

$$\Delta S\approx -H(d\ln\mu/dT),$$

where μ is the shear modulus of the lattice. For simplicity one can rewrite this expression by defining $\beta=d(\mu/\mu_0)/d(T/T_m)$ obtaining

$$\Delta S\approx\beta H/T_m. \quad (2)$$

In this expression μ_0 is the modulus at $T=0$ and T_m is the melting temperature. β may be obtained for a large number of materials from some work of Köster.[4] For Ta and α-Fe the values of β are 0.40 and 0.43, respectively.

It follows from Eq. (1) that once D_0 is known from experiment, ΔS may be calculated. It is also true that if all the energy of activation goes into lattice strain energy, then ΔS is given by Eq. (2). A comparison of $\Delta S/R$ calculated by the two methods is given in Fig. 2. Here are shown data for C in α-Fe and Ta, N in

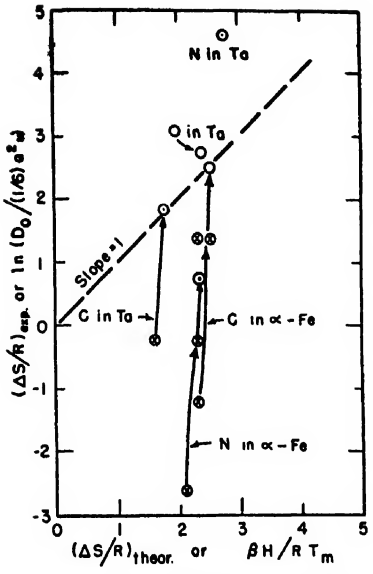

FIG. 2. $(\Delta S/R)$ as computed from Eq. (1) using diffusion experimental data *vs.* $\Delta S/R$ as computed from Eq. (2). For each material successive points are taken from the literature and the present letter as follows.

α-Fe and Ta, and O in Ta. The open circles represent the best data available at present; the other circles represent earlier data as given in the caption to Fig. 2. If $\Delta S/R$ computed by Eqs. (1) and (2) were identical, then all the points should lie on the dashed line. The trend of the measurements toward better agreement between $\Delta S/R$, as computed by the two methods, is quite apparent. This trend toward better agreement presumably results from the better values of D_0 obtainable by extension of the measurements over a wider range of temperature.

A Remark about Standardization and "A Dimensional Analysis of Metal Cutting" *

ANDRÉ MARTINOT-LAGARDE
Associate Professor of Mechanics of Fluids, Lille University, France
September 8, 1950

ANALOGOUS non-dimensional variables appear in both metal cutting and mechanics of fluids. Therefore, it seems convenient to choose exactly the same non-dimensional variables. For instance in mechanics of fluids $c\rho Vl/K$ (c specific heat, ρ mass density, V velocity, l length, K thermal conductivity) is called the "Péclet number." This note is to propose writing the same number for metal cutting, instead of its inverse, used by Drucker and Ekstein, and using the same designation also. The velocity indeed is the variable which varies the most frequently, and it is convenient that every non-dimensional variable be proportional to such a quantity.

* D. C. Drucker and H. Ekstein, J. App. Phys. **21**, 104–107 (1950).

Tearline Patterns in Ferrochromium

C. A. ZAPFFE AND F. K. LANDGRAF
Baltimore, Maryland
August 14, 1950

IN the course of studying fractographic patterns,* special formations have frequently been observed within the fracture traverse which are believed to relate to conditions of original crystal growth. Some suggestively similar patterns, however, are discussed from another viewpoint in the recent paper by Kies, Sullivan, and Irwin in this journal.[1] Their contribution is an important advance in the interpretation of fracture patterns, and specifically those previously classified as Type II expressing transient conformations of the fracturing stress.[2] It also focuses attention upon a principal current problem in the interpretation of certain fracture patterns—the distinguishing between Types I and II. Many fractographs, without possible question, reveal structural features of the solid; but others clearly refer only to stress. Because the correct identification often has important implications for theories of the solid state, several complex examples are submitted here, taken from a study of chromium-rich iron.

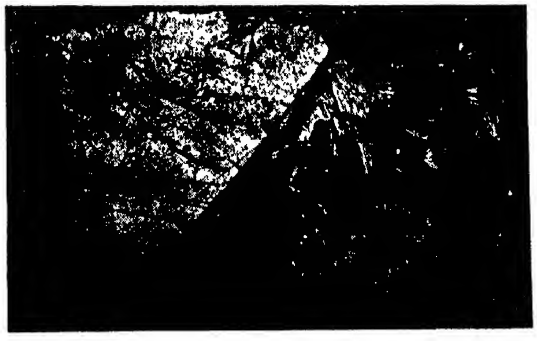

FIG. 1. Fractograph of ferrochromium containing 70 percent Cr and 0.05 percent C, showing a transition from transgranular to intergranular fracture traverse.

In Fig. 1, transgranular and intergranular fractures lie within the same general plane of focus. To the left of the diagonal boundary, fracture has followed a cleavage plane of the icositetrahedron {112}, displaying a relatively flat traverse with traces of intersecting planes which can be identified as also belonging to the icositetrahedral form. The traverse then shifts from a planar to a banal path along grain or lineage boundaries.

In Fig. 2 some of the fanlike forms visible on the banal traverse of the previous figure are shown in more detail. The condition here is particularly interesting because of an irregular boundary roughly bisecting the field. Patterns somewhat similar to these, as has been shown by Kies, Sullivan, and Irwin, can be obtained

FIG. 2. Intergranular surfacial detail in fractured 70 percent ferrochromium containing 0.17 percent C.

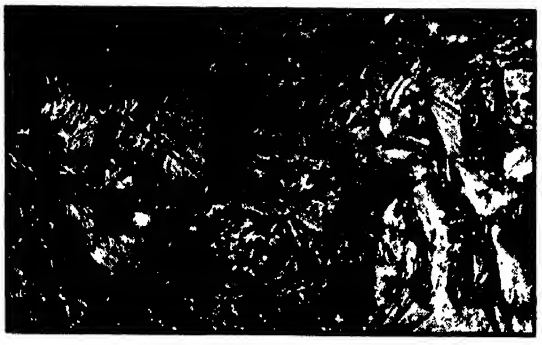

FIG. 3. Fractograph of ferrochromium containing 0.75 percent nitrogen, showing a boundary [lightly retouched for reproduction] which sharply separates the upper and lower halves of the field.

by special stress conformations during fracture of amorphous or rheologically isotropic bodies. However, solid metals show pronounced directionalism, both from crystal perfection and from crystal imperfection; and according to the theory advanced earlier in this study,[3] the present authors prefer the interpretation that these formations relate to original crystal growth in which clusters of molecules—"micelles"—have assumed a common orientation to provide the single grain, but have carried into the solid state certain aspects of their original micellar form and a general imperfection pattern of their cumulative mismatching. It is suggested that the grain under observation in Fig. 2 has grown from the lower right as the result of a commonly oriented accumulation of two major lineages and several minor ones. This growth then possibly halted along the observed boundary during solidification, beginning again with renewed nucleation, as indicated in the pattern. On the other hand, descriptions given by Kies, Sullivan, and Irwin are impressive in suggesting that at least a portion of this pattern might be Type II, the indicated nucleations being nucleations of fracture with or without further impression of imperfection structure.

In Fig. 3 a particularly puzzling pattern appears in which a boundary of the type in the previous figure delineates with sharp contrasts the upper and lower portions of the field. It is possible that elaborately complex stress formations during fracture approached simultaneously from above and below, meeting at the indicated boundary to form the observed pattern.

On the other hand, it is submitted as the preferred interpretation here that an unusual growth condition is being observed in which dendritic formations, separately nucleated in the liquid phase and growing with lineage characteristics, have approached from solidification directions above and below in the fractograph, the two masses mutually exhausting the remanent liquid phase as solidification progressed, producing thereby both the boundary and the branching fractographic forms.

Note on "Interference of Growing Spherical Precipitate Particles"

HERSHEL MARKOVITZ
Mellon Institute of Industrial Research, University of Pittsburgh, Pittsburgh, Pennsylvania
July 28, 1950

IN a recent article Wert and Zener[1] derived the differential equation

$$\tau dW/dt=(3/2)(1-W)W^{1/3}$$

to which a solution was desired with the condition that at $t=0$, $W=0$. An analytical integration of this equation is

$$\frac{t}{\tau}=\frac{2}{3}\left[\frac{1}{2}\ln\left(\frac{1+x+x^2}{(1-x)^2}\right)+\sqrt{3}\tan^{-1}\left(\frac{-x\sqrt{3}}{2+x}\right)\right],$$

where $W=x^3$. If various values of W are substituted, corresponding values of t can be obtained. As far as one can tell from their Fig. 3, this solution seems to lead to somewhat better agreement with the experimental results than the numerical integration performed by the authors.

Electron Microscopy of Wet Biological Tissues by Replica Techniques*

IRWIN W. FISCHBEIN
School of Forestry, University of California, Berkeley, California
(Received April 20, 1950)

The study of wet biological tissues *in situ* using the electron microscope was made possible by modifying existing replica techniques and developing a new wet replication method. The shortcomings of existing replica techniques are discussed and the modifications necessitated are described.

Replicas of wet tissues were produced in extremely thin polystyrene films which could be observed directly in the electron microscope; however, superior results were obtained by preparing silica replicas from the replicated polystyrene films. A modified two-replica silica method proved satisfactory but the three-replica silica method developed was preferable. Electron micrographs of wet wood fiber surfaces used to illustrate these techniques reveal new data concerning submicroscopic cell wall structure.

The problem of interpreting replicas of partially degraded and disorganized materials is illustrated and discussed briefly.

INTRODUCTION

THE successful application of a replica method for the electron microscopy of wet biological structures has not been reported although several replica techniques for dry organic materials have been described.[1–4] While some features of cell wall organization have been revealed by the application of replica methods to dry plant fibers, results in general have been quite unsatisfactory.[1,2] This was the experience in the present study after a survey of existing replica techniques. Failure to obtain satisfactory replicas was attributed in part to the plant tissue being thoroughly dry before embedding took place because plant cell walls are saturated with water in the natural state. Furthermore, it was reasoned that micellar systems in the swollen state would reveal more of their submicroscopic structural arrangement since the microinterstices are distended with water. Therefore, it was necessary to develop an effective wet replication method and at the same time to modify certain aspects of existing replica techniques.

SHORTCOMINGS OF EXISTING REPLICA TECHNIQUES

Gold-shadowed replicas of dry wood fiber surfaces formed by embedding with heat and pressure in thin polystyrene films,[3] or by casting thin films from Collodion[4] and Formvar[5] solutions, failed to show adequate fine structure and contrast. The exact reason for the thin-film replicas failing to show the desired fine structure and contrast is not clear. It may be due in part to improper gold-shadowing technique since varying the thin-film thickness did not affect the contrast conditions.

Because of the excellent contrast generally obtainable with silica replicas, the low pressure silica replica method developed by Barnes, Burton and Scott for the study of organic surfaces was tried.[1] In applying this method, the tissue surface was completely desiccated before replication took place. In addition, excessive destruction of the silica replica occurred during the washing procedure. This probably resulted from the prolonged and vigorous washing necessary for the complete dissolution of the 1-mil polystyrene film specified in the method. In the cases where intact replica film areas were obtained and observed in the electron microscope, the silica replicas failed to show

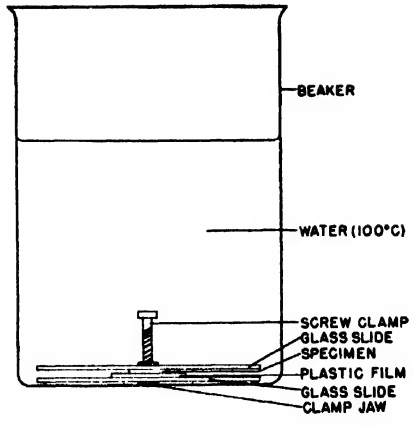

FIG. 1. Sandwiched replica unit with pressure applied submerged in a beaker of hot distilled water for wet replication.

the degree of fine structure to be expected but the contrast conditions were excellent.

The problem of desiccation of the specimen during replication was obviated by the introduction of a new wet replication method. The excessive destruction of the silica replicas during washing was circumvented by the use of extremely thin polystyrene films in the washing procedure and by the introduction of a different solvent and washing apparatus.

Certain shortcomings of the modified two-replica silica method developed in this study were overcome by the use of a third replica. The resulting three-replica silica method was found to be superior from the standpoint of ease of manipulation and of revealing fine structure.

THE WET REPLICATION METHOD

Satisfactory replicas of wood microtome sections, wood fibers, cambial cells and bacterial cells in the wet state were obtained by the following method:

1. The wet object to be replicated is placed on the replicating plastic which is sandwiched between two clean glass microscope slides. A few drops of distilled water are placed on the object before applying the upper glass slide.

2. Pressure is applied directly over the object by means of a medium-sized pinch clamp or Hoffman screw clamp.

3. The sandwiched unit with the pressure applied is completely submerged in a beaker of distilled water at 100°C. (See Fig. 1.) The correct amount of pressure to be applied by the screw clamp is readily attainable in a few trials. When too much pressure is applied, the glass slides crack during heating. The correct pressure is slightly less than that which will cause the glass slides to crack. If a medium-sized pinch clamp is used, this problem does not arise; however, the screw clamp is much easier to manipulate and gives more uniform pressure. The unit remains in the boiling water for approximately 7 minutes when polystyrene or polyethylene are the replicating plastics. The unit is then removed and allowed to cool to room temperature before releasing the pressure clamp.

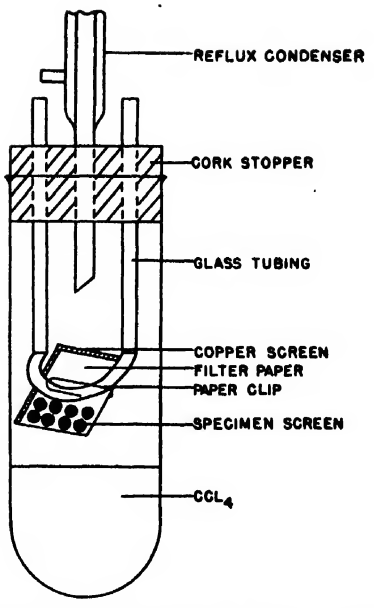

FIG. 2. Apparatus used to wash the polystyrene film from the silica replicas by solvent condensation.

4. The object is allowed to dry and is removed from the plastic replica by mechanical stripping with a tweezer or with a readily adhering pressure sensitive tape.

Although only the use of polystyrene and polyethylene are described in this paper for the initial replica, any plastic with a similar softening point and resistance to water absorption could be used.

A thin-film polystyrene replica made by the wet method in a polystyrene film cast on a glass slide from a 1 percent polystyrene solution in benzene showed more fine structure when gold-shadowed than one made by the dry method. However, the contrast and fine structure observed were much less than that obtainable by the silica methods.

MODIFIED TWO-REPLICA SILICA METHOD

The standard two-replica silica method[6] was modified in the following manner in order to obtain satisfactory silica replicas of wet tissues:

1. An extremely tenuous film is obtained on a clean glass microscope slide by dipping the slide into a 1 percent solution of polystyrene in benzene and allowing the slide to dry while held in a vertical position on a piece of paper toweling. A replica is produced in this thin film by the wet replication method.

2. The thin-film replica is cut into $\frac{1}{8}$-inch squares on the microscope slide with a scalpel or sharp knife and the replica squares are floated from the slide onto a

[6] C. H. Gerould, J. App. Phys. 18, 333 (1947).

water surface by slowly inserting the glass slide at a low angle into a dish of distilled water. The floating replica squares are lifted from the water surface by raising the specimen screens up under them. The specimen screens are then placed on a piece of paper toweling so that the polystyrene film will be pulled down tight and flat on the screen as the water is imbibed by the paper. These thin-film replicas are ready for silica evaporation. (If it is desired, a suitable metal such as gold, chromium, or uranium can be used to shadowcast this replica[7] which can then be observed directly in the electron microscope.)

3. The thin-film replicas mounted on specimen screens are placed in a high vacuum chamber directly above a tightly wound 15° cone-shaped coil filament of 20-mil tungsten wire for silica evaporation. The turns of the tungsten coil must be close together to prevent excess evaporation of the silica through the sides and bottom of the coil. The quantity of silica (2–3 mg) to be evaporated can be conveniently measured into the coil with a micropipette calibrated to deliver the correct volume of Ludox.† The specimen screens are supported in the inverted position above the coil with a piece of transparent cellulose adhesive tape mounted on a glass slide with the adhesive side exposed. Specimen screens readily stick to the tape when pressed lightly against the adhesive surface with a forceps. Transparent adhesive tape used in this manner is a convenient way to carry, catalogue, and store finished specimen screens.

4. After silica evaporation, the double replica mounted on the specimen screen is placed in the washing apparatus shown in Fig. 2. The specimen screens rest on the filter paper square (Whatman No. 1) and are washed gently in a liquid film formed by the condensing vapors after the filter paper is saturated. The washing time and rate are determined empirically and the heating is accomplished by means of a water bath. Only the solvent vapors which condense on the water-cooled glass condensing tube wet the filter paper. The reflux condenser is placed in the system to prevent the danger of a closed system.

After the washing schedule has been established, many finished specimen screens contain a large number of squares covered by the clean intact silica replicas. Carbon tetrachloride was superior to ethyl bromide as the washing agent in this apparatus. This may be due to the fact that carbon tetrachloride does not swell the polystyrene before dissolving it and that the washing can be more readily controlled because carbon tetrachloride is not as volatile as ethyl bromide. After the washing is completed, the filter paper is allowed to dry before the specimen screens are removed to be placed on the adhesive-taped glass slides. These clean silica replicas are ready for observation in the electron microscope.

† Ludox, 30 percent colloidal silica solution in water. Technical Grade. DuPont de Nemours Company, Baltimore, Md.

The completely clean silica replicas prepared in this manner do not display the fragility reported by Heinmets.[8] They can be observed at maximum intensities in the RCA Type EMB and EMU scopes without excessive destruction. However, since the silica films are extremely thin, maximum intensities are not necessary for careful examination. Figure 3 shows a silica replica, made in this manner, of the lumen wall surface of a tracheid of ponderosa pine which has been partially disrupted by drastic chemical treatment. Distinct fibrils which have resulted from this chemical action can be seen grading down to the limit of resolution of the instrument.

Although this method is entirely satisfactory as far as the structures revealed are concerned, the manipulation of thin-film replicas formed by pressure embedding is quite difficult. Many excellent areas are repeatedly lost during the removal of the replicated object from the thin-film polystyrene and also when the thin-film squares are floated onto the water surface. Furthermore, uniform embedding in the thin polystyrene film is very difficult because the film cast from the 1 percent solution is extremely tenuous. The result of this is that the areas most deeply embedded and, therefore, best

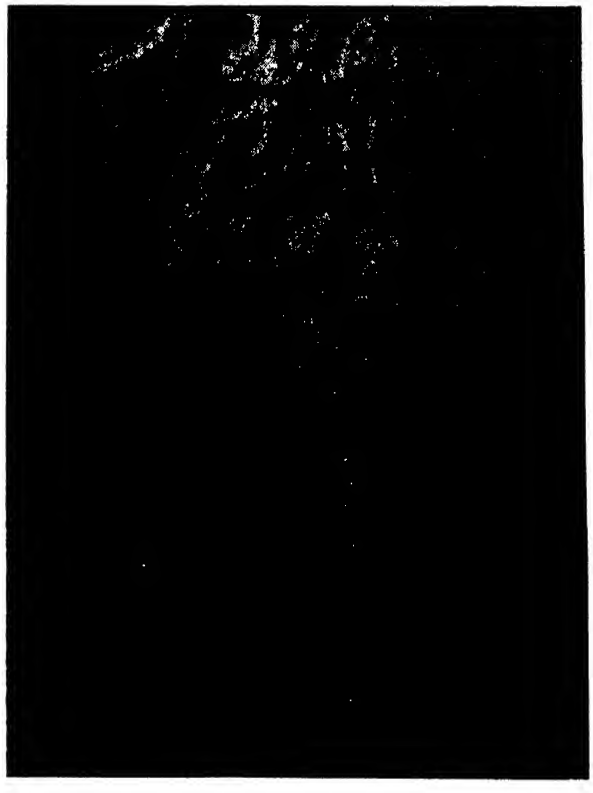

FIG. 3. Surface of the inner layer of the secondary wall of a ponderosa pine fiber after vigorous chemical treatment, showing disorganization of the fibrillar orientation. Silica replica made by the modified two-replica silica method in which the first step is a polystyrene replica of the wet tissue. ×24,000.

[8] F. Heinmets, J. App. Phys. **20**, 384 (1949).

for revealing fine structure are also the most fragile. In an effort to overcome these difficulties, another method was developed in which an extra replication step was introduced. This resulted in simpler, surer manipulation and in a deeper replica of better contrast.

THE THREE-REPLICA SILICA METHOD

The three-replica silica method is a combination of the advantages of a deep replica with adequate embedding and a uniform thin-film replica with ease in washing away the polystyrene.

The steps in the preparation of the final silica replica are as follows:

1. A 4-mils thick film of polyethylene 1-inch square is used for the initial replica, with the wet object replicated in the manner described under the wet replication method.

2. The polyethylene film, after the object has been replicated, is glued to a glass slide with ordinary mucilage. After the mucilage has dried, the object is removed from the polyethylene by teasing it out with tweezers or by stripping it with pressure sensitive tape.

3. The slide with the replicated polyethylene glued to it is immersed in a coplin jar of a 1 percent solution of polystyrene in benzene. The solution is allowed to dry while the slide is held in a vertical position on a piece of paper toweling. This produces a thin, uniform polystyrene film on the replicated polyethylene sheet.

4. The thin-film polystyrene replica is stripped from the polyethylene replica by backing the polystyrene with a thick layer of a 20 percent solution of gelatin in water.[9] After the gelatin has dried, the thin-film polystyrene replica is removed with the gelatin when it is flaked off.

5. The gelatin with the thin polystyrene replica adhering to it is cut into $\frac{1}{8}$-inch squares which are placed gelatin side down into a Syracuse watch glass of hot distilled water. The gelatin dissolves, leaving the small replica squares floating on the water surface with the replica side up. These are then transferred to a large dish of distilled water by means of a piece of 80-mesh screen.

6. The thin-film replicas are lifted from the water surface on the specimen screens which are placed on a piece of paper toweling and allowed to dry. The dry replicas are placed in the vacuum chamber for silica evaporation.

7. The polystyrene is removed by reflux washing in the washing apparatus, and the clean silica films on the specimen screens are ready for electron microscopy.

An example of the results obtainable by this method is shown in Fig. 4 which is a replica of the inner layer of the secondary wall of a redwood tracheid. The low slope of fibrillar orientation of this layer of the wall adjoining the lumen is clearly discernible. This condition of low fibrillar slope in the inner layer of the secondary wall has been observed in all normal coniferous tracheids examined and although this condition had been previously postulated, this is the first time it has been directly demonstrated.

An area from Fig. 4 is shown in Fig. 5 at a higher magnification which makes visible markings on the fibrils. These markings which appear at approximately right angles to the direction of fibrillar orientation may be the result of an alternation of areas with diminishing and increasing crystallinity. The protuberances appearing along the oriented ridges are not necessarily perfect crystalline aggregates. Rather, they can be areas with a greater degree of crystallinity than the intervening areas. If this is the case, it would support the theory put forth by Roseveare and coworkers[10] suggesting that a mechanism exists in crystallizing high polymeric systems for the systematic arrangement of the crystalline aggregates to produce a super-lattice of crystallites. This would explain the fact that in fibrillar cellulose systems planes of weakness are found to exist at right angles to the prevailing direction of fibrillar orientation.[11] The redwood microtome section from which this replica was made was not treated chemically and this is

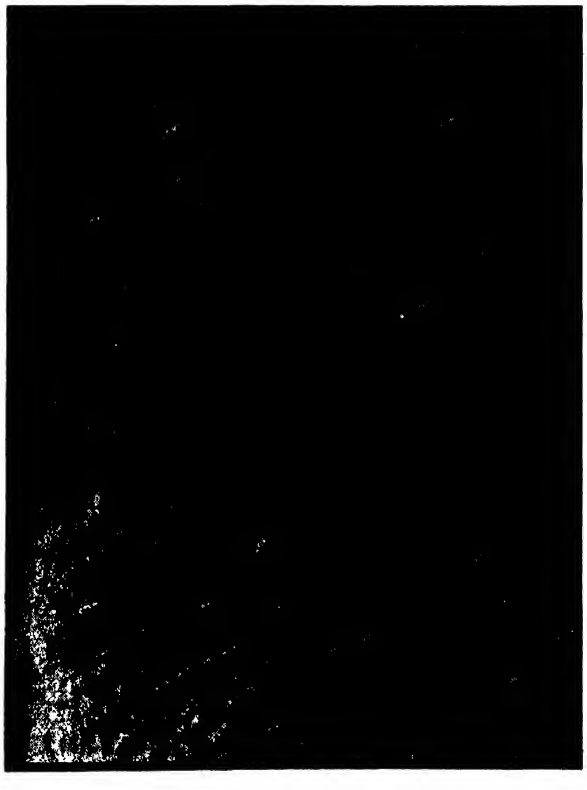

FIG. 4. Surface of the inner layer of the secondary wall of a redwood tracheid without any previous chemical treatment, showing the low slope of fibrillar orientation. The solid line denotes the fiber axis; the dashed line indicates the fibril axis. Silica replica made by the three-replica silica method in which the first step is a polyethylene replica of the wet tissue. ×18,500.

the first time an unaltered, water-saturated plant fiber wall has been shown by means of the electron microscope.

A replica of a cross section of the walls of ponderosa pine tracheids is shown in Fig. 6. This cross section (20-microns thick) was partially delignified by a holocellulose method before replication took place. The light places in the cross section are areas where lignin has been removed. The striae crossing the wall are due to knife tears produced during sectioning. The middle lamella region consists of the light colored irregular areas, where maximum lignin removal has occurred, separating the walls of adjacent cells.

At the beginning of this study it was assumed that a direct replica method in which the initial replica would be observed in the electron microscope would be preferable to any method in which additional replicas were introduced before the final replica for observation. However, this assumption proved to be incorrect and the three-replica silica method is unquestionably preferable to any other method attempted in this study. Although the three-replica silica method appears to be quite complicated, it is actually possible for an experienced technician to produce a large number of excellent silica replicas in a relatively short time. For example, in this study as many as 50 specimen screens with a large number of observable areas of intact silica replicas could be prepared in a 2-day period.

FIG. 6. Cross section of the walls of partially delignified ponderosa pine fibers. Portions of the walls and lumina of three adjoining cells is shown. Silica replica produced by the three-replica silica method. ×4500.

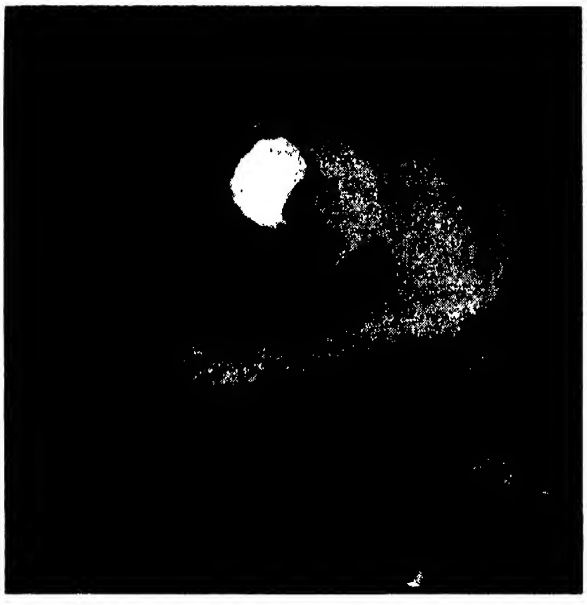

FIG. 7. Bordered pit of ponderosa pine fiber which has undergone drastic chemical treatment showing fibrils reoriented radially around the pit aperture by the replicating procedure. Silica replica produced by the three-replica silica method. ×4000.

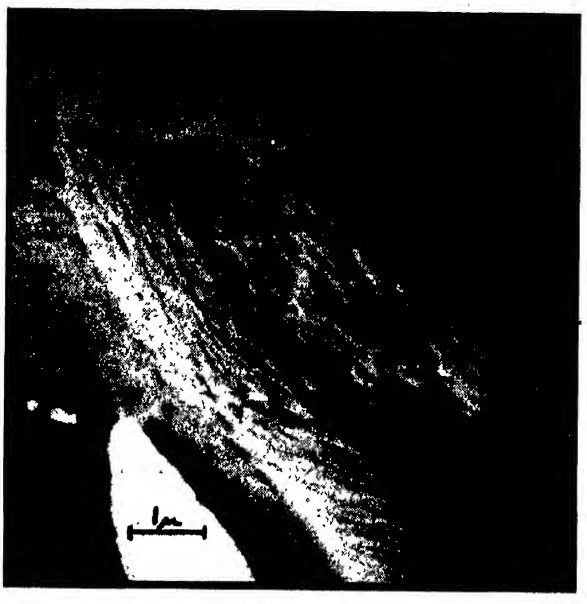

FIG. 8. Bordered pit of ponderosa pine fiber which has undergone very mild chemical treatment showing the true circular fibrillar orientation of the cellulose around the pit aperture. Silica replica produced by the three-replica silica method. ×10,000.

Using the three-replica silica method, it has been possible to use the electron microscope to study the submicroscopic structural relationships of the layers and markings of the secondary cell wall of coniferous tracheids. A later paper will discuss the results of this study.

INTERPRETATION OF REPLICAS

The interpretation of replicas of partially degraded and disorganized materials is a serious problem. In Fig. 7 is shown a replica of a bordered pit in the outer layer of the secondary wall of a fiber produced by a drastic maceration method. Fibrils with an apparent radial orientation around the pit aperture can be seen. These radially oriented fibrils were pulled into this position during the replication process. This interpretation is correct since the bordered pit in this same layer from a replica of a fiber produced by a mild maceration method shown in Fig. 8 displays circular rather than radial orientation around the pit aperture. This is in agreement with the accepted interpretation of bordered pit structure in this layer.

Loosely aggregated substances can be disorganized and reoriented by replicating pressures and, therefore, replicas of such materials should be interpreted with caution.

The author is indebted to Dr. Robert A. Cockrell of the School of Forestry and to Dr. William N. Takahashi of the College of Agriculture, University of California, for their helpful suggestions during the course of the study.

Magneto-Ionic Triple Splitting of Ionospheric Waves

O. E. H. RYDBECK
Research Laboratory of Electronics, Chalmers University of Technology, Gothenburg, Sweden
(Received November 28, 1949)

In recent years reports have appeared from various ionospheric observatories concerning the appearance of a third magneto-ionic component or a so-called z trace. The phenomenon has also been called magneto-ionic triple splitting. After having recorded a number of such triple splits at the new Kiruna observatory, we became very interested in the problem as a whole. The entire matter was examined theoretically and as a result it has been possible to show that strong coupling often exists between the ordinary and z components as a critical level. It has further been possible to show that the z wave becomes strongly excited when the collisional frequency ν approaches the critical collisional frequency ν_c of Appleton and Builder. When ν is larger than ν_c the o echo rapidly disappears and only the z and x components remain (if ν_c is sufficiently small, *i.e.* at very high latitudes). A useful expression for the transmission coefficient of the $o-z$ wave has been derived.

INTRODUCTION

TRIPLE splitting of ionospheric waves or rays was reported in 1933 by Eckersley.[1] A few years later, in 1935 and 1936, Toshniwal[2] and Harang[3] reported similar phenomena. This interesting matter did not attract much attention until after the war the chain of recording ionospheric observatories had been greatly increased. According to Meek,[4] triple splitting was observed in Canada in 1943 when the Churchill ionosphere station commenced operation. Since then the phenomenon was observed frequently at other Canadian stations as well. In Hobart, Tasmania, in 1946, Newstead observed F_2 triple splitting.[5] Seaton, reporting from College, Alaska, in 1947, presents a record of F_2 triple splitting[6] and discusses the possible mechanism of excitation of the third or z component of the downcoming wave. Further, Gipps, Gipps, and Venton at Brisbane[7] as late as August, 1948 describe a ray trace which appears to have the characteristics of the z component. It is significant that all the reports mentioned come from places of high or fairly high geomagnetic latitude.

At the Kiruna Ionospheric and Wave Propagation Observatory, which started regular recording on October 1, 1948,[8] a large number of triple splits have been recorded both in the E and the F regions. As far as is known to us, E triple splitting has only been reported earlier by Meek.[4] The fairly frequent occurrence of ionospheric triple splitting at Kiruna has made us particularly interested in the phenomenon. The purpose of the present note is to make a preliminary investigation of the excitation and properties of this interesting z component of the wave.

THEORETICAL CONSIDERATIONS

In his treatise, "On the propagation of radio waves,"[9] the author has described the coupled wave equations governing the propagation of the ordinary and extraordinary waves in a plane inhomogeneous ionosphere. With the symbols used in that work[9] and the assumption that the electron density varies in the phase propagation or z direction only these equations become

$$\frac{d^2\Pi_1}{dz^2}+(k_0^2\epsilon_1+\psi^2)\Pi_1=-\pi_2\frac{d\psi}{dz}-2\frac{d\Pi_2}{dz}\cdot\psi, \tag{1}$$

$$\frac{d^2\Pi_2}{dz^2}+(k_0^2\epsilon_2+\psi^2)\Pi_2=-\pi_1\frac{d\psi}{dz}-2\frac{d\Pi_1}{dz}\cdot\psi. \tag{2}$$

The values of ϵ_1 and ϵ_2 are given by the Appleton-Hartree formula,[10] $k_0=2\pi/\lambda_0$ (where λ_0 is the vacuum wave-length), and ψ is a coupling coefficient. One further has (if the time factor is $e^{-j\omega t}$)

$$\psi=-\frac{j}{2}\cdot\frac{d(v^2)}{dz}\cdot\frac{\delta_c}{(v^2-ja_1)(v^2+ja_2)}, \tag{3}$$

with

$$\left.\begin{aligned}a_1&=\delta_c+\delta,\\ \text{and}\quad a_2&=\delta_c-\delta.\end{aligned}\right\} \tag{4}$$

In these formulas

$$\delta=\nu/\omega, \tag{5}$$

where ν is the frequency of collision and $\omega=2\pi\cdot f$, the wave angular frequency, is a loss angle measure of the medium. The critical loss angle is

$$\delta_c=\nu_c/\omega, \tag{6}$$

where ν_c is the critical collisional frequency of Appleton-

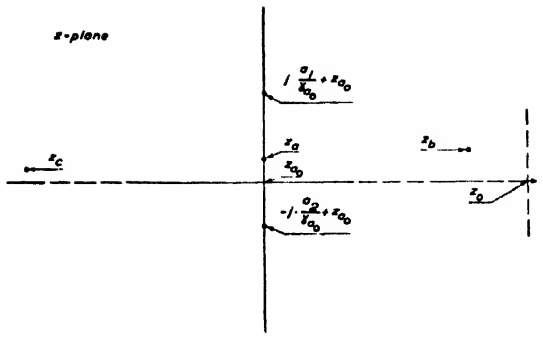

FIG. 1. Showing the location of the zero of n^2 and the poles of ψ in the z plane.

Builder,[11] *viz.*,

$$\nu_c = \tfrac{1}{2}\cdot(\sin^2\theta/\cos\theta)\cdot\omega_H, \tag{7}$$

and θ is the angle between the z axis and the direction of the terrestrial magnetic field. Further $\omega_H = 2\pi\cdot f_H$ is the angular frequency of gyration of the free electron in this field, and

$$\nu^2 = (\omega_c^2/\omega^2) - 1, \tag{8}$$

where ω_c is the ordinary wave critical angular frequency of the electron density level in question. For a parabolic layer formed between $z = z_0 - \Delta h$ and $z = z_0 + \Delta h$, for example, one would have

$$\omega_c^2 = \omega_{cm}^2\{1 - [(z - z_0)/\Delta h]^2\}, \tag{9}$$

where ω_{cm} is the ordinary wave critical angular frequency of the layer.

In the wave equations (1) and (2) we assume that index (1) denotes the ordinary or o component and index (2) the "unusual" z component.

For the unperturbed o wave functions we use the following approximations*

$$\overset{(2)}{\Pi_1}{}^{0(1)} = (\pi W_1/2n_1)^{\frac{1}{2}}\exp(\pm j\pi/6)\cdot\overset{(1)}{H}_{1/3}{}^{(2)}(W_1), \tag{10}$$

where $n_1 = (\epsilon_1)^{\frac{1}{2}}$ is the index of refraction of the o mode and W_1 the phase integral

$$W_1 = \int_{z_a}^{z} k_0 n_1 dz = W_1(z_a, z). \tag{11}$$

It is important to note that z_a is the location of the zero of ϵ_1, i.e., the branch point of n_1. When we have losses, this point (or points) lie in the complex z plane.

Assuming that to the left of the layer $n_1 = e^{-j\pi}$, $\Pi_1{}^{0(1)}$ apparently represents a wave incident upon the layer. Neglecting the possible formation of a z wave we see that the coefficient of reflection, at the lower boundary $z_0 - \Delta h$, becomes

$$R \cong \exp[j\cdot 2\{W_1(z_a, z_0 - \Delta h) - \pi/4\}] \tag{12}$$

if the layer is not very thin and $\omega \neq \omega_{cm}$.

For the unperturbed z wave functions we use similar wave functions denoted $\overset{(2)}{\Pi_2}{}^{0(1)}$ with

$$W_2 = \int_{z_b}^{z} k_0 n_2 dz = W_2(z_b, z), \tag{13}$$

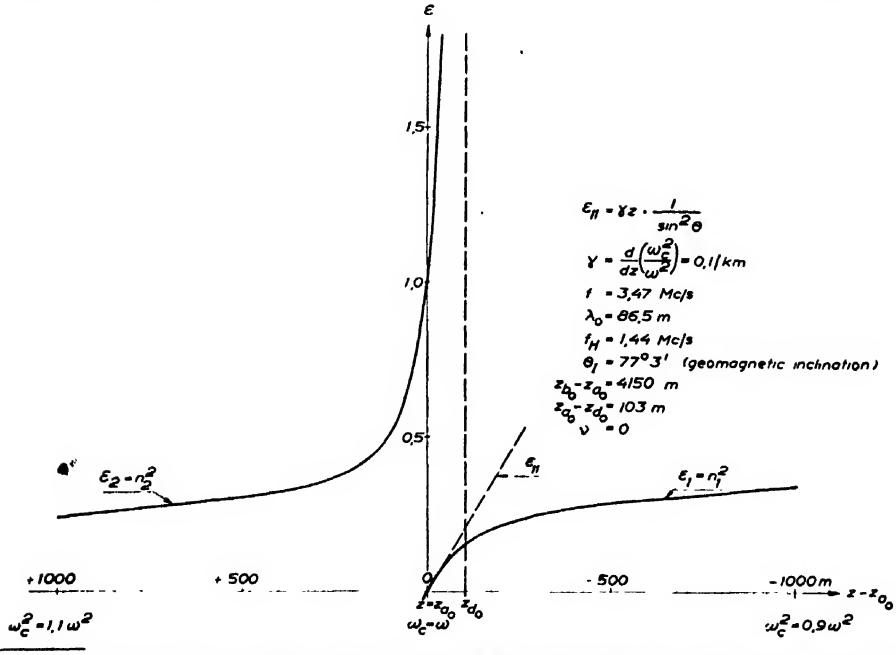

FIG. 2. Index of refraction in the neighborhood of $\omega_c = \omega$ when $\nu = 0$. *Note.* $|\epsilon_2| = \infty$ for $z = z_d$, at which point (branch point of Rai)

$$\frac{\omega_c^2}{\omega^2} = \frac{1 + j\delta}{1 + \dfrac{\gamma^2\sin^2\theta}{(1+j\delta)^2 - \gamma^2}}.$$

[11] E. V. Appleton and G. Builder, "The ionosphere as a doubly refracting medium," Proc. Phys. Soc. 45 (1933).

* Generally sufficiently accurate except in the neighborhood of a second zero of ϵ_1. When two zeros come very close (not of immediate interest in this connection) parabolic wave functions have to be used. See O. E. H. Rydbeck, "On the propagation of waves in an inhomogeneous medium," Report No. 7 from the Research Laboratory of Electronics. Trans. Chalmers University of Technology **74**, 23 (1948).

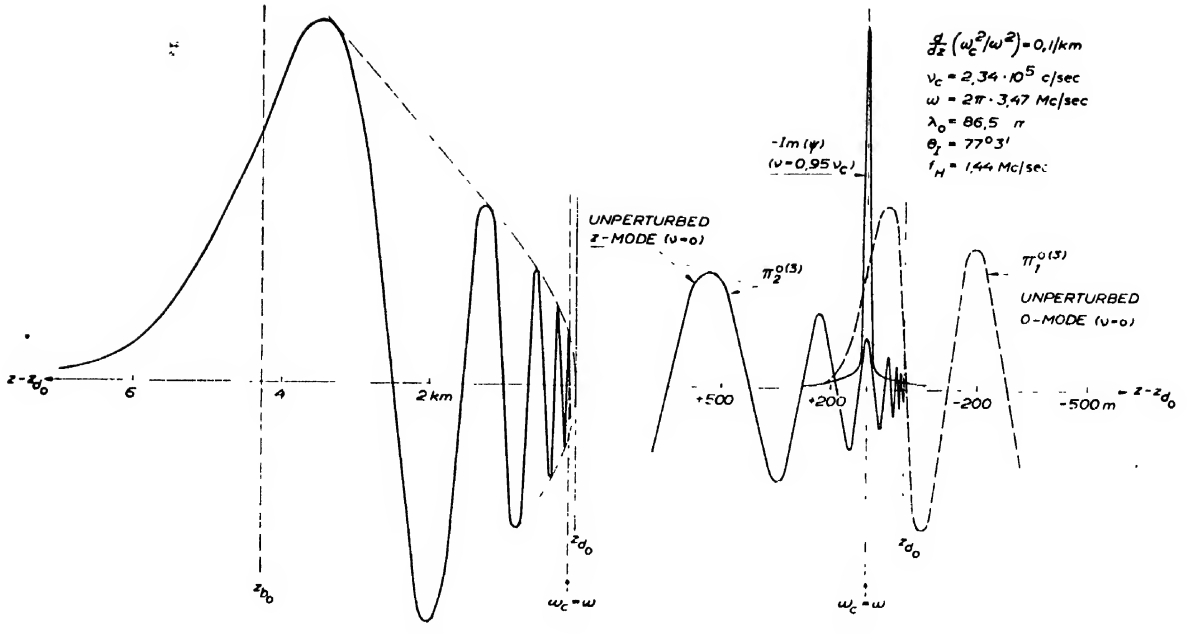

FIG. 3. The coupling coefficient and the unperturbed wave functions in the interaction region.

where z_b is the position of the appropriate ϵ_2 zero. A fundamental question apparently is to study the behavior of n_1 and n_2 in the z plane. To this question we will return briefly after first having studied the nature of the coupling coefficient.

Denoting by $z=z_{a0}$ the interaction level where $\omega_c^2=\omega^2$ (also branch point of n_1 when $\nu=0$), we use the following approximation in the neighborhood of this level, *viz.*,

$$\nu^2=\left\{\frac{d}{dz}\left(\frac{\omega_c^2}{\omega^2}\right)\right\}_{z_{a0}}(z-z_{a0})=\gamma_{a0}(z-z_{a0}). \tag{14}$$

Under these circumstances we have

$$\psi=-\frac{j}{2}\cdot\frac{\delta_c/\gamma_{a0}}{\{(z-z_{a0})-ja_1/\gamma_{a0}\}\{(z-z_{a0})+ja_2/\gamma_{a0}\}}. \tag{15}$$

It is extremely interesting, from an interaction point of view to find, that

$$\int_{-\infty}^{+\infty}\psi dz=\begin{cases}0, & \nu>\nu_c\\ -j\pi/2, & \nu<\nu_c\end{cases}. \tag{16}$$

Returning now to the question of the refractive index, we find it convenient to use the following form of the Appleton-Hartree formula, *viz.*,

$$n_{\frac{1}{2}}^2=1-\frac{(\nu^2+1)(-\nu^2+j\delta)}{(1+j\delta)(-\nu^2+j\delta)-\cos\theta\cdot y\{\delta_c\mp[\delta_c^2+(-\nu^2+j\delta)^2]^{\frac{1}{2}}}. \tag{17}$$

One easily verifies that n_1^2 is zero for $\nu^2=j\delta$, and n_2^2 zero for $\nu^2=\pm y+j\delta$, where $y=\omega_H/\omega$. Thus, even considering the losses the zeros of n_1^2 and n_2^2 are independent of θ.

Denoting by z_c the position of the n_2^2 zero corresponding to $\nu^2=-y+j\delta$, we find for the parabolic layer

$$z_a\cong z_0-\Delta h\left[1-\left(\frac{\omega}{\omega_{cm}}\right)^2\right]^{\frac{1}{2}}+j\frac{\delta\cdot\Delta h}{2}\cdot\frac{\omega/\omega_{cm}}{[(\omega_{cm}/\omega)^2-1]^{\frac{1}{2}}}(\omega^2<\omega_{cm}^2), \tag{18a}$$

$$z_b\cong z_0-\Delta h\left[1-\left(\frac{\omega}{\omega_{cms}}\right)^2\right]^{\frac{1}{2}}+j\cdot\frac{\delta\Delta h}{2}\cdot\frac{\omega^2/\omega_{cm}^2}{[1-(\omega/\omega_{cms})^2]^{\frac{1}{2}}}\quad[\omega^2<\omega_{cms}^2=\omega_{cm}^2/(1+y)], \tag{18b}$$

and

$$z_c\cong z_0-\Delta h[1-(\omega/\omega_{cmz})^2]^{\frac{1}{2}}+j\frac{\delta\Delta h}{2}\cdot\frac{\omega^2/\omega_{cm}^2}{[1-(\omega/\omega_{cmz})^2]^{\frac{1}{2}}}\quad[\omega^2<\omega_{cmz}^2=\omega_{cm}^2/(1-y)]. \tag{18c}$$

Thus,

$$\mathrm{Im}(z_b)>\mathrm{Im}(z_a)>\mathrm{Im}(z_c).$$

It is especially interesting to find that

$$\mathrm{Im}(z_a)=(a_1-a_2)/2\gamma_{a0}, \tag{19}$$

$$\frac{1}{\gamma_{a0}}=\frac{\Delta h}{2}\cdot\frac{\omega/\omega_{cm}}{[\omega_{cm}^2/\omega^2-1]^{\frac{1}{2}}}.$$

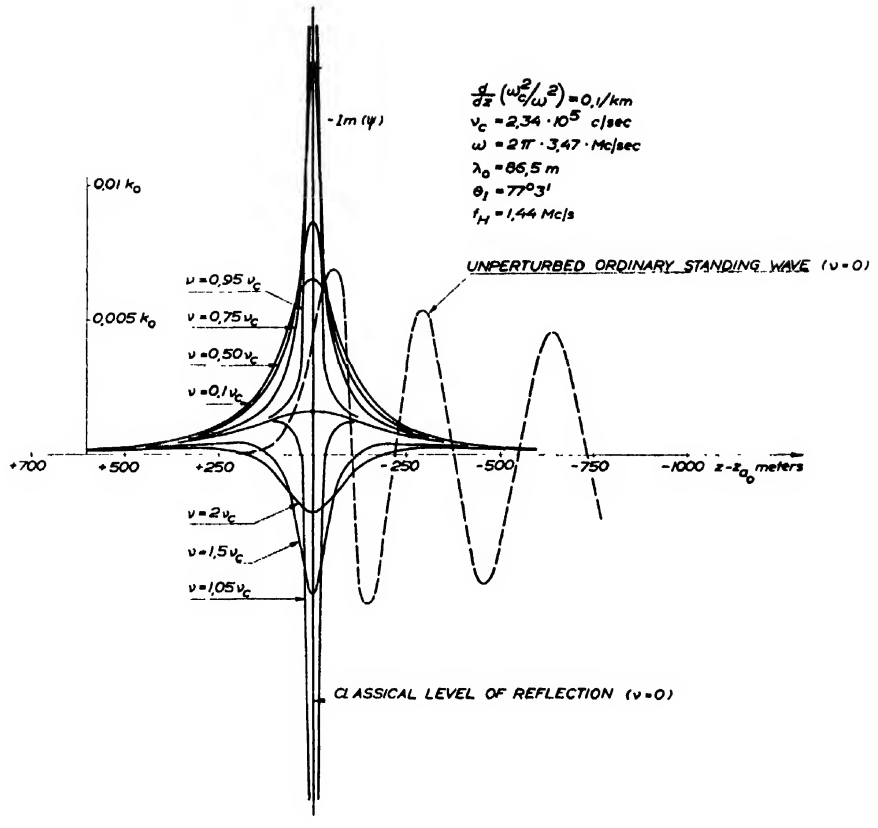

FIG. 4. Demonstrating the nature of $-\mathrm{Im}(\psi)$.

As $\mathrm{Re}(z_a) = z_{a0}$ this means that the zero of n_1^2 is located midway between the poles $ja_1/\gamma_{a0} + z_{a0}$ and $-ja_2/\gamma_{a0} + z_{a0}$ of ψ. The situation is depicted in Fig. 1.

It is further interesting to note that

$$(n_2)_{z=z_a} = 1 \tag{20}$$

and that at the poles $n_1 = n_2$.

We have in Fig. 2 plotted the variation of ϵ_1 and ϵ_2 for $\nu = 0$, a normal electron density gradient and geomagnetic conditions of the Kiruna observatory. The unperturbed standing wave functions,

$$\Pi_1^{0(3)} = \Pi_1^{0(1)} + \Pi_1^{0(2)} \quad \text{and} \quad \Pi_2^{0(3)} = \Pi_2^{0(1)} + \Pi_2^{0(2)},$$

corresponding to these ϵ-variations are shown in Fig. 3 for $\nu = 0$ together with $-\mathrm{Im}(\psi)$ for $\nu = 0.95\nu_c$. This figure demonstrates that the coupling actually takes place within a very narrow region of a few hundred meters effective extension.

It is of particular interest in this connexion to demonstrate the peculiar nature of ψ for various ν-values. The variation of the important component $-\mathrm{Im}(\psi)$ is therefore depicted in Fig. 4 from which it is easy to understand that the "interaction integral" (16) is zero when $\nu > \nu_c$.

Let us next study the first-order approximations to solutions of the excited z waves, running up and down between z_d and z_b. Introducing

$$\xi_1^{(1)}(z) = -\Pi_1^{0(1)} \cdot \frac{d\psi}{dz} - 2 \cdot \frac{d\Pi_1^{0(1)}}{dz} \cdot \psi, \text{ etc.,} \tag{21}$$

we find the first-order z wave approximations

$$\Pi_2^{(1)} = -\Pi_2^{0(1)} \cdot \frac{1}{w_2^0} \cdot \int_{b_1}^{z} \Pi_2^{0(2)} (\xi_1^{(1)} + \xi_1^{(2)}) dz \tag{22}$$

and

$$\Pi_2^{(2)} = \Pi_2^{0(2)} \cdot \frac{1}{w_2^0} \cdot \int_{b_2}^{z} \Pi_2^{0(1)} (\xi_1^{(1)} + \xi_1^{(2)}) dz. \tag{23}$$

Here b_1 and b_2 are lower and upper boundaries of the effective interaction region. Further, w_2^0 is the Wronskian of the pair $\Pi_2^{0(1)}$, $\Pi_2^{0(2)}$. With our form of functions $w_2^0 = j \cdot 2k_0$.

Of practical interest for the moment only is to study $\Pi_2^{(1)}$ when $z > b_2$ and $\Pi_2^{(2)}$ when $z < b_1$, i.e., we are not going to study in detail how the Π_2-functions build up within the interaction zone.

At first sight it appears as if one of the two terms of (21) would complicate the treatments of the interaction integrals (22) and (23). On the contrary one finds, after partial integration, that the presence of both these terms makes it possible to analyze the interaction integrals fairly simply.

We thus find for $z>b_2$:†

$$\Pi_2^{(1)} = -\Pi_2^{0(1)} \cdot \frac{1}{w_2^0} \cdot \int_{b_1}^{b_2} \left\{ \Pi_1^{0(2)} \cdot \Pi_2^{0(2)} \left(\frac{\Pi_1^{0(2)'}}{\Pi_1^{0(2)}} - \frac{\Pi_2^{0(2)'}}{\Pi_2^{0(2)}} \right) \psi + \Pi_1^{0(1)} \cdot \Pi_2^{0(2)} \left(\frac{\Pi_1^{0(1)'}}{\Pi_1^{0(1)}} - \frac{\Pi_2^{0(2)'}}{\Pi_2^{0(2)}} \right) \psi \right\} dz, \quad (24)$$

and similarly for $z<b_1$

$$\Pi_2^{(2)} = \Pi_2^{0(2)} \cdot \frac{1}{w_2^0} \times \int_{b_2}^{b_1} \left\{ \Pi_1^{0(2)} \cdot \Pi_2^{0(1)} \left(\frac{\Pi_1^{0(2)'}}{\Pi_1^{0(2)}} - \frac{\Pi_2^{0(1)'}}{\Pi_2^{0(1)}} \right) \psi + \Pi_1^{0(1)} \cdot \Pi_2^{0(1)} \left(\frac{\Pi_1^{0(1)'}}{\Pi_1^{0(1)}} - \frac{\Pi_2^{0(1)'}}{\Pi_2^{0(1)}} \right) \psi \right\} dz. \quad (25)$$

We are of course principally interested in Eq. (24) which yields the amplitude of the wave propagating toward z_b. As far as the interaction integral is concerned replacing b_1 by $-\infty$ and b_2 by $+\infty$ does not appreciably affect its value if b_1 and b_2 are well outside the main interaction zone. We thus write

$$\underset{z>b_1}{\Pi_2^{(1)}} = -\Pi_2^{0(1)} \cdot \frac{1}{w_2^0} \cdot J_2^{(1)}(b_1, b_2) \cong -\Pi_2^{0(1)} \cdot \frac{1}{w_2^0} \cdot J_2^{(1)}(-\infty, +\infty). \quad (24a)$$

If the path of integration is displaced to encircle the pole z_2 of ψ, it is possible to show that the dominant contribution to $J_2^{(1)}$ actually comes from the pole. This pole also is a branch point of n_1 and n_2 (though not a zero point), and in the first order approximation we may still use the approximate wave functions (10).

We have already mentioned that at the ψ-poles $n_1=n_2$. The distance between the poles and z_a, δ_c/γ_{a0}, is quite large. For the locality in question (Kiruna) $\nu_c \cong 2.1 \cdot 10^5$ sec.$^{-1}$ and with the gradient chosen this distance is greater than about 100 meters. The amplitude of W_1 at the poles therefore will be at least of the order 3, the corresponding phase angle with the chosen orientation somewhere between $-\pi/2$ and $-3\pi/4$ at $z_{a0}+j\cdot a_1/\gamma_{a0}$ and between $+\pi/2$ and $+3\pi/4$ at $z_{a0}-ja_2/\gamma_{a0}$. For $W_2[z_{a0}, \pm j\cdot(a_2'/\gamma_{a0})+z_{a0}]$ the amplitude is about three times as large with phase angles approximately $\mp\pi/2$. We can therefore use the asymp-

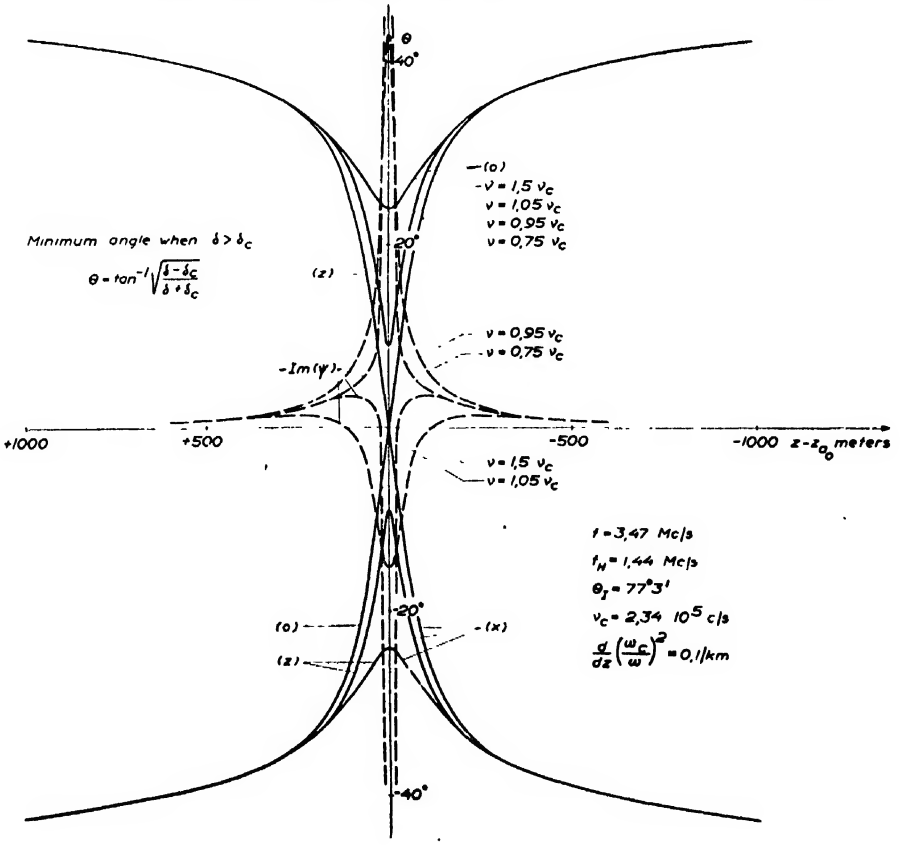

FIG. 5. Depicting the variation in polarization in the coupling region.

† *Note.* $\Pi_1^{0(2)'} = d\Pi_1^{0(2)}/dz$, etc.

totic representation of the Hankel functions at the poles and as there $n_1=n_2$ we infer that the first term of $J_2^{(1)}$ practically disappears (the parenthesis tends to zero). Moreover, $|\Pi_1^{0(2)}|\ll|\Pi_1^{0(1)}|$ at the lower pole. It can therefore safely be said that the first term of $J_2^{(1)}$ does not contribute to its value. We have thus shown that only the "incident" wave function produces the z wave proceeding in the same direction. This is only virtual as the $\Pi_1^{0(2)}$ function must be present to make the integral converge over the path. Also from a physical point of view $\Pi_1^{0(1)}$ cannot be present without $\Pi_1^{0(2)}$.

For the $\Pi_2^{(2)}$-component the result is similar. This time, however, we have to evaluate the residue at $z_{a0}+j\cdot a_1/\gamma_{a0}$ as the wave function products are bounded only in the upper half-plane. Virtually only the "reflected" wave function $\Pi_1^{0(2)}$ contributes to the residue and therefore to the $\Pi_2^{(2)}$-component.

As at the pole

$$\frac{\Pi_1^{0(1)\prime}}{\Pi_1^{0(1)}}-\frac{\Pi_2^{0(2)\prime}}{\Pi_2^{0(2)}}\cong 2\cdot jk_0\cdot n_{\text{pole}},$$

we find

$$\Pi_{2\,z>b_2}^{(1)}(z)\cong\Pi_2^{0(1)}\cdot\exp\Big[-j\Big\{W_1\Big(z_{a0},-j\cdot\frac{a_2}{\gamma_{a0}}+z_{a0}\Big)-W_2\Big(z_{a0},-j\frac{a_2}{\gamma_{a0}}+z_{a0}\Big)\Big\}\Big]\cdot\pi/2\exp(-j\pi/2).$$

Actually we should have started with unit amplitude value of the wave incident at $z=z_0-\Delta h$. The $\Pi_1^{0(1)}(z)$ wave function of the interaction integral therefore should have been replaced by $\Pi_1^{0(1)}(z)/\Pi_1^{0(1)}(z_0-\Delta h)$. Denoting the pole positions by z_1 and z_2, respectively, and introducing this scaled-down wave function we find, if $z>b_2$ but $z\neq z_b$ that

$$\Pi_2^{(1)}(z)\cong\frac{\pi}{2}\cdot\frac{1}{(n_2)^{\frac{1}{2}}}\cdot\exp[j\{W_1(z_{a0},z_0-\Delta h)+W_2(z,z_{a0})\}]\cdot\exp[j\{W_2(z_{a0},z_2)-W_1(z_{a0},z_2)-\pi/2\}]. \quad (26)$$

As the first exponential is the straight phase integral up to z (though with exchanged refractive index after the z wave "takes over") we are led to introduce the first order transmission coefficient T^+ of direction into the layer, *viz.*,

$$T^+\cong(\pi/2)\cdot\exp[j\{W_2(z_{a0},z_2)-W_1(z_{a0},z_2)-\pi/2\}]. \quad \nu<\nu_c. \quad (27)$$

As

$$z_2-z_{a0}=-j\frac{\delta_c-\delta}{\gamma_{a0}}=-j\frac{\nu_c-\nu}{\omega}\cdot\frac{\Delta h}{2}\cdot\frac{\omega/\omega_{cm}}{[(\omega_{cm}^2/\omega^2)-1]^{\frac{1}{2}}},$$

we see that as ν approaches ν_c, $|T^+|$ approaches $\pi/2$.

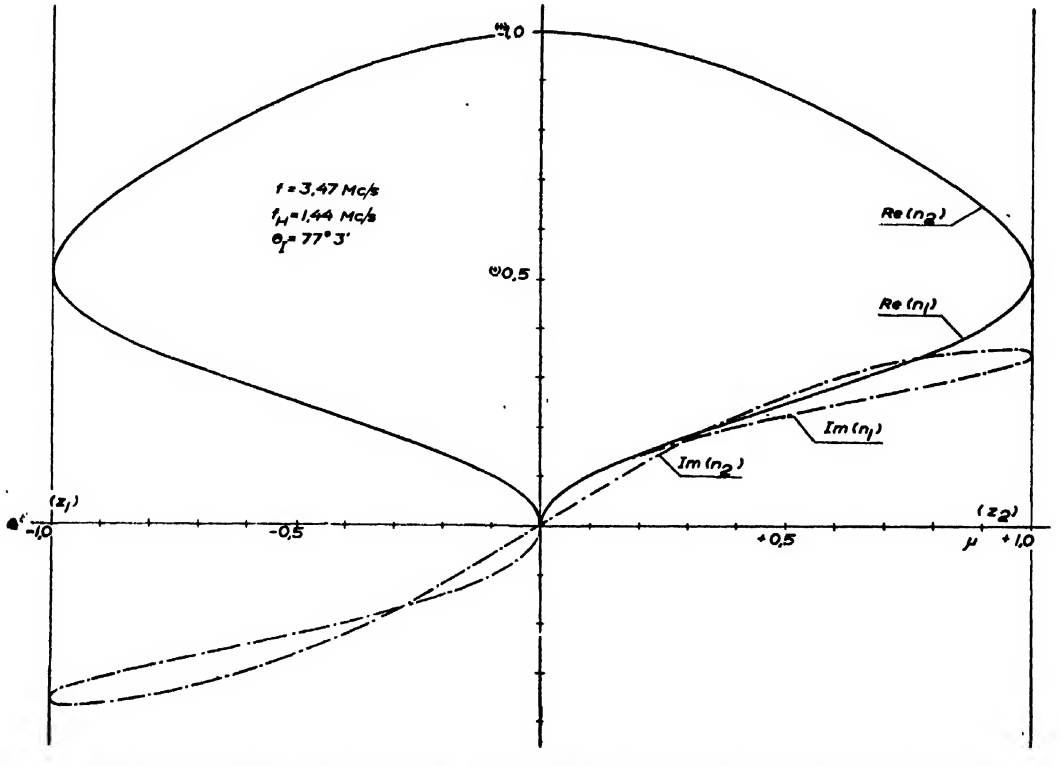

FIG. 6. Showing the variation of the refractive indices for the O^- and Z^- modes along the imaginary axis, joining the ψ-poles Z_1 and Z_2. $[\mu=-(\nu^2-j\delta)/j\delta_c.]$

This indicates very strong coupling, as indeed one would expect. When, namely, ν approaches ν_c the mathematical reflection point, z_a, comes farther and farther away from the interaction point z_{a0}. The interaction pole, z_2, at the same time comes closer and closer to the interaction point and more and more of the incident wave energy is transformed into the z wave. Finally there appears to be complete transformation. However, when the coupling becomes so strong, our first-order approximations cannot be accurate enough. However, if approximations of higher order are also considered, one finds that as ν approaches ν_c the amplitude factor $\pi/2$ of T^+ effectively is reduced to 1.[12] For practical calculations we therefore put

$$T^+\cong\exp[j\{W_2(z_{a0}, z_2)-W_1(z_{a0}, z_2)-\pi/2\}]. \quad \nu\leq\nu_c. \quad (27a)$$

It is obvious that as ν becomes larger than ν_c, z_2 moves into the upper half-plane, and thus in the first-order approximation

$$T^+=0, \quad \nu>\nu_c. \quad (27b)$$

How can this result be explained physically? Let us look at Fig. 5 where we have depicted the polarization of the o and x (z) components as functions of distance in the neighborhood of $\omega_c^2=\omega^2$. The polarization curves only cross each other when $\nu\leqslant\nu_c$ (compare the earlier results of Mary Taylor[13]) and at the level $\omega_c^2=\omega^2$ where the o and z components have the same polarization, in this case plane. At this level the main coupling must occur.

We have further plotted $-\mathrm{Im}(\psi)$ as a function of distance in Fig. 5 in order to show how rapidly the polarization varies through the coupling range when $\nu\leqslant\nu_c$. When ν approaches ν_c the coupling becomes very strong in a narrow region where the difference in polarization is quite small.

As n_1 and n_2 represent the same quantity in different Riemann-surfaces, the cuts joining these surfaces run from z_1 and z_2, say to respectively $v^2=\pm j\infty$. If $\pi_2^{0(1)}$ is "carried" through the cut from the n_2 to the n_1 plane, one immediately infers that along the axis of reals ($z<z_{a0}$) it represents an o wave in the latter plane, traveling in the same direction as $\pi_1^{0(1)}$. Obviously the transformation coefficient, in this geometrical interpretation, becomes

$$T_{0z}\cong\exp[j\{W_2(z_{a0}, z_2)-W_1(z_{a0}, z_2)\}]. \quad \nu\leq\nu_c. \quad (27c)$$

When $\nu>\nu_c$ the axis of reals runs through the cut and the o wave automatically transforms into a z wave, *i.e.* we have longitudinal transmission. Therefore

$$T_{0z}\cong 1, \quad \nu\geq\nu_c \quad (28)$$

which, of course, in no way contradicts the result (27b) of the coupling theory.

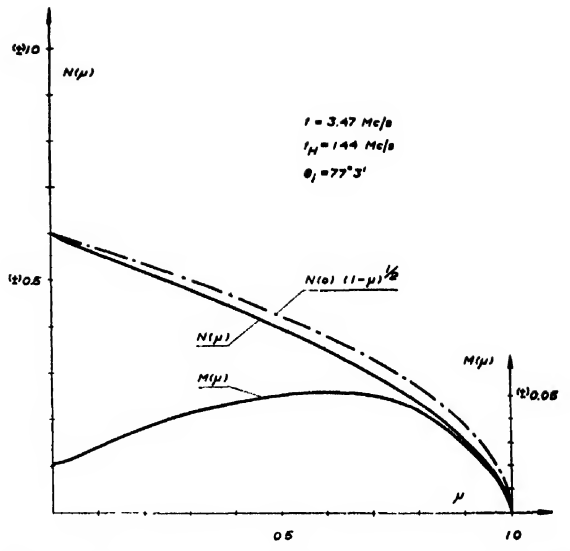

FIG. 7. Depicting the variation of $N(\mu)$ and $M(\mu)$ along the axis of the ψ-poles. $[\mu=-(\nu^2-j\delta)/j\delta_c.]$

Thus according to both the coupling theory and the geometrical interpretation one approximately has

$$\left.\begin{aligned} R_z\cong&\exp[j\cdot 2\{W_1(z_{a0}, z_0-\Delta h) \\ &+W_2(z_b, z_{a0})-\pi/4\}\cdot(T_{0z})^2, \quad \nu\leq\nu_c \\ \text{and} \\ R_z\cong&\exp[j\cdot 2\{W_1(z_b, z_0-\Delta h)-\pi/4\}]. \quad \nu\geq\nu_c \end{aligned}\right\}. \quad (29)$$

When $\nu>\nu_c$, R_0 rapidly becomes smaller and only the z and x components are recorded (if ν_c is sufficiently small).

Finally it should be mentioned that a detailed study of the connection relation between the wave functions in the n_1 and n_2 planes shows that theoretically an infinite (but highly attenuated) group of waves are running up and down between the principal branch points.[12]

However, one should not be led to believe that transmission conditions as a whole are optimal for the z wave when $\nu\cong\nu_c$. The regular path attenuation naturally becomes quite considerable unless ν_c is fairly low as at high latitudes.

The ratio between the two reflection coefficients becomes ($\nu\leq\nu_c$)

$$R_z/R_0\cong\exp[j\cdot 2\{W_2(z_{b0}, z_{a0})+W_2(z_b, z_{b0}) -W_1(z_a, z_{a0})\}]. \quad (T_{0z})^2. \quad (30)$$

Assuming $W_2(z_b, z_{b0})$ roughly equal to $W_1(z_a, z_{a0})$, a reasonable assumption when $\nu<\nu_c$, we infer from (30) that the probability of observing both the o wave and the z wave must increase when we approach such regions where ν is small and $|T|^2$ large. Let us therefore next study how $|T|^2$ varies with the collisional frequency.

As

$$T_{0z}\cong\exp\left[j\left\{k_0\int_{z_{a0}}^{z_2}(n_2-n_1)dz-(\pi/2)\right\}\right]. \quad \nu<\nu_c. \quad (27a)$$

It is of particular interest to plot n_2-n_1 from z_2 to z_{a0} (and then to z_1) along the axis between the ψ-poles. To that end we introduce

$$-\nu^2+j\delta=\mp j\mu\delta_c,$$

where the upper sign denotes the direction from z_a to z_1 and μ runs from 0 to 1. We then obtain the two simple expressions

$$n_1^2=\frac{1-(1-\mu^2)^{\frac{1}{2}}+\frac{1}{2}\mu^2\cdot\tan^2\theta}{1-(1-\mu^2)^{\frac{1}{2}}-[j\mu(1+j\delta)/y\cos\theta]}, \quad (31)$$

$$n_2^2=\frac{1+(1-\mu^2)^{\frac{1}{2}}+\frac{1}{2}\mu^2\cdot\tan^2\theta}{1+(1-\mu^2)^{\frac{1}{2}}-[j\mu(1+j\delta)/y\cos\theta]} \quad (32)$$

where it is no serious neglect to drop $j\delta$. It is therefore a comparatively simple matter to plot the variation of n_2 and n_1 along the axis between the poles. The result is shown in Fig 6. We immediately note that the difference between $\mathrm{Im}(n_2)$ and $\mathrm{Im}(n_1)$ always is very small indicating a practically negligible phase change.

Equation (27a) can be written

$$T_{0z}\cong\exp\left[-j\left\{k_0\delta_c(1-\mu)M(\mu)/\gamma_{a0}-\frac{\pi}{2}\right\}-k_0\delta_c(1-\mu)N(\mu)/\gamma_{a0}\right], \quad (33)$$

where $\mu=\nu/\nu_c$,

$$N(\mu)=\frac{1}{1-\mu}\int_\mu^1\{\mathrm{Re}(n_2)-\mathrm{Re}(n_1)\}d\mu \quad (34)$$

and

$$M(\mu)=\frac{1}{1-\mu}\int_\mu^1\{\mathrm{Im}(n_2)-\mathrm{Im}(n_1)\}d\mu. \quad (35)$$

We also have with very good accuracy

$$T_{0z}^2\cong\exp[-2k_0\delta_c(1-\mu)|N(\mu)|/\gamma_{a0}], \quad (36)$$

as at least for $|\mu|<1$, $|M(\mu)|<0.05$ (for the y and θ-values chosen). This is demonstrated by Fig. 7. The magnitude of $M(\mu)$ always is very small which indicates negligible net phase shift.

It is very interesting to note that $N(\mu)$, for the geomagnetic values chosen, is represented quite well by $N(0)(1-\mu)^{\frac{1}{2}}$. From (36) we finally obtain the practically useful formula

$$T_{0z}^2\cong\exp\left[-\frac{\nu_c\cdot\Delta h}{c_0}\left(1-\frac{\nu}{\nu_c}\right)^{\frac{1}{2}}|N(0)|\cdot\frac{\omega/\omega_{cm}}{(\omega_{cm}^2/\omega^2-1)^{\frac{1}{2}}}\right]. \quad \nu\leq\nu_c. \quad (37)$$

$$(\omega<\omega_{cm})$$

Figure 8 illustrates this result for typical E layer values and Kiruna geomagnetic conditions.

The critical collisional frequency, ν_c, increases rapidly with decreasing geomagnetic latitude as shown in Fig. 9. For comparison a height scale corresponding to the daylight ν-values has also been introduced in order to show the relative position of the ionized layer.

It is thus clear from what has been said and, again, from the nature of relation (37) that $o-z-o$ E trans-

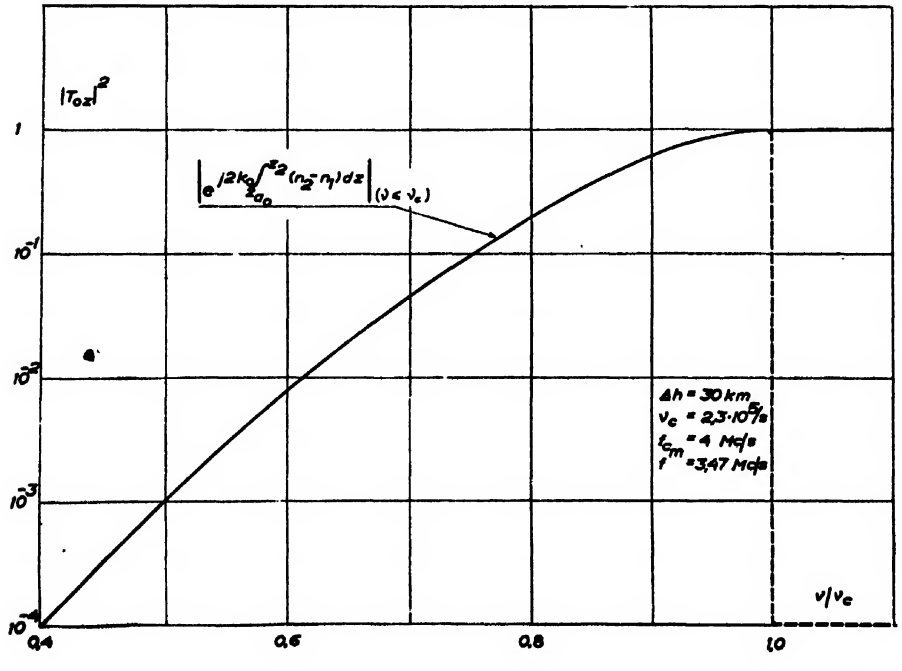

FIG. 8. The total transmission coefficient as a function of ν.

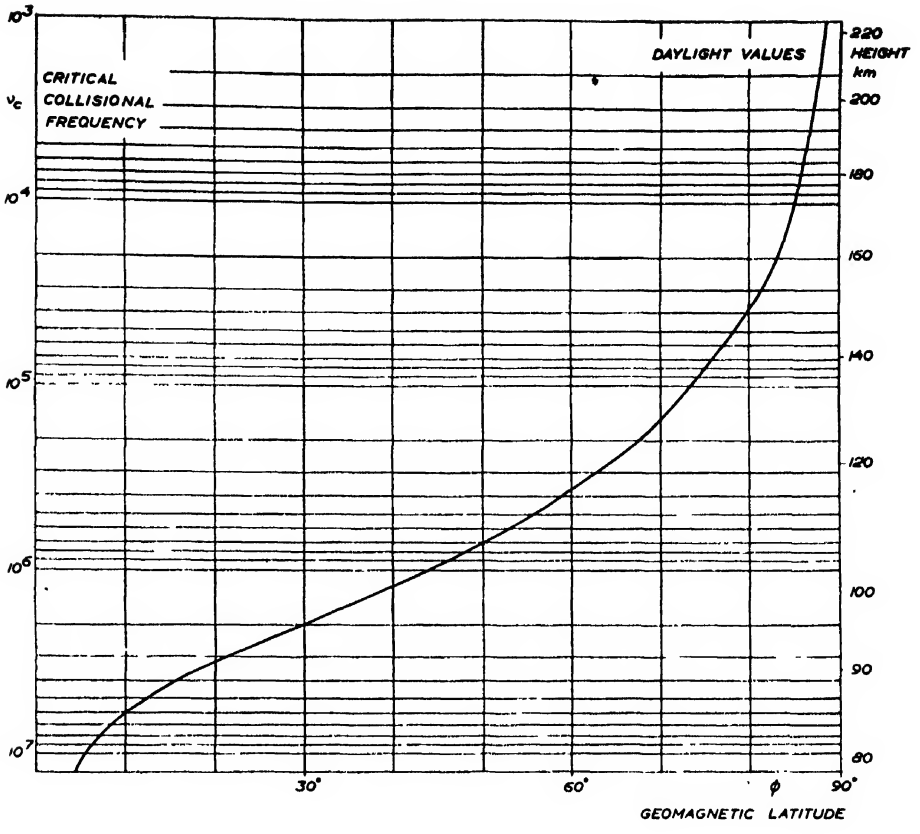

FIG. 9. The variation of critical collisional frequency with geomagnetic latitude.

mission of appreciable strength only is possible at high latitudes, preferably above 70°N or below 70°S. This is in full accord with experimental facts, both others' and our own.

EXPERIMENTAL RESULTS

It appears from Fig. 9 that at Kiruna, for example,[8] where the geomagnetic latitude is about 65°, triple splitting cannot occur with great strength much below about 120 km but that it must occur with considerable intensity slightly above that height. This is in complete agreement with our experience. We record triple penetration of the E layer almost regularly and in Fig. 10 is shown one of the typical records obtained with the new 16-kw panoramic recorder.[14] It is interesting to note that on this occasion, as so many times before, the $o-z-o$ component is almost as strong as the o component. One notes the characteristic fact that $o-z-o$ wave reflected from the F_2 layer disappears when the o wave penetrates the E layer. The reason for this is clear, both physically and from (37). This feature of the z trace has already been reported by Meek.[4] Actually the z trace is much delayed and absorbed when the o wave begins to penetrate.

It is clear both from the form of relation (37) and from Fig. 9 that at Kiruna, for example, T^2 is considerably smaller for the $o-z-o$ wave in the F_2 layer. However, on account of the small ν and therefore low attenuation on the whole, the z trace can be seen on F_2 records although usually not as frequently as near the lower critical ν_c-level. Figure 11 is a clear-cut sample of F_2 triple splitting recorded recently at Kiruna.

Figure 12 finally shows another characteristic example of E layer triple splitting which again shows that the z trace disappears near f_{E0}.

The present investigation has shown that with respect to the o and z waves when $\nu < \nu_c$ the layers of the iono-

sphere act as if they constituted coupled transmission lines. The "ordinary" line runs from $z_0 \pm \Delta h$ to $\pm z_{a0}$ the "z" line from $\pm z_{a0}$ to $\pm z_{b0}$, or from $+z_{a0}$ to $-z_{a0}$ when the $o-z-o$ wave penetrates. It is not possible to detect any difference in polarization between the o and $o-z-o$ waves outside the layers. There they are, in fact, both ordinary waves.

The Equivalent Circuit for the Transmission of Plane Elastic Waves through a Plate at Oblique Incidence

WILLIAM T. THOMSON
University of Wisconsin, Madison, Wisconsin
(Received April 20, 1950)

Equations are developed for the transmission of a plane elastic wave through a plate at oblique incidence with unequal fluid medium on each side of the plate. The plate transmitting both the dilatation and shear wave is reduced to a simple equivalent circuit with impedances which are functions of the incidence angle.

INTRODUCTION

THE transmission of plane elastic waves through a stratified solid medium at oblique incidence was recently treated by the author.[1] When the solid medium is reduced to a single plate surrounded by a fluid medium, the problem is somewhat simplified. The latter case has been studied by Reissner,[2] and Smyth and Lindsay.[3] Reissner's equation for transmission is conveniently expressed in terms of two factors M and N which are also used in this paper.

To make the problem more general, the fluid on each side of the plate will be assumed to be different. This, however, has no effect on the equivalent circuit, other than that of altering the terminal conditions.

Nomenclature

The symbols used are identical to those of reference 1 with few additions.

Δ', Δ'' = progressive and reflected dilatation in solid.
ω', ω'' = progressive and reflected rotations in solid.
c_Δ = velocity of dilatation wave in solid.
c_ω = velocity of rotation or shear wave in solid.
c_0 = velocity of propagation in first fluid medium.
c_2 = velocity of propagation in second fluid medium.
ρ = density of plate.
ρ_0, ρ_2 = density of fluid mediums.
p = angular frequency in radians per sec.
l, m, n = direction cosines of normal to advancing wave with respect to x, y, z axis.
σ = normal stress perpendicular to xy plane.
τ = shearing stress in xy plane.
ξ = particle velocity in z direction.
d = thickness of plate.
λ_Δ = wave-length of dilatational wave in plate.
$P=(pn_\Delta d)/c_\Delta$.
$Q=\dfrac{pn_\omega d}{c_\omega}$.
φ', φ'', φ''' = incident, reflected, and transmitted wave amplitudes in fluid.
θ_0 = angle of incidence.

$$F=\left(\frac{\cos\theta_0}{\rho_0 c_0}\right)\left(\frac{\rho c_\Delta}{\cos\theta_\Delta}\right)\left(\frac{\cos^2 2\theta_\omega}{\sin P}\right)$$

$$G=\left(\frac{\cos\theta_0}{\rho_0 c_0}\right)\left(\frac{\rho c_\omega}{\cos\theta_\omega}\right)\left(\frac{\sin^2 2\theta_\omega}{\sin Q}\right)$$

Same coefficients as those of Reissner's paper, reference 2, but rearranged in symmetric form.

$N=F+G$.
$M=F\cos P+G\cos Q$.

DEVELOPMENT OF EQUATIONS

Choosing the coordinate axes as shown in Fig. 1, the equations of reference 1 apply. From Eqs. (7), (8), and (16) of Thomson's article[1] we can write the following equations corresponding to the six boundary conditions.

The shear stress at the plate boundaries is zero:

$$\tfrac{1}{2}(\Delta'-\Delta'')\sin 2\theta_\Delta+(\omega'+\omega'')\cos 2\theta_\omega=0, \tag{1}$$

$$(i/2)(\Delta'+\Delta'')\sin 2\theta_\Delta\sin P+\tfrac{1}{2}(\Delta'-\Delta'')\sin 2\theta_\Delta\cos P +i(\omega'-\omega'')\cos 2\theta_\omega\sin Q +(\omega'+\omega'')\cos 2\theta_\omega\cos Q=0. \tag{2}$$

The particle velocity is continuous at plate boundaries:

$$c_\Delta n_\Delta(\Delta'-\Delta'')-2c_\omega l_\omega(\omega'+\omega'')=c_0 n_0(\varphi'-\varphi''), \tag{3}$$

$$ic_\Delta n_\Delta(\Delta'+\Delta'')\sin P+c_\Delta n_\Delta(\Delta'-\Delta'')\cos P -2ic_\omega l_\omega(\omega'-\omega'')\sin Q -2c_\omega l_\omega(\omega'+\omega'')\cos Q=c_2 n_2\varphi'''. \tag{4}$$

The normal stress is continuous at plate boundaries:

$$\rho c_\Delta^2(\Delta'+\Delta'')\cos 2\theta_\omega-2\rho c_\omega^2(\omega'-\omega'')\sin 2\theta_\omega =-c_0^2\rho_0(\varphi'+\varphi''), \tag{5}$$

$$\rho c_\Delta^2(\Delta'+\Delta'')\cos 2\theta_\omega\cos P+i\rho c_\Delta^2(\Delta'-\Delta'')\cos 2\theta_\omega\sin P -2\rho c_\omega^2(\omega'-\omega'')\sin 2\theta_\omega\cos Q -2i\rho c_\omega^2(\omega'+\omega'')\sin 2\theta_\omega\sin Q=-c_2^2\rho_2\varphi'''. \tag{6}$$

From Eqs. (1), (2), (3), and (4) we obtain the following:

$$\omega'+\omega''=-\tfrac{1}{2}(\varphi'-\varphi'')\sin 2\theta_0, \tag{7}$$

$$\omega'-\omega''=-\frac{i}{2}(\varphi'-\varphi'')\sin 2\theta_0\frac{\cos Q}{\sin Q}+\frac{i}{2}\varphi'''\frac{c_2 n_2}{c_0 n_0}\frac{\sin 2\theta_0}{\sin Q}, \tag{8}$$

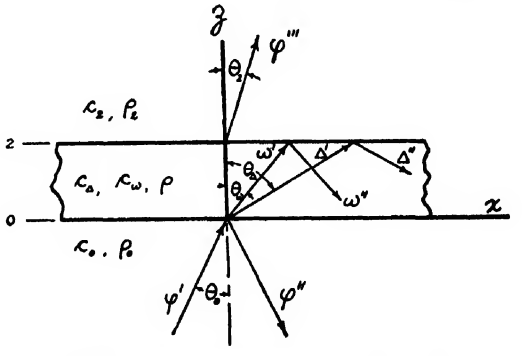

FIG. 1. Dilatational and shear waves in solid plate.

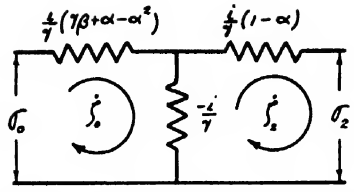

FIG. 2. Equivalent circuit for a plate transmitting dilatational and shear waves.

$$\Delta'-\Delta''=(\varphi'-\varphi'')\sin2\theta_0\frac{\cos2\theta_\omega}{\sin2\theta_\Delta}, \tag{9}$$

$$\Delta'+\Delta''=i(\varphi'-\varphi'')\frac{\sin2\theta_0\cos2\theta_\omega\cos P}{\sin2\theta_\Delta\sin P}-i\varphi'''\frac{c_2n_2}{c_0n_0}\frac{\sin2\theta_0\cos2\theta_\omega}{\sin2\theta_\Delta\sin P}. \tag{10}$$

Substituting these into Eqs. (5) and (6) we obtain

$$\varphi'-\varphi''=\frac{\varphi'''}{N}\frac{c_2}{c_0}\left[M\frac{n_2}{n_0}+i\frac{c_2\rho_2}{c_0\rho_0}\right], \tag{11}$$

$$\varphi'+\varphi''=\frac{\varphi'''}{N}\frac{c_2}{c_0}\left[M\frac{c_2\rho_2}{c_0\rho_0}+i(N^2-M^2)\frac{n_2}{n_0}\right], \tag{12}$$

$$\frac{\varphi'''}{\varphi'}=\frac{2N(c_0/c_2)}{M\left(\frac{c_2\rho_2}{c_0\rho_0}+\frac{n_2}{n_0}\right)+i\left[(N^2-M^2)\frac{n_2}{n_0}+\frac{c_2\rho_2}{c_0\rho_0}\right]}. \tag{13}$$

$$T=\frac{c_2\rho_2|\varphi'''|^2}{c_0\rho_0|\varphi'|^2}=\frac{4N^2(c_0/c_2)(\rho_2/\rho_0)}{M^2\left(\frac{n_2}{n_0}+\frac{c_2\rho_2}{c_0\rho_0}\right)^2+\left[\frac{c_2\rho_2}{c_0\rho_0}+(N^2-M^2)\frac{n_2}{n_0}\right]^2}, \tag{14}$$

$$\frac{\varphi''}{\varphi'}=\frac{M\left(\frac{c_2\rho_2}{c_0\rho_0}-\frac{n_2}{n_0}\right)+i\left[(N^2-M^2)\frac{n_2}{n_0}-\frac{c_2\rho_2}{c_0\rho_0}\right]}{M\left(\frac{c_2\rho_2}{c_0\rho_0}+\frac{n_2}{n_0}\right)+i\left[(N^2-M^2)\frac{n_2}{n_0}+\frac{c_2\rho_2}{c_0\rho_0}\right]}, \tag{15}$$

$$R=\frac{c_2\rho_2|\varphi''|^2}{c_0\rho_0|\varphi'|^2}=\left\{\frac{M^2\left(\frac{c_2\rho_2}{c_0\rho_0}-\frac{n_2}{n_0}\right)^2+\left[(N^2-M^2)\frac{n_2}{n_0}-\frac{c_2\rho_2}{c_0\rho_0}\right]^2}{M^2\left(\frac{c_2\rho_2}{c_0\rho_0}+\frac{n_2}{n_0}\right)^2+\left[(N^2-M^2)\frac{n_2}{n_0}+\frac{c_2\rho_2}{c_0\rho_0}\right]^2}\right\}\frac{c_2\rho_2}{c_0\rho_0}. \tag{16}$$

Equations (14) and (16) are the transmission and reflection coefficients of the plate. When the two fluid mediums are the same, these equations reduce to

$$T=\frac{|\varphi'''|^2}{|\varphi'|^2}=\frac{4N^2}{4M^2+(N^2-M^2+1)^2}, \tag{17}$$

$$R=\frac{|\varphi''|^2}{|\varphi'|^2}=\frac{(N^2-M^2-1)^2}{4M^2+(N^2-M^2+1)^2}, \tag{18}$$

which agree with those of Reissner.

DEVELOPMENT OF THE EQUIVALENT CIRCUIT

In the impedance theory of tubes and horns[4] it is common practice to write the pressure and volume current at one point in terms of corresponding quantities at another point. This idea was utilized in the paper of reference 3 to consolidate the transmission equations. With this same general scheme, it is possible to go further and develop the equivalent circuit for the plate transmitting the dilatation and shear waves.

We first write the equations for σ and $\dot{\xi}$ at the plate boundaries in terms of φ', φ'', and φ''' by substituting Eqs. (7), (8), (9), and (10) in the left side of Eqs. (3), (4), (5), and (6).

$$\sigma_0=i(\varphi'-\varphi'')\rho_0c_0^2M-i\varphi'''\rho_0c_0^2N(c_2n_2/c_0n_0), \tag{19}$$

$$\dot{\xi}_0=(\varphi'-\varphi'')c_0\cos\theta_0, \tag{20}$$

$$\sigma_2=i(\varphi'-\varphi'')\rho_0c_0^2N-i\varphi'''\rho_0c_0^2M(c_2n_2/c_0n_0), \tag{21}$$

$$\dot{\xi}_2=\varphi'''(c_2n_2/n_0)\cos\theta_0. \tag{22}$$

[4] Stewart and Lindsay, *Acoustics* (D. Van Nostrand Company, Inc., New York, 1930), 4th edition, Appendix III and IV.

We next seek a solution in the form

$$\sigma_2 = \alpha\sigma_0 - i\beta\dot{\zeta}_0, \tag{23}$$

$$\dot{\zeta}_2 = \alpha\dot{\zeta}_0 - i\gamma\sigma_0. \tag{24}$$

Substituting Eqs. (19) to (22) in Eqs. (23) and (24) and equating coefficients of like terms of $(\varphi' - \varphi'')$ and φ''' we obtain the following

$$\alpha = M/N, \tag{25}$$

$$\beta = (\rho_0 c_0/\cos\theta_0)(M^2 - N^2)/N, \tag{26}$$

$$\gamma = -(\cos\theta_0/\rho_0 c_0)1/N, \tag{27}$$

$$\alpha^2 + \beta\gamma = 1. \tag{28}$$

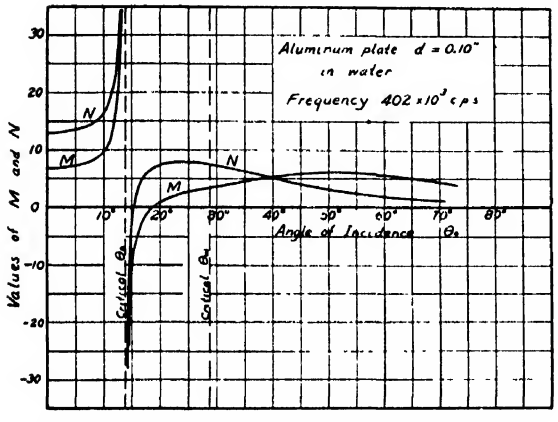

FIG. 3. Values of M and N for aluminum plate in water.

It is thus possible to write the circuit equations

$$\sigma_0 - \sigma_2 = (i/\gamma)(1-\alpha)\dot{\zeta}_2 + (i/\gamma)(\gamma\beta + \alpha - \alpha^2)\dot{\zeta}_0, \tag{29}$$

$$\sigma_2 = (-i/\gamma)(1-\alpha)\dot{\zeta}_2 + (-i/\gamma)(\dot{\zeta}_0 - \dot{\zeta}_2), \tag{30}$$

from which the equivalent circuit of Fig. 2 is obtained.

For this problem, the impedance of the fluid medium 2 is $\sigma_2/\dot{\zeta}_2 = -(\rho_2 c_2)/\cos\theta_2$ while that of medium 0 is $\sigma_0/\dot{\zeta}_0 = -(\rho_0 c_0/\cos\theta_0)(\varphi' + \varphi''/\varphi' - \varphi'')$. The circuit impedances are only functions of N, M, and the quantity $(\rho_0 c_0)/\cos\theta_0$.

Computation

The equations show that M and N contain only one singularity at the critical angle of the dilatational wave. The transmission at this angle is, however, not zero.

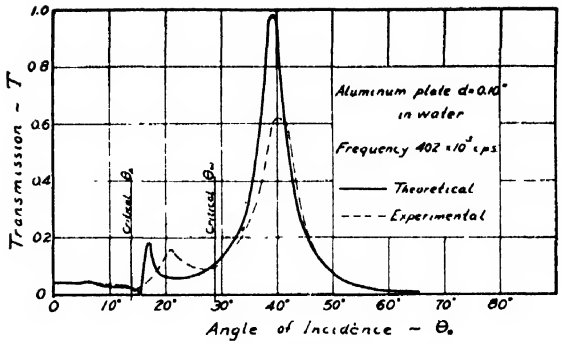

FIG. 4. Transmission curves for aluminum plate in water.

Also, for small ratios of the plate thickness to the wavelength, M and N are nearly equal for all values of θ_0, and further simplification of the transmission equations and the equivalent circuit is possible. The transmission becomes equal to zero only when $N = 0$.

Due to the rather lengthy computations involved, theoretical calculations are shown only for a single case of an aluminum plate 0.10-inch thick immersed in water with an ultrasonic beam of 402 kilocycles/sec. The thickness ratio for the plate at this frequency is $d/\lambda_\Delta = 0.1628$, which cannot be classified in the thin plate region where $N = M$. For an aluminum plate $d = 0.015$ inch at the same frequency, the curves for N and M practically coincide.

The curves for N and M shown in Fig. 3 are typical in that the singularity is evident at the critical angle of the dilatation wave and the point $N = 0$ corresponding to zero transmission occurs at a slightly larger angle. The corresponding transmission curve is shown in Fig. 4 with a comparison with experimental values taken from the dissertation* of Mr. Gerald Cohen. The transmission peak occurs near 40°, which is well beyond the critical angles for dilatation and shear. The disagreement in the peak values is evidently due to dissipation which is not accounted for in the theoretical equations.

The author is indebted to the staff of the Computing Service of the University of Wisconsin for the calculations and to the Navy Research Laboratory of the University for sponsoring the investigation carried out by Mr. Cohen.

Nine heavy lubricating oils, four light lubricating oils, three aircraft engine fuels, one diesel fuel, and distilled water were tested for their air solubility and for the rate of solution and evolution of air when equilibrium is disturbed. The technique consisted of shaking of a container partly filled with liquid and taking accurate pressure measurements of the air above the liquid. Since air in solution exerts no pressure, the variation of pressure during and after the agitation furnished information on the amount of air that went into or came out of solution and their time rates. The solution was considered to have reached equilibrium when further shaking no longer changed the air content of the liquid.

A wide variation exists in the solubility constants and rates, but the rate of evolution was always found to be proportional to the supersaturation, and the rate of solution to the undersaturation, under otherwise similar conditions. At room temperature the air solubility constant for distilled water is 1.84 percent, for a gasoline approximately 20 percent, and for (light and heavy) lubricating oils approximately 10 percent. The "half-life" for evolution on the other hand was 3.86 sec. for distilled water, 0.13–0.24 sec. for gasoline, 3.6–7.6 sec. for light, and 11.6–51.4 sec. for heavy lubricating oils.

The investigation gave some insight into the phenomenon of cavitation which is still largely shrouded in mystery.

SYMBOLS

t = Time (sec.)
p_0 = Atmospheric pressure (p.s.i.)
p = Gas pressure above the liquid generally (at time t) (p.s.i.)
p_e = Gas pressure above the liquid at the beginning of the evolution or solution process (p.s.i.)
p_e, p_e' = Equilibrium or saturation pressure (gas pressure above the liquid in case of equilibrium) (p.s.i.)
Δp = Pressure difference: $p_e - p_0$ (p.s.i.)
V_l = Volume of used liquid (cu. ft.)
V = Volume of free gas dissolved in the liquid generally (at time t) (cu. ft.)
V_g = Volume of the gas section of the container (cu. ft.)
V_e, V_e' = Volume of free gas dissolved in the liquid at equilibrium (cu. ft.)
ΔV = Volume of free gas evolved from the liquid in time t (cu. ft.)
S = Solubility constant —
r = Gas-liquid volume ratio —
R_E = Rate of evolution (1/sec.)
R_S = Rate of solution (1/sec.)
T_E = Half-life of evolution (sec.)
$(T_E)_0$ = Limiting value of half-life, if $r \to \infty$ (sec.)
T_S = Half-life of solution (sec.)
s, $(-s)$ = Supersaturation (undersaturation) —.

THREE possible relations can exist between the saturation pressure and the gas pressure above the liquid:

(a) $p_e = p_0$. Case of equilibrium. The liquid can neither release nor absorb more gas.

(b) $p_e > p_0$. Case of supersaturation. The amount of gas dissolved in the liquid is greater than the amount which would correspond to the existing gas pressure. Therefore, evolution process *can* take place.

(c) $p_e < p_0$. Case of undersaturation. The amount of gas dissolved in the liquid is less than the amount which would correspond to the existing gas pressure. Therefore, solution process *can* take place. (It will be discussed later that evolution or solution process does not necessarily take place and the existence of that depends upon several other factors.)

The case of equilibrium obeys the well-known Henry's (Henry-Dalton's) law which says that if no change in molecular structure occurs during the solution or evolution process, then the free volume of dissolved gas in the liquid is directly proportional to the absolute pressure

$$V_e = S \frac{p_e}{p_0} V_l. \tag{1}$$

Next the case of supersaturation is considered. A container is partly filled with saturated liquid and gas, the gas pressure being equal to the saturation pressure. If the gas pressure is slightly reduced, diffusion and surface evasion will take place, which will be called "quiescent evolution." No bubble formation will accompany this evolution process. Our experiments have shown that the ratio between the rates of evolution obtained under agitated and quiescent conditions is always in the thousands, therefore in the following discussion, the "quiescent evolution" will be neglected.

Considering the slowly obtained small pressure drop and neglecting the quiescent evolution, a slightly supersaturated liquid is obtained. If the container is kept at rest and the pressure is further reduced very slowly to atmospheric pressure, then a supersaturated liquid is obtained. We wish to point out that considerable (up to 100 percent) supersaturation was often produced without any bubble formation.

If the pressure drop is produced suddenly, rapid evolution does take place. The liquid surface suffers a break which is equivalent to agitation and immediate bubble formation can be observed. If the liquid is well stirred or agitated, supersaturated liquid cannot be produced. If we consider breaks in the liquid surface, caused by a sudden pressure drop, as a special sort of

* Professor of Engineering Research.
† Associate Professor of Applied Mechanics.

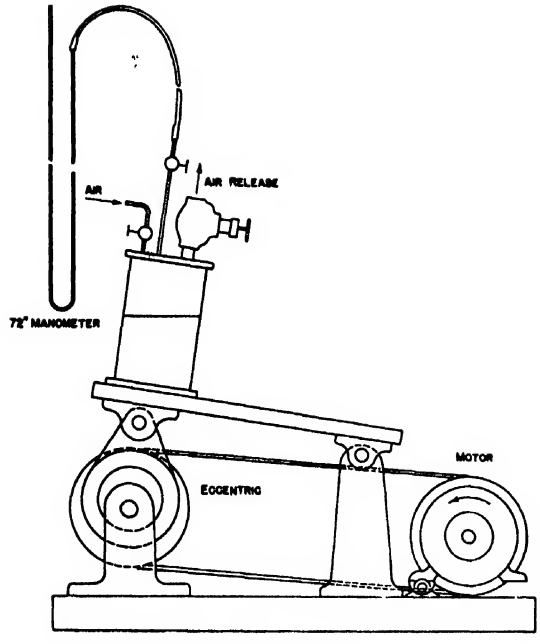

FIG. 1. Shaker.

agitation, it may be stated that bubble formation in a moderately supersaturated liquid can only set in if the liquid is agitated.

RATE OF EVOLUTION

The rate of evolution is defined as the time rate of change of the volume of free gas in solution per unit volume of the liquid

$$R_E=\frac{d}{dt}\left(\frac{V}{V_l}\right). \tag{2}$$

In order to obtain the $V(t)$ function, the following experiment was done:

First the p_e equilibrium or saturation pressure was slowly reduced to p_g, keeping the container in rest and so avoiding any bubble formation. Then agitation was started, such as shaking of the container as shown in Fig. 1. A cylindrical container of 3400 cc was shaken with a frequency of 400 cycles per minute and with a stroke of one inch. With the agitation, the evolution process starts and gas leaves the liquid. To measure the volume of the evolved gas, two methods have been used.

In the direct method, the gas pressure before the evolution process would start, must be brought to atmospheric: $p_g=p_0$. The container then is closed and connected with a volume measuring instrument. The amount of evolved air is recorded as a function of the time, keeping the pressure above the liquid always atmospheric. The original volume of dissolved air (before agitation) can be computed from formula (1). If the instantaneously recorded volume of evolved free gas is V_m, then

$$V=V_e-V_m.$$

Because accurate instantaneous recording of V_m involved experimental difficulties, we used an indirect method based on pressure measurement. The gas pressure above the liquid pressure was reduced from p_e equilibrium pressure to p_g gas pressure, which in this method need not be atmospheric. Then the container was closed and connected to a manometer. The effect of agitation was that the pressure (p) increased from p_g to a new equilibrium pressure p_e'. Obviously $p_g<p_e'<p_e$, i.e., the new equilibrium pressure is greater than the reduced gas pressure, but less than the original equilibrium pressure; they are related by Eq. (3):

$$V=S\frac{p_e'}{p_0}V_l-\frac{p-p_e'}{p_0}V_g. \tag{3}$$

The p_e' final equilibrium pressure can also be predicted from the equilibrium equation as:

$$p_e'=\frac{V_g p_g+V_l S p_e}{V_g+V_l S}=\frac{r p_g+S p_e}{r+S}.$$

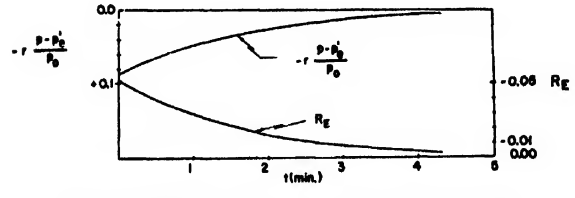

FIG. 2. Pressure *vs.* time and rate *vs.* time curves for lubricating oil.

Substituting Eq. (3) in Eq. (2), the rate of evolution is

$$R_E=-r\frac{d}{dt}\frac{p-p_e'}{p_0}.$$

Knowing r, p_e', p_0 and measuring p, the rate of evolution, R_E, can be obtained as a function of the time by graphical differentiation.

Such a plot, for a lubricating oil, is shown in Fig. 2. As the pressure appears to approach the saturation pressure p_e', the rate of evolution R_E is approaching zero.

It did not seem unreasonable to assume that the rate of evolution is always proportional to the supersaturation (and the rate of solution to undersaturation):

$$R_E=kS=k\frac{V_e'-V}{V_l}. \tag{4}$$

If this were the case Eq. (2) could be integrated with the result:

$$\frac{d}{dt}\left(\frac{V}{V_l}\right)=k\frac{V_e'-V}{V_l}$$

$$V=(V_e-V_e')e^{-kt}+V_e'. \tag{5}$$

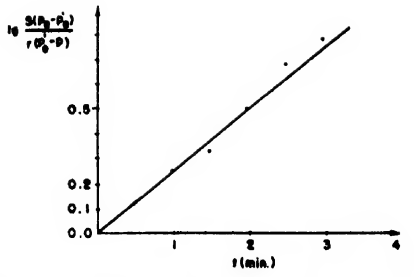

FIG. 3. Pressure *vs.* time curve plotted on semilog base.

If assumption (4) is correct then plotting $\lg(V-V_e')$ against time t should give a straight line. After a simple transformation we get in place of Eq. (5)

$$-\frac{p-p_e'}{p_0}=-\frac{S}{r}\frac{p_e-p_e'}{p_0}e^{-kt}, \tag{6}$$

therefore plotting $\lg[S(p_e-p_e')/r(p_e'-p)]$ against t should also give a straight line which should go through the origin.

Figure 3 shows a plot for the above mentioned lubricating oil which was selected at random. In the course of the tests performed on 18 liquids some 150 of such plots were made for both solution and evolution runs. Except for slight inaccuracies, attributable to experimental errors, all turned out to be straight lines going through the origin. The conclusion was clear: the rate of evolution *is* proportional to the supersaturation (the rate of solution to the undersaturation) and represents, therefore, an exponential function of time.

Inspecting Eq. (5) it is seen that at zero time $V=V_e$ and if $t\to\infty$, $V\to V_e'$. Finally the total evolved gas is V_e-V_e' but infinite time is required for its evolution. Consider the time required for the evolution of one-half of the total evolved gas $(V_e-V_e')/2$ and designate it by the symbol T_E. When $t=T_E$, $V_e-V=(V_e-V_e')/2$, therefore from Eq. (5)

$$k=\frac{ln2}{T_E}=\frac{0.693}{T_E}. \tag{7}$$

T_E is designated "half-life" of evolution and is equal to the time required to half complete the gas evolution. With this new designation the gas content of the supersaturated liquid is:

$$V=(V_e-V_e')\exp\left(-0.693\frac{t}{T_E}\right)+V_e'. \tag{8}$$

In an actual case the V_e and V_e' values are not known —at least they have to be computed using the

$$V_e=S\frac{p_e}{p_0}V_l \quad \text{and} \quad V_e'=S\frac{p_e'}{p_0}V_l$$

formulas. Equation (8) can be transformed to a more useful form

$$V=\frac{S}{r+S}\frac{V_l}{p_0}\left[r(p_e-p_0)\exp\left(-0.693\frac{t}{T_E}\right)+rp_0+Sp_e\right]. \tag{9}$$

With formula (9), V, the value of free gas still dissolved in the liquid at time t can be evaluated. In many engineering applications, however, it is more important to know the amount of the evolved gas from $t=0$ to $t=t$; $\Delta V=V_e-V$. This is given by:

$$\Delta V=\frac{Sr}{S+r}\frac{p_e-p_0}{p_0}V_l\left[1-\exp\left(-0.693\frac{t}{T_E}\right)\right]. \tag{10}$$

Formula (10) furnishes two as yet unmentioned results. The $Sr/(S+r)$ factor can be represented by hyperbolas going through the origin, whether S or r is considered as the variable.

Due to the fact that the asymptotes are parallel with the horizontal axis, the effect of change in r (keeping S constant) is appreciable if r is small, but it can be neglected if r is great, (Figure 4.). For thin liquid layers $(r\to\infty)$ the $Sr/(S+r)$ value is represented by S. The last factor, $1-\exp(-0.693\,t/T_E)$ is the well-known exponential function starting with zero value at time zero and approaching to 1 if $t\to\infty$.

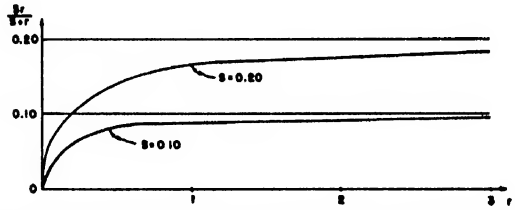

FIG. 4. The $Sr/(S+r)=f(r)$ hyperbolas for different S values.

The initial tangent (at $t=0$) to the curve is $0.693/T_E$ which together with Fig. 5 show that if the half-life time is great the evolution is slow.

An example with actually obtained values explains better the $V=f(t)$ function.

For the heavy lubricating oil referred to, the solubility constant S was 0.0815 with respect to air. The used air-oil volume ratio was $r=2$. The measured half-life was $T_E=1.205$ min. The volume of used liquid was $V_l=63.5$ cu. in. The initial saturation pressure was $p_e=38.45$ p.s.i.g. and the air pressure above the oil $p_0=21.86$ p.s.i.g.

With the above figures from formula (10):

$$\Delta V=5.6[1-\exp(-0.575t)]$$

if ΔV is in cu. in. and t in minutes. Formula (9) gives the free volume of air in solution. Substituting the numerical values: $V=5.6\exp(-0.575t)+13.1$.

Figure 6 shows the volume of evolved air and Fig. 7 the volume of air in solution in function of time.

Going back to the definition of the rate of evolution and substituting in formula (2) for V the value obtained in formula (9), it is found that the rate is a function of the half-life (T_E), of the solubility constant (S), of the gas-liquid ratio (r), of the pressure difference ($p_e - p_0$), of the atmospheric pressure (p_0) and of the time (t). It was investigated experimentally whether these variables are related to each other or are independent. It was found that the half-life is related to the gas-liquid ratio and the solubility constant but none of the other variables involved are related to each other.

For a given liquid and gas combination S is the only constant with which the evolution process can be described inasmuch as S is not a function of the other variables. Even the solubility constant varies with temperature, but in this investigation the temperature was kept constant. For the same gas-liquid combination, the half-life varies with the gas-liquid volume ratio. Therefore half-lives can be compared only at a certain r

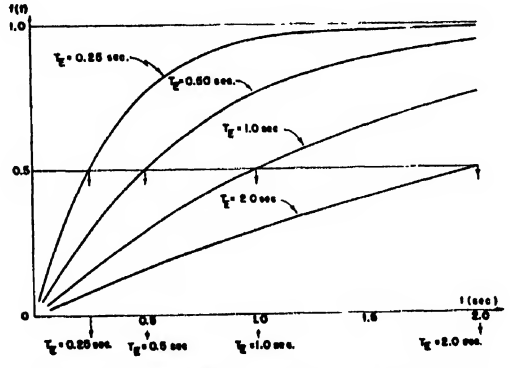

FIG. 5. The $1-e^{-0.693(t/T_E)}=f(t)$ exponential curves for different T_E values.

value. Obviously the half-life depends also upon the method of agitation, therefore a standardized agitation is required in order to compare data. It was found that the relation between T_E and r can be described with an exponential function. Increasing the gas-liquid volume ratio by varying r from very small values up to 4.5 the following relation was indicated:

$$T_E=(T_E)_0/(1-e^{-cr}),$$

where $(T_E)_0$ is limiting value of half-life if $r\to\infty$, i.e., if we deal with a very thin liquid film, and c is a constant. On the other hand, keeping r constant, a relation is expected between the half-life, solubility constant, viscosity, density, surface tension, etc. These investigations are extended to other details too and at the present time are conducted at the Virginia Polytechnic Institute, Department of Applied Mechanics.

SOLUTION

After the foregoing detailed discussion of the evolution process, the solution process can be settled very shortly. In the solution process a disturbed undersaturated liquid is approaching to an equilibrium condition. The analogy between evolution and solution processes is complete, therefore the same letters and steps can be used in deriving the same formula.

The gas pressure above the liquid p_g is now greater than the saturation pressure p_e. Closing this p_g pressure in the container and connecting it with a manometer or pressure gauge, after an agitation, the p_g pressure will drop to a p_e' new equilibrium pressure and some of the gas originally above the liquid will be dissolved. The definition of the rate of solution is $R_S=d/dt(V/V_l)$. The rate of solution will always be positive, due to the fact that the free volume of dissolved gas is increasing if the time is increasing. During the solution process, the pressure drops from p_g to p_e' and $p_g>p_e'>p_e$.

The $T_E(r, S)$ function was discussed already and the same can be said about the $T_S(r, S)$ function. It should not be a surprise however that using the same liquid and gas (S) as well as the same gas-liquid volume ratio (r) for an evolution and a solution process, the half-lives will not be the same. The experiments performed showed that with no exception the half-life for evolution was always shorter than that for solution, which means that the evolution process is quicker than the solution process. This difference between T_S and T_E can be explained by considering the mechanism of evolution and solution. The mechanism actually changes the effective value of r during the evolution process by exposing more surface through bubble formation, but it results in only negligible changes in r during solution. A detailed analysis of this question will be published in another paper.

RESULTS

The experimental investigation included 18 liquids and one gas, air. The liquids tested were heavy and light lubricating oils, a diesel fuel, distilled water and aircraft engine fuels. The smallest value of the solubility constant (1.84 percent) was obtained for water. For heavy lubricating oils it varied between 7.75 percent and 9.18 percent, for light oils between 9.70 percent and 11.30 percent. For the tested diesel fuel S was roughly 12 percent and the maximum obtained

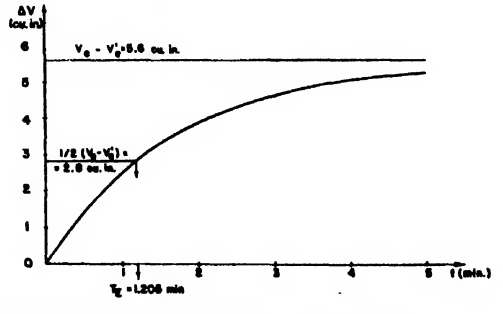

FIG. 6. Volume of evolved air for heavy lubricating oil *vs.* time. Half-life, $T_E=1.205$ min.; $S=0.0815$; $r=2$; $V_l=63.5$ cu. in.; $p_e=38.45$ p.s.i.g.; $p_g=21.86$ p.s.i.g.

value of S was 25.14 percent in case of an aircraft engine fuel.

Discussing results obtained regarding half-lives, first a standard agitation has to be established, then a certain gas-liquid ratio has to be decided at which the values can be compared. The following values of half-lives correspond to a gas-liquid ratio, $r=4$. The frequency used was 400 cycles per minute and the stroke one inch. Without any special temperature controlling equipment the results were reproducible; the usual room temperature variations did not seem to effect the results.

For heavy oils, the solution and evolution process is slow, therefore the half-lives are long. As it was explained, the evolution process is quicker than the solution. The shortest half-lives were obtained for evolution of fuels (0.128 sec.) and the longest for solution of heavy oils (414.0 sec.). In Table I the solubility constants and the half-lives for solution as well as for evolution are shown for the tested liquids.

From the tabulated data, the behavior of the liquids can be predicted after a brief and simple computation.

RELATION BETWEEN CAVITATION AND GAS EVOLUTION

In ordinary practice liquids display no tensile strength and when the absolute pressure in a liquid drops below zero, the liquid tears apart. In fact, discontinuity in the form of vapor-filled bubbles, usually occurs as soon as the pressure in the liquid is reduced to its vapor pressure. Hence, cavitation is generally associated with the vapor pressure of the liquid and is expected to take place whenever and wherever the hydraulic pressure reaches vapor pressure.

Our observations with bubble formation have convinced us that this widely held view generally is incorrect, though it appears to be valid under certain specific circumstances.

Cavitation is failure (of continuity) of the liquid in tension. Like failure in solids, it is largely controlled by contamination and surface conditions. The true tensile strength of liquids (no contamination and no surface flaw) is extraordinarily high. Our information on the tensile strength of liquids is very limited because of the practical difficulty of subjecting a column of pure liquid to tension. The great difference between solids and liquids is not so much in their tensile strengths, but in their shearing strength. To test a solid rod in tension we clamp its two ends and pull them apart. The absence of shearing strength prevents us from clamping a liquid column. A liquid cannot be handled without a container. The adhesion between the liquid and the container is frequently less than the cohesion between the liquid particles themselves. Under such circumstances, the true negative pressure which is necessary to tear liquid particles apart cannot be determined. Such tests can yield only a minimum value because in measuring the tensile strength of a chain one learns something about its weakest link, nothing more.[1]

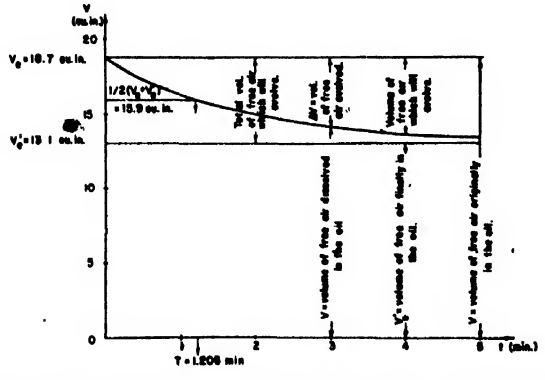

FIG. 7. Free volume of air in solution for heavy lubricating oil *vs.* time. (Specifications same as on Fig. 6.)

The weak link may be somewhere else. If the liquid is not completely degassed, it will usually contain some entrained air in the form of microscopic or submicroscopic bubbles either in the bulk of the liquid or near a solid contaminant or near the container wall. Such a bubble, whatever its size, represents on the one hand a flaw within the liquid and on the other hand, an adjacent gas phase into which dissolved gas can diffuse or liquid vapor can evaporate. Under such a condition, visible cavitation (macrocavitation) will take place easily and promptly. However, this represents a "false cavitation in which the cavities were derived from pre-existing gas nuclei rather than de novo."[2]

In spite of all these experimental handicaps it has been shown[2,3] that liquid water can stand a negative pressure of 50 atmospheres and more without visible failure.

Weyl and Marboe[1] tested the gas release from water saturated with carbon dioxide at atmospheric pressure. They subjected the CO_2 saturated water to a partial vacuum. When the liquid was held in an ordinary "clean" glass container, a pressure drop from 760 to 50 mm Hg abs. readily produced gas bubbles. However, if the glass container was thoroughly cleaned with dichromate-sulphuric acid solution, bubbles failed to appear upon evacuation. Clean glass powder in the liquid did not cause the release of gas bubbles either, but glass powder which had been exposed to laboratory air for a short time did. Also when the surface of the container was not thoroughly cleaned, release of gas supersaturation promptly accompanied the drop in pressure. This directed attention to the chemical structure of the contacting phases.

In our tests the container used was made of steel and Lucite. No precaution was made to have them chemically clean. With water we were unable to produce any appreciable supersaturation without observing bubble formation. However, with petroleum hydrocarbons,

[1] Weyl and Marboe, Research **2**, 19 (1949).
[2] Pease and Blinks, J. Phys. Colloid Chem. **51**, 556, No. 2 (1947).
[3] E. N. Harvey, J. App. Phys. **18**, 161 (1947).

which wet both steel and Lucite, we observed considerable supersaturations (100 percent) without bubble release, provided the liquid was kept in a quiescent state. However, when the liquid was agitated, gas supersaturation was released rapidly.

Gas may be present in a liquid in two forms, dissolved gas and entrained gas. The dissolved gas is actually no gas at all. It is invisible (the liquid is clear), and does not increase its volume and compressibility by any appreciable amount. Entrained gas is dispersed in the liquid in the form of bubbles which may give the liquid a turbid appearance. The equilibrium amount of entrained air (or ambient gas) in a quiescent liquid is zero. Churning tests showed that it reaches a maximum at certain degree of agitation and decreases again when that degree of agitation is exceeded.

From these observations the following picture emerges. No vapor-cavitation can take place without entrained air (or other gas) in the liquid. As soon as there is an air bubble, that bubble promptly fills up with vapor, provided the hydraulic pressure in the liquid is lower than its vapor pressure. As long as there is no air bubble, no vapor can form (except on the surface if the liquid has one). Evaporation takes place when liquid in the vapor phase leaves the liquid in the liquid phase. This requires an interface. Vapor cannot leave the liquid unless it goes some place. If there are air bubbles, it goes into the air bubbles through the liquid-air interface. Without air nuclei there is no evaporation (except on top surface if there is one) and no cavitation. With air nuclei present, bubble growth through gas release will set in as soon as the hydraulic pressure drops below the saturation pressure which corresponds to the air actually held in solution.

It has generally been observed that in flowing water cavitation bubbles appear whenever and wherever the hydraulic pressure drops below the vapor pressure of the water, approximately 0.36 p.s.i.a. at 70°F. This observation is the consequence of two extraneous circumstances. The first is that flowing water always contains some entrained air in the form of small bubbles either in the bulk of the liquid or adjacent to solids in contact with the water. The second is that in water, having a low air solubility, the release of dissolved air (rate of evolution) is very slow if the pressure is reduced a small amount from the saturation pressure. Therefore, the bubble growth is very slow. If the bubbles were submicroscopic at the start of the experiment (at saturation pressure), they will remain submicroscopic when the pressure is reduced a small fraction of an atmosphere. However, when the pressure reaches the vapor pressure, there is a relatively fast vapor release into the air bubbles and then their growths become visible to ordinary observation. The term "cavitation" is frequently applied to this phase of bubble growth. Then cavitation appears to set in at a locality where the pressure of the flowing water drops below its vapor pressure.

TABLE I. Summary of experimental results.

		Solubility constant (%)	Half-life at $r=4$ for evolution solution (seconds)		Kin. viscosity at 70°F (centistokes)
1	Heavy lubricating oil	7.75	51.4	414	823–974
2	Heavy lubricating oil	8.14	43.0	292	823–974
3	Heavy lubricating oil	8.15	45.0	386	762–974
4	Heavy lubricating oil	8.24	48.2	396	762–974
5	Heavy lubricating oil	8.61	37.2	244	762–974
6	Heavy lubricating oil	8.62	34.8	252	562–670
7	Heavy lubricating oil	9.05	31.0	125.4	325–411
8	Heavy lubricating oil	9.11	17.9	50.2	249–346
9	Heavy lubricating oil	9.18	11.6	32.7	88.7

18	Distilled water	1.84	3.86	7.930	1.0

In order to accurately describe what takes place it is necessary to define our terms. A liquid is considered to be in *equilibrium* when its content of dissolved gas is constant with respect to time. *Cavitation* is any discontinuity in the bulk of the liquid, irrespective of the size of the cavity and whether it is filled with void, gas, or vapor. *Microcavitation* refers to bubbles of microscopic or submicroscopic size. *Macrocavitation* refers to visible bubbles. The liquid is *quiescent* when all of its parts are at rest relative to the container, except for their thermal motion. The liquid is in *agitation* when some or all of it is not quiescent.

With these definitions:

1. A liquid is in equilibrium if it has been either quiescent or under an invariable type of agitation for a sufficient length of time to assume saturation in all parts. The equilibrium is upset if either the pressure or the temperature changes locally or in the whole.

2. A quiescent liquid in equilibrium with air has a zero amount of entrained air and a saturation amount of dissolved air.

3. An agitated liquid in equilibrium has a certain amount of entrained air and a saturation amount of dissolved air.

4. A quiescent liquid, originally in equilibrium, will not cavitate until it is subjected to a negative pressure which is equal to the tensile strength of the liquid (not less than −750 p.s.i. for water).

5. A liquid in agitation and exposed to air for any length of time cavitates continuously inasmuch as it contains entrained air in the form of nuclei (microcavitation).

6. In the bulk of the liquid (a place other than the surface) neither gas evolution nor vapor evolution can take place in the absence of gas nuclei (microcavitation).

7. In an originally gas free liquid, microcavitation may set in (1) if air is introduced into it under the surface, (2) if the liquid is supersaturated *and* has chemically weak bonds with the container wall or solid contaminants, (3) if it is subjected to agitation.

8. Microcavitation will turn into macrocavitation as a result of either gas evolution, or vapor evolution, or both. Gas evolution begins at any pressure lower than saturation pressure; vapor evolution begins only below the vapor pressure of the liquid.

This explains the behavior of flowing water under ordinary conditions. Under some agitation the water contains a certain amount of entrained air in the form of microscopic or submicroscopic bubbles which are invisible. Ordinarily it also contains some air nuclei in the microscopic crevices of the container, submerged

solids, and solid contaminants. If the hydraulic pressure drops slightly, in the whole or at certain localities, slow evolution of dissolved air will follow which may be undetectable by ordinary observation. If the pressure drops suddenly, air evolution is accelerated and bubble growth may become observable before the rising bubbles reach the top surface of the water. Such bubbles will appear first near solid surfaces, not only because the hydraulic pressure usually is the lowest at such spots, but also because the chemical bonds there are weaker than the cohesion between the water molecules. If the pressure drops below the vapor pressure of the liquid, evolution of vapor into the nuclei will begin at a relatively high rate, thus resulting in fast bubble growth. Frequently this is regarded as the beginning of incipient cavitation.

With liquids other than water, or quiescent water, or with pure denucleated water flowing in a chemically clean container, the walls of which are well wetted by the water (hydrophilic material), cavitation will not, as a rule, begin at vapor pressure. A much lower pressure is required to start microcavitation and a higher than vapor pressure is sufficient to turn microcavitation into macrocavitation, both depending on exterior circumstances.

This investigation was done in 1948 and 1949 at the sponsorship of the Air Materiel Command U. S. Air Force.

Electrical Conductivity Method for Measuring Self-Diffusion of Metals

J. H. DEDRICK*
Sylvania Electric Products, Inc., Bayside, New York

AND

G. C. KUCZYNSKI
Bogota, Colombia

(Received May 29, 1950)

A method has been proposed to measure self-diffusion in metals by measurement of the contact conductance of an interface between two metallic spheres or hemispheres. By combining Kuczynski's equation for self-diffusion with Bowden and Tabor's equation for the contact conductance between two metallic spheres a relationship has been obtained between contact conductance and the time of heating of the spheres. Thus by measurement of junction conductance as a function of time of heating, for different temperatures, diffusion coefficients and the heat of self-diffusion can be evaluated in the normal manner. A similar relationship has been obtained for two spheres or hemispheres initially pressed together to give a known contact conductance before heating.

ONE of the authors[1] developed a theory of sintering, verified by extensive experimental work, showing that the initial bonding of like metallic particles upon heating is a volume diffusion process. The relationship developed was

$$X^6/a^2 = 40\sigma\delta^3/kT \cdot Dt, \qquad (1)$$

where X is the radius of the interface between the particles (assumed to be circular) a the original radius of the particles, σ the surface tension of the material, δ the interatomic jump distance, k the Boltzman constant, T the absolute temperature, t the time, and D the coefficient of self-diffusion. This relationship shows that the fifth power of the interface radius between the particles is proportional to the time of sintering. Values of D, D_0 (frequency factor) and Q (heat of self-diffusion) obtained in this manner on copper and silver agree well with those obtained by radioactive tracer methods.

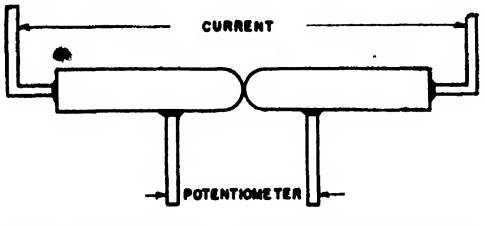

FIG. 1. Method of measuring junction conductance.

The technique used to measure the interface radius as a function of time for a given temperature was to sinter spherical metallic particles to a base plate and to measure the radius by metallographic means. This method was later changed by using wire wound around a mandrel of the same material. The use of blown-up low magnification photographs has also been resorted to for measuring contact radii of particles.[2] In this case a single close packed layer of particles was used.

This article relates to another method which might be used to measure heats of self-diffusion and self-diffusion coefficients based upon a relationship between Eq. (1) and the contact conductance of an interface between two metallic spheres or hemispheres.

* Now at Reynolds Metals Company, Louisville, Kentucky.

[1] G. C. Kuczynski, "Self-Diffusion in sintering of metallic particles," Metals Trans. 169–178 (February, 1949).

[2] J. H. Dedrick and A. Gerds, J. App. Phys. 20, 1042–1044 (1949).

Bowden and Tabor[3] in their work on measurement of the area of contact between stationary surfaces, have shown that the junction conductance (C_j) between two metallic spheres of radius a, or crossed cylinders, joined at the contact by a circle of radius X, where X is small compared to a, is given by

$$C_j = 2\lambda X, \tag{2}$$

where λ is the specific conductance of the bulk material. Using crossed cylinders of silver (0.90-cm radius) and increasing the contact area by varying the load, they found a direct proportionality between conductance and contact radius up to a value of the latter of 0.08 cm which is approximately 18 percent of the cylinder radii.

By combining (1) and (2) the following relationship is obtained between junction conductance and time of heating of two spheres or two hemispheres in contact with each other:

$$\frac{(C_j/2\lambda)^5}{a^2} = 40\sigma\delta^3/kT \cdot Dt. \tag{3}$$

Thus from measurements of junction conductance as a function of time of heating, for different heating temperatures, D values could be obtained and D_0 and Q evaluated in the normal manner. This method makes it unnecessary to resort to metallographic work, and one set of specimens could be used for different times of sintering at a given temperature. The possibility of continuous recording of junction conductance as a function of time of heating also presents itself. A schematic sketch for the measurement of the junction conductance between two hemispherically ended specimens is shown in Fig. 1.

The discussion up to this point has been based upon the assumption that the initial point junction conductance will be very low and thus neglected. However, if this is not so, a different mode of attack would have to be resorted to and it appears that the simplest approach would be to initially press the spheres or hemispheres together with a certain force and thus produce an initial junction radius X_0, as shown in Fig. 2, from which the initial junction conductance C_j^0, prior to heating, could be measured.

In this case, it would be necessary to use the following

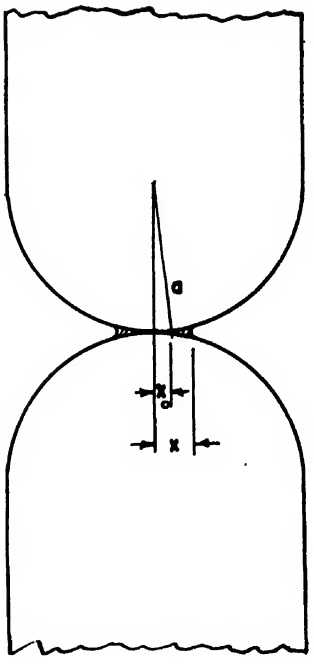

FIG. 2. Sketch of contact junction between two pressed hemispherical ended rods.

relationship based upon the geometry of the figure:

$$\frac{X^5 - X_0^5}{5} - 2X_0^2\frac{X^3 - X_0^3}{3} + X_0^4(X - X_0) = At, \tag{4}$$

where $A = (40\sigma\delta^3)/kT(a - X_0)^2D$, and which reduces to (1) when X_0 equals zero. If X is not very much larger than X_0 (4) can be written as $(4/3)X_0^2(X - X_0)^3 = At$, or

$$X = X_0\left\{1 + \left(\frac{3A}{4X_0^5}\right)^{\frac{1}{3}} t^{\frac{1}{3}}\right\}, \tag{5}$$

and by combining (2) and (5), one obtains

$$C_j = C_j^0\left\{1 + \left(\frac{24A^5}{(C_j^0)^5}\right)^{\frac{1}{3}} t^{\frac{1}{3}}\right\},$$

or

$$C_j = C_j^0\{1 + Kt^{\frac{1}{3}}\}, \tag{6}$$

where K is a constant for a given material, for a given temperature of heating and a known initial junction conductance. Thus as in the case of initially unpressed spheres or hemispheres, measurements of junction conductance as a function of time, for different heating temperatures will allow for determination of D values and evaluation of D_0 and Q.

A Simple Interferometric Test for Conical Flow

J. H. Giese, F. D. Bennett, and V. E. Bergdolt
Ballistic Research Laboratories, Aberdeen Proving Ground, Maryland
(Received May 3, 1950)

In conical flows the velocity, pressure, and density do not vary on lines through the vertex of the cone. In this paper it is shown that for interferograms of general conical flows $\delta(y, z)/z=f(y/z)$, where y and z are any set of Cartesian coordinates with origin at the image of the vertex of the cone, and δ is the fringe shift at y, z. Thus, for strictly conical flow, a graph of $\delta(y, z)/z$ *versus* y/z should be a single curve. This suggests a test for approximate conicity that requires very little computation. This test is applied to interferograms obtained from a number of approximately axisymmetric flows at various Mach numbers about cone-cylinders in free flight. Plotted fringe shift data from the region near the nose fall into a narrow band, an indication of approximate conicity. They also closely check the corresponding theoretical fringe shift curve calculated for Taylor-Maccoll flow.

I. INTRODUCTION

INTERFEROMETRY offers an extremely attractive technique for investigation of gas flows. When it can be employed, an extensive region of the flow field can be surveyed almost instantaneously without disturbing the flow. Accordingly, it is well suited for examining supersonic flows about objects in free flight, as well as those about stationary models in wind tunnels. If the flow is plane or axisymmetric, the density distribution can be computed from fringe shifts observed on an interferogram, though the latter case involves formidable amounts of calculation. At present the quantitative interpretation of interferograms in less symmetrical flows, such as those about yawing bodies of revolution or about more general shapes, seems to be limited to the comparison of measured and theoretical values of fringe shifts. The calculation of theoretical fringe shifts for general flows with little or no symmetry is difficult and tedious at best, and the results depend so strongly on the shape of the body and its orientations relative to the incident stream and the interferometer beam that it seems impossible to reach interesting general conclusions without actually performing the computations. In the important special case of conical flow, however, one can easily make a useful deduction about the functional form of the theoretical fringe shift. Before this is derived, a brief digression on conical flow seems apropos.

A steady flow of a fluid with no viscosity or heat conduction is said to be *conical* if the velocity components, pressure, and density do not vary along lines emanating from some fixed point, which will be called the *vertex*.[1–3] The use of these terms is justified intuitively by applying similarity considerations to flows about one infinite nappe of a general cone placed in a uniform supersonic incident stream. If the vertex of the flow is placed at infinity, plane and swept-back plane flows result.[1] Owing to the remarkable geometrical structure of conical flow, its theory is considerably simpler than that of more general three-dimensional flows and has been developed to a much greater extent. The best known examples of non-linearized conical flows with vertices at finite locations are Taylor-Maccoll flow about a non-yawing right circular cone;[2–4] Prandtl-Meyer expansion around an edge;[3] and the flow over a wedge with attached plane shock wave.[3] The linearized theory has been applied by numerous authors to determine flows over objects ranging from elliptic cones to delta-wings.

The great theoretical interest and value of conical flows make it essential to determine how closely they correspond to flows that can actually be produced in real fluids. The commonest type of test is a measurement of the pressure distribution on the surface of a conical model in a supersonic wind tunnel.[4] Under good test conditions, the pressure is found to be reasonably constant on lines through the vertex of the model, and the observed pressures check the available linearized or non-linearized theoretical values to within a few percent. For flows about cones of revolution and wedges, measured and theoretical shock wave angles have also been compared.[4] As far as interferometry is concerned, Ladenburg[5] has found contours of constant density in the flow about a cone of revolution in an approximately axisymmetric jet. At large enough distances from the vertex of the cone, his measured densities are very nearly constant on radial lines through the vertex and check the theoretical Taylor-Maccoll values to well within two percent.

In this paper a test for conicity, based directly on interferogram fringe shifts, will be developed and applied to data obtained from conical regions in flows about bodies in free flight.

II. THEORETICAL CONSIDERATIONS

A. Functional Form of Fringe Shift

The following reasoning leads to a simple method for interpreting interferograms of general conical flows. Let

[1] A. Busemann, Luftfahrtforschung 12, 210–220 (1935).
[2] A. Busemann, Zeits. f. angew. Math. Mech. 9, 496–498 (1929).
[3] A. Ferri, *Elements of Aerodynamics of Supersonic Flows* (New York, 1949), Chapters 2, 3, 12.
[4] G. I. Taylor and J. W. Maccoll, Proc. Roy. Soc. A139, 278–311 (1933).
[5] Ladenburg, Winckler, and Van Voorhis, Phys. Rev. 73, 1359–1377 (1948).

the vertex of the flow be at the origin of a system of rectangular coordinates. Assume that the interferometer beam that traverses the flow is parallel to the x-axis, while the photographic plate is normal thereto, so the projections of the y- and z-axes onto the plate define rectangular coordinates with origin at the image of the vertex. At (y, z) on the plate, in the absence of magnification, the fringe shift $\delta(y, z)$ is defined by

$$\delta(y, z) = (K/\lambda) \int_{a(y,z)}^{b(y,z)} [\rho(x, y, z) - \rho_u] dx, \qquad (1)$$

where ρ_u is the density of the undisturbed fluid, assumed constant; $\rho(x, y, z)$ is the actual density at (x, y, z); K is the Gladstone-Dale constant for the fluid, i.e., the ratio of small increments of index of refraction to the corresponding small increments of density; λ the vacuum wave-length of the light used to form fringes; and the limits of integration $a(y, z)$ and $b(y, z)$ are the x coordinates of the points where the light ray through (y, z) crosses the conical shock wave, outside of which $\rho(x, y, z) = \rho_u$. For any $t > 0$

$$\delta(ty, tz) = (K/\lambda) \int_{a(ty,tz)}^{b(ty,tz)} [\rho(x, ty, tz) - \rho_u] dx.$$

Since the flow is conical, $\rho(x, ty, tz) = \rho(x/t, y, z)$, and since (ty, tz), (y, z), and $(0, 0)$ are collinear, $a(ty, tz) = ta(y, z)$, and $b(ty, tz) = tb(y, z)$. Hence

$$\delta(ty, tz) = (K/\lambda) \int_{ta(y,z)}^{tb(y,z)} [\rho(x/t, y, z) - \rho_u] dx.$$

Let $\xi = x/t$ to obtain

$$\delta(ty, tz) = t(K/\lambda) \times \int_{a(y,z)}^{b(y,z)} [\rho(\xi, y, z) - \rho_u] d\xi = t\delta(y, z), \qquad (2)$$

i.e., $\delta(y, z)$ is homogeneous of degree one. Now let $t = 1/z$, to find $\delta(y, z)/z = \delta(y/z, 1) = f(y/z)$ for some function f. Hence, *for conical flow a plot of* $\delta(y, z)/z$ *versus* y/z *should be a curve*,* a conclusion that can also be obtained from similarity considerations. To test a flow qualitatively for conicity by means of an interferogram, it suffices to measure $\delta(y, z)$ as a function of y on a series of traces $z =$ constant, and to observe how closely the points y/z, $\delta(y, z)/z$ come to falling on a curve. Since this procedure involves very little computation with the measured data, it can be used advantageously in either the axisymmetrical or non-axisymmetrical conical case.

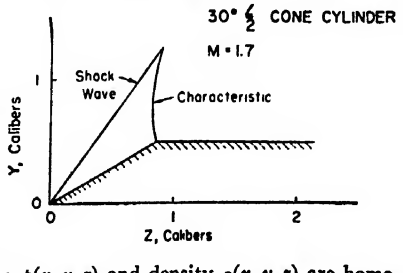

FIG. 1. Theoretical conical flow region.

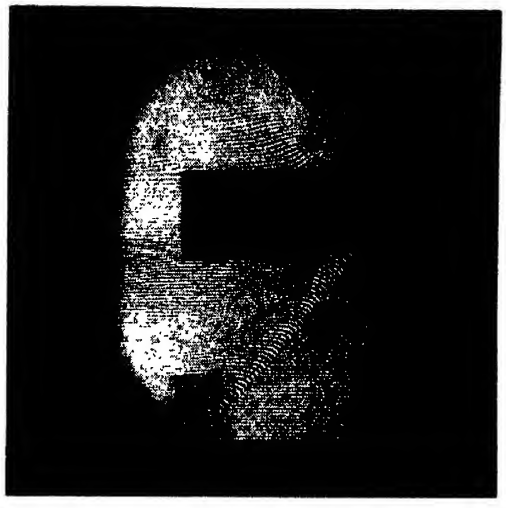

FIG. 2. Interferogram of cal. 30, 30° half-angle cone cylinder, $M = 1.7$, $p = 1$ atmos., room temperature.

B. Flows Containing Conical Regions

Let us turn, now, to the problem of producing an approximately conical flow to which to apply this test. Earlier remarks suggest the use of a conical model. If the flow is supersonic, the effects of the disturbance produced by ending the cone at some finite distance from its vertex will merely be propagated downstream without influencing conditions near the vertex. Thus at supersonic speeds high enough to assure the presence of an attached conical shock wave, the flow about a conical model in a wind tunnel or about a projectile with a conical nose should contain a finite region of conical flow bounded by the following surfaces as indicated in Fig. 1: a conical segment of the shock wave; the conical part of the model's surface; and a characteristic surface through the curve at which the physical cone ends. In particular, if the model is axisymmetric and does not yaw, then near its vertex there will be a region of Taylor-Maccoll flow.

C. Taylor-Maccoll Fringe Shifts

In order to provide a quantitative comparison for the measurements of flows about cone-cylinders that will be presented later, theoretical fringe shift curves will be required. These can be computed as follows: In conical flow that is axisymmetric about the z-axis,

$$\rho = \rho(\theta), \quad \tan^2\theta = (x^2 + y^2)/z^2,$$

$$\lambda\delta(y, z)/2K\rho_u z = \int_0^b (\rho(\theta)/\rho_u - 1) dx/z$$

* Since the pressure $p(x, y, z)$ and density $\rho(x, y, z)$ are homogeneous of degree zero, plots of $(p - p_u)/\frac{1}{2}\rho_u q_u^2$ or of ρ/ρ_u (where ρ_u and q_u are the density and speed of the undisturbed flow) *versus* y/z on a surface $x/z = f(y/z)$ should also be curves. Of course, such plotting is equivalent to testing for constancy of p and ρ on lines through the vertex.

where $b^2=z^2\tan^2\theta_w-y^2$; $\tan\theta_s \leqq y/z \leqq \tan\theta_w$; and θ_s and θ_w are the semi-vertex angles of the cone and shock wave, respectively. Integrate the constant term in the integrand, and transform the variable from z to θ to obtain

$$\lambda\delta(y,z)/2K\rho_u z=\int_{\tan^{-1}y/z}^{\theta_w}[\rho(\theta)/\rho_u]\tan\theta\sec^2\theta \times(\tan^2\theta-y^2/z^2)^{-\frac{1}{2}}d\theta-(\tan^2\theta_w-y^2/z^2)^{\frac{1}{2}}. \quad (3)$$

Behind the shock wave, $p/p_0=(\rho/\rho_0)^\gamma$, where p is the local static pressure; p_0 and ρ_0 are the stagnation pressure and density, respectively; and γ is the ratio of the specific heat at constant pressure to that at constant volume. The local speed of sound, a, is defined by $a^2=dp/d\rho=\gamma p/\rho$. Then $\rho/\rho_0=(a/a_0)^{2/(\gamma-1)}$, where a_0 is the stagnation speed of sound. Similarly, $\rho_u/\rho_{01}=(a_u/a_{01})^{2/(\gamma-1)}$, where ρ_{01} and $a_{01}=a_0$ are the stagnation density and speed of sound, respectively, ahead of the shock wave. By Bernoulli's equation, $\frac{1}{2}q_u^2+a_u^2/(\gamma-1)=a_0^2/(\gamma-1)$, where q_u and a_u are the undisturbed speeds of flow and of sound, respectively. Then $(a_0/a_u)^2=1+\frac{1}{2}(\gamma-1)M^2$, where $M=q_u/a_u$ is the Mach number of the undisturbed flow. Thus

$$\rho/\rho_u=(\rho_0/\rho_{01})[1+\tfrac{1}{2}(\gamma-1)M^2]^{1/(\gamma-1)}(a(\theta)/a_0)^{2/(\gamma-1)}.$$

Since θ_w, ρ_0/ρ_{01}, and $a^2(\theta)$ (in velocity units such that $a_0=1$) have been tabulated as functions of θ_s, M, and θ by Kopal[6] by numerical integration $\lambda\delta(y,z)/2K\rho_u z$ can be determined as a function of y/z. The singularity of the integrand at $\theta=\tan^{-1}y/z$ can easily be avoided by splitting the integration into two parts: one with respect to θ from some convenient $\theta_0>\tan^{-1}y/z$ to θ_w; the other with respect to x from 0 to $(z^2\tan^2\theta_0-y^2)^{\frac{1}{2}}$. In actual use, the values of $\delta(y,z)/z$ so computed will have to be multiplied by a magnification factor appropriate to the experimental optical system. It must also be mentioned, as an aid to plotting, that one can easily show that $d[\delta(y,z)/z]/d(y/z)$ is infinite at $y/z=\tan\theta_w$.

III. EXPERIMENTAL RESULTS AND DISCUSSION

Flows to be tested for conicity were produced by firing cal. 0.30 cone-cylinders at an absolute pressure of one atmosphere in the range described Bergdolt *et al.*[7] During these firings interferograms of which Fig. 2 is typical were obtained from a Mach-Zehnder interferometer with two-inch plates, used in conjunction with a rotating mirror which approximately stopped the images of the bullets. The light employed was from the 5460A line of mercury, produced during a flash of about 2 microseconds duration from a BH6 mercury tube. Other relevant data are appended to the plots of smoothed fringe shift measurements shown in Figs. 3 to 6.

In general, the points plotted in Figs. 3 to 6 lie in

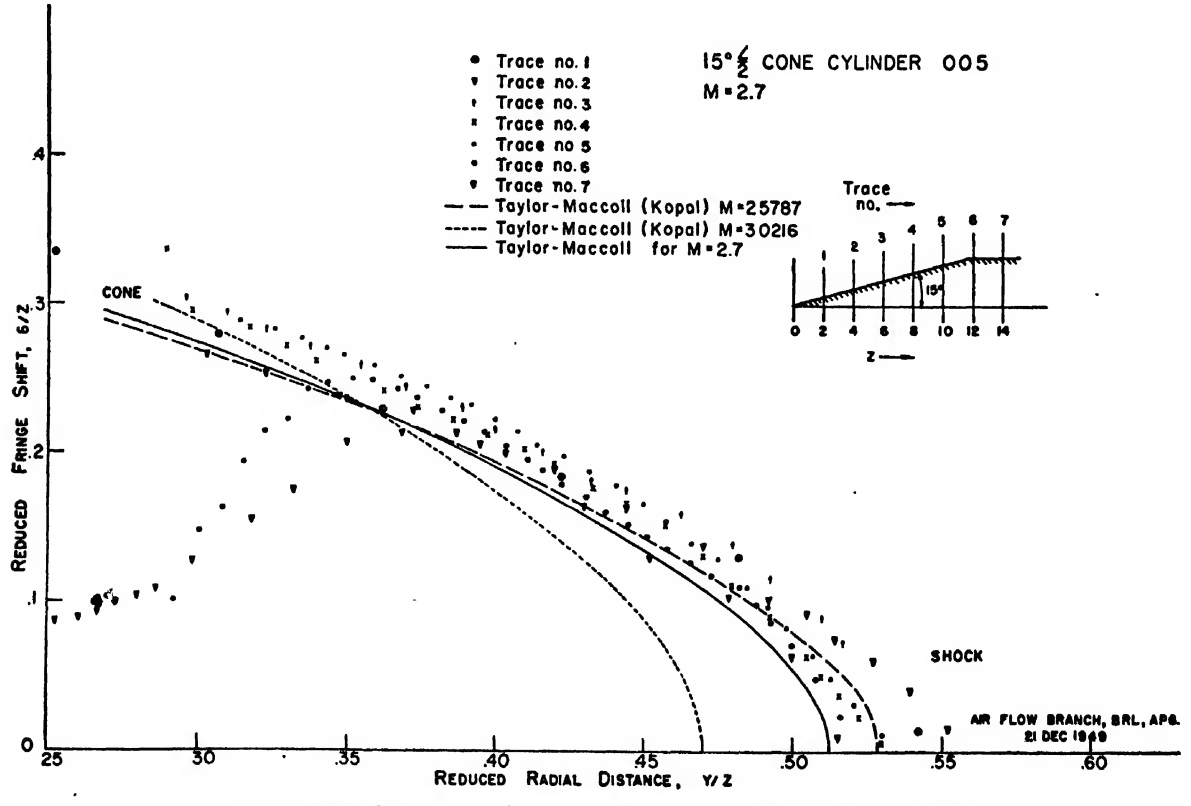

FIG. 3. Conical flow test plot showing departure from conicity in expansion region.

[6] Z. Kopal, *Tables of Supersonic Flow around Cones* (Cambridge, Mass., 1947).
[7] Bergdolt, Greenwald, and Sleator, Phys. Rev. 76, 879 (1949).

rather narrow bands, which encourages the belief that these flows came fairly close to being conical. In Fig. 3, for traces beyond the shoulder of the cone-cylinder, the points near the shock wave lie close to the conical flow band, while those near the body fall far outside. This verifies that the region of conical flow is really qualitatively of the theoretical form shown in Fig. 1. Actually this is also clear by direct inspection of Fig. 2, where the trace of the characteristic surface that bounds the region of conical flow is plainly discernible. Since the vertex of a conical flow is a singularity of the theoretical flow field, close to which the velocity and other properties of the flow have large gradients, even for a perfectly pointed model one would expect the behavior of a real viscous fluid to differ considerably there from that of the theoretical perfect fluid. The actual body, however, must have a slightly blunted nose, so the shock wave must be detached and doubly curved rather than conical. *A fortiori*, one would expect deviations from conicity near the tip of the body; however, the present measurements do not seem to exhibit such effects. In Figs. 3 and 6, points of the first trace bear no particu larly significant relation to those of others farther downstream. In Figs. 4 and 5, on the other hand, points of the first traces are systematically displaced above the rest. The magnitude of this displacement is consistent with the assumption that an error of the order of 0.2 mm was made in determining the location of the vertex on the interferogram. Such errors can arise, for example, if the vertex falls on a dark fringe. For an interferogram with well defined vertex, no such displacements are observed, and all of the plotted points fall within a narrow band, as in Fig. 6.

Estimates of the erratic experimental error $\Delta\delta$ in fringe shift indicate that $\Delta\delta \leqslant 0.05$ for all of the measurements reported here. For a given trace, percentage error in δ will vary from a large value near the shock wave to a minimum at the projectile body. Fringe shift generally increases from the tip of the projectile toward the rear; so percentage erratic error is higher for low trace number than for high.

For the data represented in Fig. 6 $\Delta\delta \leqslant 0.05$ indicates error for trace No. 1 of 18 percent or less at the projectile boundary. This upper bound falls to 10 percent for trace No. 2, 6 percent for trace No. 3, 4 percent for trace No. 5, and less than 3 percent for the remaining traces. These estimates apply to the δ/z values as well; for the erratic error in location of z is of the order of a few tenths percent even for smallest z.

IV. COMPARISON WITH TAYLOR-MACCOLL FLOW

A quantitative check of observed fringe shifts requires a corresponding theoretical flow model. In the present case the obvious choice, Taylor-Maccoll flow, must be justified by inquiring how well the fundamental assumptions of uniformity ahead of the shock wave, inviscidness, steadiness, and axisymmetry are satisfied. As far as viscosity is concerned, reasonably high

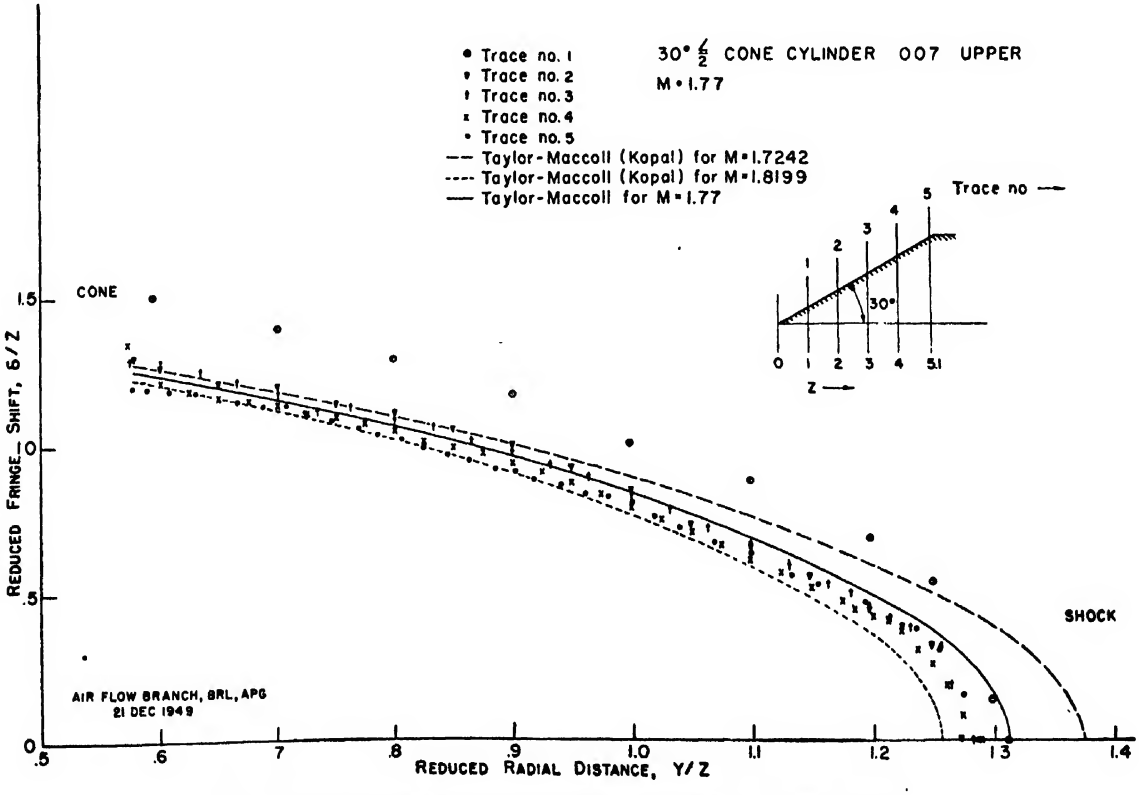

FIG. 4. Conical flow test plot of upper half of interferogram shown in Fig. 2.

Reynolds numbers, on the order of 3×10^5 based on the altitude of the cone, lead one to expect only very thin boundary layers. Actually, no boundary layer effects are readily perceptible on the interferograms, since the appearance of the fringes near the cone discloses nothing comparable to the hooks in Bershader's fringes in a well developed boundary layer.[8] Though the body is spin stabilized, on the cone the component of velocity due to spin is at most 4 percent of the forward velocity and thus will certainly not contribute significantly to viscosity effects. Unsteadiness may be produced by the deceleration and oscillation of the bodies. A rough estimate of the deceleration is 700 ft./sec.^{2}. At a velocity of 2000 ft./sec. the relative change in velocity is approximately $\Delta v/v=0.7\times10^{-5}$ during the time required for passage through the conical region, which is less than 20 microseconds outside the boundary layer. A crude upper bound on the frequency of oscillations in the flow can be derived from the fact that the fringes are steady and sharply defined during a 2 microsecond exposure. As for oscillations of the body, the precessional and nutational components of its motion have frequencies of less than 20 and 200 cycles/sec., respectively. The corresponding periods are quite long by contrast with the time of passage through the conical region. The fact that the body is in free supersonic flight in still air assures one that the flow ahead of the shock will be uniform; this is confirmed by the straightness of the undisturbed fringes. Finally, as for axisymmetry, though small yaws are inevitable, for conventional projectiles at normal pressures it is difficult to produce large yaws. Actually, measurement of the interferograms shows that the inclination of the body's axis to the trajectory is about half a degree in this projection. As a check on the influences of such small yaws and of the differences in fringe geometry, results from the upper and lower halves of the same interferogram are shown in Figs. 4 and 5.

Granting that conditions favorable for approximately Taylor-Maccoll flow occur in the present case, there will still be errors in the data. Two types will be considered here. First, in the calculation of Taylor-Maccoll fringe shifts by the method of Section II, it is assumed that the interferometer beam is normal to the axis of symmetry. Now the dynamic history along the trajectory cannot easily be predicted with great precision; moreover, it will vary from one round to the next with the geometrical and physical properties of the body. If for this reason the curvature of the trajectory and the oscillations of the body are neglected, the best approximation to the axis of symmetry is that of the gun barrel. The inclination of the interferometer beam relative to this axis was probably within two degrees of orthogonality. Calculations show that the effects of such an error in inclination are negligible. Secondly, no instrumentation

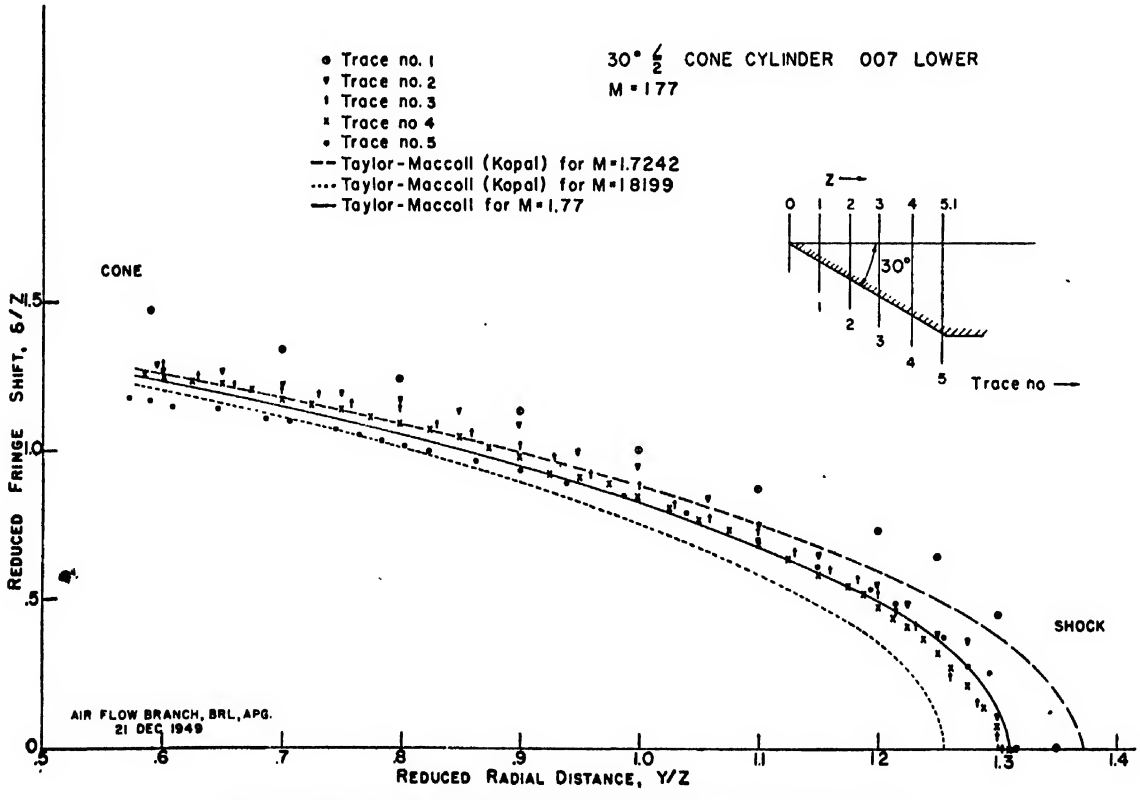

FIG. 5. Conical flow test plot of lower half of interferogram shown in Fig. 2.

[8] D. Bershader, Rev. Sci. Inst. 20, 260–275 (1949).

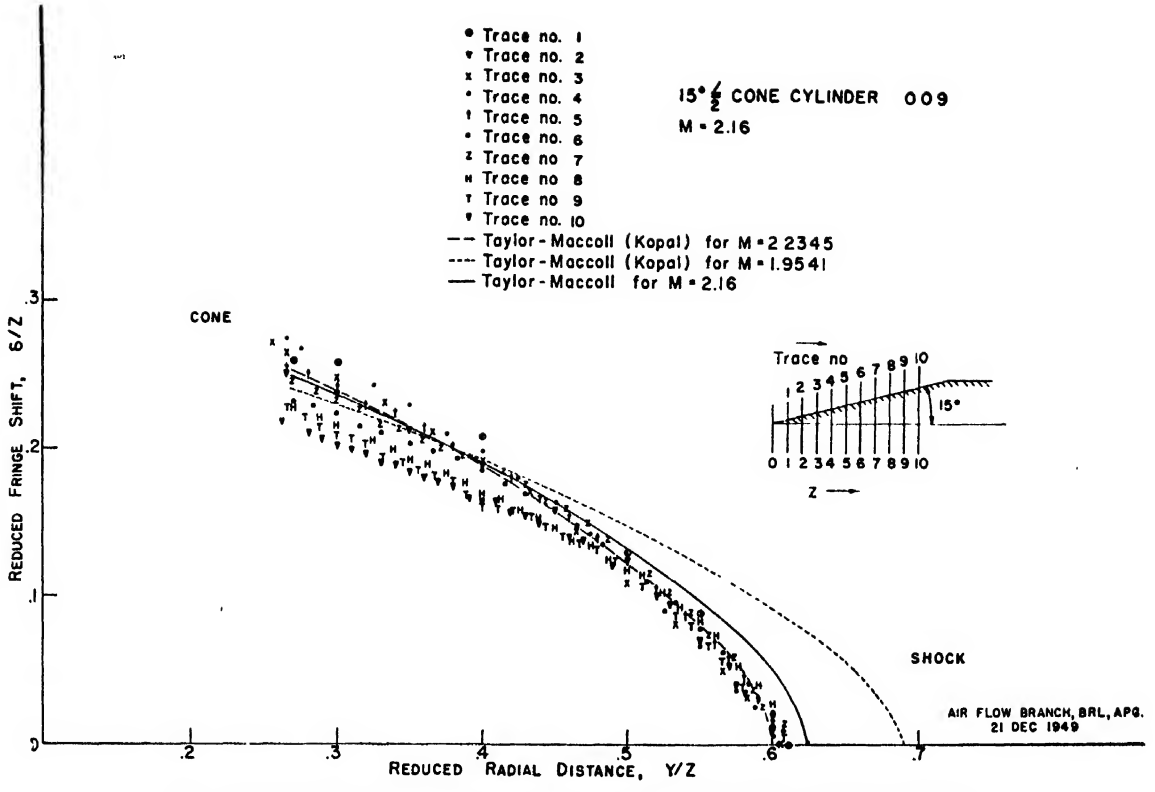

FIG. 6. Conical flow test plot for cal. .30, 15° half-angle cone cylinder—best data available.

for directly measuring velocities was available for the present firings. As a first approximation, the velocity was taken to be the average observed in firings of the same type of body with the same weight of powder in other ranges equipped with counter chronographs. A more refined estimate of the Mach number was based on the theoretical shock wave angle in Taylor-Maccoll flow, which is justified, *a posteriori*, by the agreement that will be found between the experimental data and the theoretical curves.

Figures 4 and 5 show fringe shift curves for $M=1.72$ and 1.82, calculated with $\gamma=1.4$ for Taylor-Maccoll flows tabulated in reference 6. The curve for $M=1.77$ was obtained by linear interpolation between the other two. In general, the agreement between the experimental data and theoretical curves is good, the poorer agreement in Fig. 5 being caused, possibly, by errors in the location of the axis and vertex. The scatter of the points at the shock ends of the curves may be partly due to curvature of the shock wave and partly to measurement errors, the fringe shifts being smallest there. At the cone end of the curves, the spread could conceivably originate in the boundary layer, since the traces farthest downstream, in which coordinate errors are least, seem in some instances to be displaced toward lower values.

From the quantitative estimates of error given in the last paragraph it appears that the scatter of points near the projectile body for traces posterior to No. 5 should be less than 3 percent from a mean curve. Inspection of the plotted points in Fig. 6 confirms this view. It is noteworthy that as trace number increases these latter traces fall increasingly below the Taylor-Maccoll curve for $M=2.16$ as well as below the mean curve for the first 5 traces. Translation of the data for any trace to bring the shockwave point into coincidence with that of the calculated Taylor-Maccoll curve does not improve matters much, since near the cone the latter traces still fall below the theoretical curve by several percent. We see then that the data suggests two types of deviation from conical flow (1) deviation from the Taylor-Maccoll theoretical flow of the latter traces and (2) deviation of the latter traces from the conical flow defined by the mean curve of the former traces. It is possible that these deviations can arise in the boundary layer as suggested above; however further study is required to obtain more than tentative conclusions to this effect.

Theory of Collinear Antennas

RONOLD KING
Cruft Laboratory, Harvard University, Cambridge, Massachusetts
(Received May 1, 1950)

If N collinear antennas are individually center driven, the only transmission line in the neutral plane is the one for a central unit if N is odd. Since lines that are not in a neutral plane constitute antennas, such an array is not practically useful.

For a single driven unit with symmetrical, parasitic, collinear elements, the driving transmission line is in the neutral plane and may be replaced by an equivalent generator and terminal-zone network. An array with two parasites is analyzed. Since the currents in the halves of the three units are not alike, three simultaneous integral equations occur. By making reasonable assumptions these are reduced to the single equation of the isolated antenna but with a different kernel. Approximate expressions are obtained for the currents and for the mutual and self-impedances of the elements.

The collinear antenna with outer elements driven from the central one by phase-reversing stubs is studied. For three elements components of the currents in the several possible modes are obtained with different degrees of approximation. The in-phase currents in the antennas are greatest, and are obtained with considerable accuracy. The currents in the outer units are not symmetrical, but with elements of length $\lambda/2$ the odd components of the currents are shown to be negligible.

1. INTRODUCTION AND GENERAL FORMULATION OF THE PROBLEM

THE analysis of the two individually driven collinear antennas in Fig. 1a is complicated by the fact that the axes of the transmission lines are not in neutral planes of the electromagnetic field. As a result, the forces acting on currents and charges in the two conductors of each line are not equal and opposite even at distances from the antennas that are great compared with the normal terminal zone[1] near each junction. Therefore, the transmission lines are not balanced, and the codirectional currents on each pair of conductors (or on the outside of the shield if a coaxial line is used) contribute significantly to the electromagnetic field at distant points. The actual radiating system in Fig. 1a is not limited to the two collinear antennas but includes the transmission lines. Clearly, such a system is not practically useful since its circuit and field properties depend on the length and orientation of the feeder lines.[2]

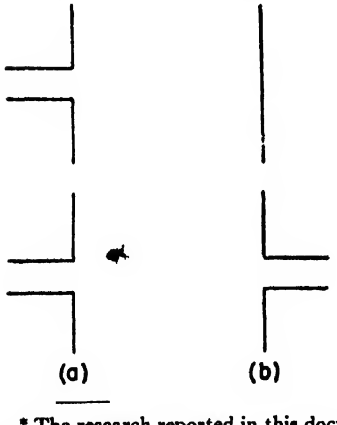

FIG. 1. Arrays of two collinear antennas.

The same difficulty exists if one of the two elements is parasitic as in Fig. 1b; or if three individually center-driven elements are used as in Fig. 2a. On the other hand, the array in Fig. 2b, in which only the central one of an odd number of collinear elements is directly driven, does not have the same serious disadvantage. The single transmission line is in the neutral plane of the array, so that unbalanced currents are not excited and radiation from the line is negligible.

The complication introduced by the two-wire line in Fig. 2b differs in no essential way from that already resolved for a single, center-driven antenna.[1] The presence of the two parasitic elements has no effect on the coupling between antenna and line since this is confined to short distances from the line-antenna junction of the order of magnitude of ten times the line spacing. It follows that the same terminal-zone network designed for a single isolated center-driven antenna may be used in conjunction with the antenna, treated as though driven by a discontinuity in scalar potential. This and following sections are concerned with the analysis of a three-element collinear array arranged and numbered as in Fig. 2b but with the central unit driven by a discontinuity in scalar potential, i.e. by a two-wire line with negligible line spacing. The analysis is carried out conveniently in the following parts:

(1) *The Symmetrical Problem:* The elements of the array are individually center-driven by discontinuities in scalar potential given by

$$V_{10}=V_{1}{}^{s}=V^{s};\quad V_{20}=V_{30}=V_{2}{}^{s}=f^{s}V^{s}. \qquad (1.1a)$$

$V_{2}{}^{s}$ is so chosen that the currents at the centers of the identical outer elements are equal to the current at

* The research reported in this document was supported in part by the Navy Department (ONR), the Signal Corps of the U. S. Army, and the U. S. Air Force, under contract N5-ori-76, T.O. 1/.

[1] R. King, J. App. Phys. 20, 832–850 (1949).

[2] An approximate analysis of the two-element collinear array in which no account is taken of the practical problem of driving the array is that of C. W. Harrison, Jr., Proc. I.R.E., 33, 398–408 (1945). Zeroth-order mutual impedances given by Harrison coincide with those derived in this paper. The general solutions differ in that Harrison did not include the effect of the coupled antenna in the kernel of the integral equation, nor did he take account of the distribution of current in deriving his expansion parameter.

the center of the middle element. That is, so that

$$I_2^s(z_2=0)=I_3^s(z_3=0)=I_1^s(z_1=0) \qquad (1.1b)$$

where z_1, z_2, and z_3 are measured from the centers of the elements indicated by the subscripts.

(2) *The Antisymmetrical Problem:* The three elements of the array are individually center-driven by

$$V_{10}=V_1^a=V^a; \quad V_{20}=V_{30}=-V_2^a=-f^aV^a \qquad (1.2a)$$

V_2^a is chosen that the currents at the centers of the outer elements are equal in magnitude but opposite in direction to the current at the center of the middle unit. That is, so that

$$I_2^a(z_2=0)=I_3^a(z_3=0)=-I_1^a(z_1=0). \qquad (1.2b)$$

(3) *The Parasitic Array:* By superimposing the solutions for the currents in problems (1) and (2) in the special case when

$$V_2^a=V_2^s \quad \text{or} \quad f^aV^a=f^sV^s, \qquad (1.3a)$$

the effective driving voltages and driving-point currents are

$$\begin{cases} V_{10}=V^s+V^a=V^a(1+f^a/f^s)=V^a(1+k), & (1.3b) \\ I_1(z_1)=I_1^s(z_1)+I_1^a(z_1), & (1.3c) \end{cases}$$

and

$$V_{20}=V_2^s-V_2^a=0, \qquad (1.3d)$$

$$I_2(z_2)=I_2^s(z_2)-I_2^a(z_2)$$

$$=I_{\text{even}}^s(z_2)+I_{\text{odd}}^s(z_2)-I_{\text{even}}^a(z_2)-I_{\text{odd}}^a(z_2). \qquad (1.3e)$$

Since $V_{20}=0$, the outer units are parasitic. Moreover, since the currents in the outer units are not symmetrical with respect to the centers of the respective elements,

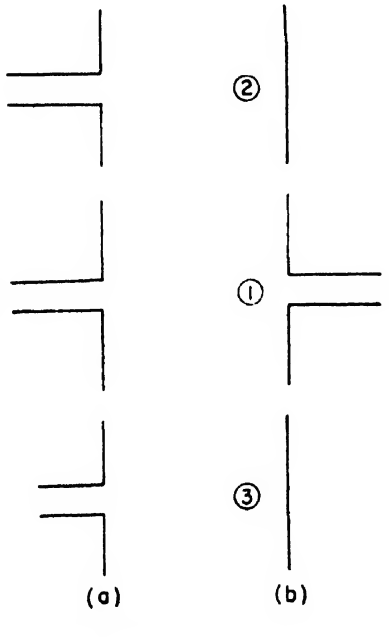

FIG. 2. Arrays of three collinear antennas.

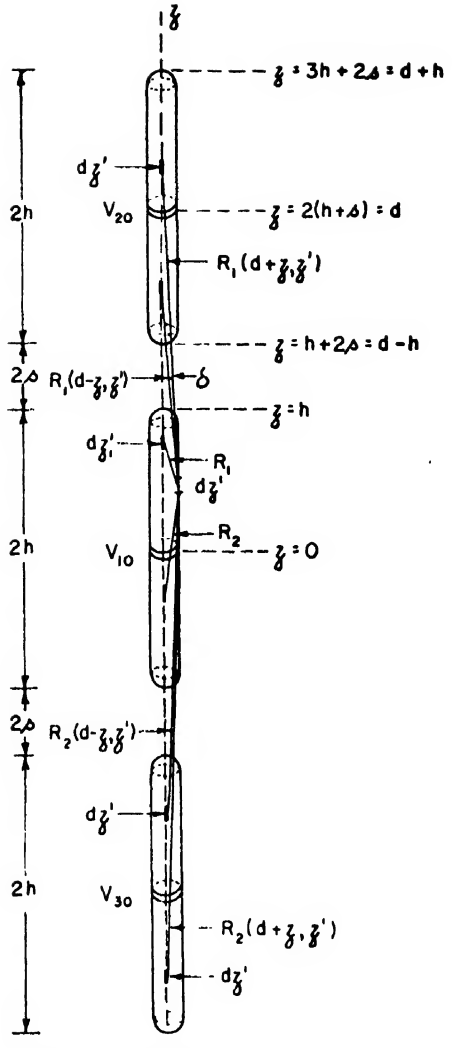

FIG. 3. Collinear array with slice generators.

the symmetrical and antisymmetrical currents are each the sum of even and odd components that must be determined separately.

(4) *The General Problem:* If the following condition is satisfied in place of (3a) or (3d):

$$V_{20}=V_2^s-V_2^a=-I_2(z_2=0)Z_L, \qquad (1.4)$$

the solution with each outer unit center-loaded with a lumped impedance Z_L is obtained. Note that $I_3(-z_3)=I_2(z_2)$.

The particular array studied in this and following sections is in Fig. 3. The three antennas are identical, each of half-length h and radius a. The conditions

$$a\ll h; \quad 2\pi a/\lambda_0=\beta_0 a\ll 1 \qquad (1.5)$$

are postulated. The distance between centers of the antennas is d, the distance between adjacent ends is $2s$ so that $d=2(h+s)$. The origin of a cylindrical system of coordinates r, θ, z, is at the center; the z-axis coin-

cides with the axes of the cylinders. The centers of the three units are at $z=0, \pm d$. Each unit is center-driven by discontinuities in scalar potential. Referring to Fig. 3 the conditions for the symmetrical drive are as in (1.1a), i.e.,

$$V_{10}=\lim_{\delta\to 0}[\phi(\delta)-\phi(-\delta)]=V_1^s=V^s \tag{1.6a}$$

$$V_{20}=\lim_{\delta\to 0}[\phi(d+\delta)-\phi(d-\delta)]=V_2^s=f^sV^s \tag{1.6b}$$

$$V_{30}=\lim_{\delta\to 0}[\phi(-d+\delta)-\phi(-d-\delta)]=V_2^s=f^sV^s \tag{1.6c}$$

where V_2^s or f^s is so chosen that (1.1b) is satisfied, i.e.,

$$I_3^s(-d)=I_2^s(d)=I_1^s(0). \tag{1.6d}$$

Similarly, the conditions for the antisymmetrical drive are as in (1.2a) with V_2^a or f^a chosen so that (1.2b) is satisfied, i.e.,

$$I_3(-d)=I_2(d)=-I_1(0). \tag{1.7}$$

Since the array is symmetrical with respect to its center, for both sets of driving conditions,

$$I(-z)=I(z); \quad q(-z)=-q(z), \tag{1.8a}$$

$$A(-z)=A(z); \quad \phi(-z)=-\phi(z). \tag{1.8b}$$

The subscript z is omitted on current and vector potential, since only z-components are involved. The vector and scalar potentials, evaluated at $r=a$ on the surfaces of the conductors, are

$$A(z)=\frac{1}{4\pi\nu_0}\left(\int_{-d-h}^{-d+h}+\int_{-h}^{h}+\int_{d-h}^{d+h}\right)I(z')K_1(z,z')dz'$$

$$=\frac{1}{4\pi\nu_0}\left(\int_0^h+\int_{d-h}^{d+h}\right)I(z')K(z,z')dz' \tag{1.9a}$$

$$\phi(z)=\frac{1}{4\pi\epsilon_0}\left(\int_0^h+\int_{d-h}^{d+h}\right)q(z')K(z,z')dz', \tag{1.9b}$$

where

$$K(z,z')=K_1(z,z')+K_2(z,z')=\frac{e^{-j\beta_0R_1}}{R_1}+\frac{e^{-j\beta_0R_2}}{R_2} \tag{1.9c}$$

and where

$$R_1=((z-z')^2+a^2)^{\frac{1}{2}}; \quad R_2=((z+z')^2+a^2)^{\frac{1}{2}}. \tag{1.9d}$$

The differential equation for the vector potential is the same as for a single antenna, viz.,

$$\frac{\partial^2A(z)}{\partial z^2}+\beta_0^2A(z)=j\frac{\beta_0^2}{\omega}z^iI(z); \quad (r=a). \tag{1.10a}$$

The solution consists of three equations of the form

$$A(z)=\frac{-j}{\nu_0}[C_1\cos\beta_0z+C_2\sin\beta_0z]; \quad (r=a) \tag{1.10b}$$

with different constants C_1 and C_2 in the equations applying, respectively, to the three sections of conductor extending from 0 to h, $d-h$ to d, d to $d+h$. A particular integral involving z^i as a factor has been omitted from (1.10b); it usually contributes negligibly.

Since the currents in the upper half of the central unit and the lower and upper halves of the upper unit are all different, the rigorous solution for these currents is complicated. Fortunately, an approximate solution may be obtained by making assumptions that are reasonable and that lead to integral equations like that for a single antenna.

2. THREE-ELEMENT COLLINEAR ARRAY; GENERAL ANALYSIS OF CENTRAL ANTENNA

The current $I_1(z)$ in the upper half of the central unit depends primarily upon the following integral equation valid at $r=a$ with $0\leqq z\leqq h$.

$$J_a+(J_b+J_c)=\frac{-j4\pi}{\zeta_0}[C_1\cos\beta_0z+\tfrac{1}{2}V_{10}\sin\beta_0z]. \tag{2.1}$$

For the upper sign, $V_{10}=V^s$; for the lower sign $V_{10}=V^a$. In (1),

$$J_a\equiv\int_0^h I_1(z')K(z,z')dz', \tag{2.2a}$$

$$J_b\equiv\int_{d-h}^{d}I_2(z')K(z,z')dz'$$

$$=\int_0^h I_2(d-z')K(z,d-z')dz', \tag{2.2b}$$

$$J_c\equiv\int_{d}^{d+h}I_2(z')K(z,z')dz'$$

$$=\int_0^h I_2(d+z')K(z,d+z')dz'. \tag{2.2c}$$

The current $I_1(z)$ in the central unit occurs also in two equations similar to (1) with integrals evaluated, respectively, over the halves of antenna 2. With (1) these constitute three simultaneous integral equations in the currents.

Equation (1) was obtained by substituting (1.9a) in (1.10b), evaluating $C_2=\frac{1}{2}V_{10}$, and replacing ν_0/ν_0 by its equivalent, $\zeta_0=376.7$ ohms. The last integrals in (2.2b) and (2.2c) are derived from the first integrals by changing the variable of integration to u, by setting $z'=d-u$ in (2.2b) and $z'=d+u$ in (2.2c), and then substituting z' for u. Note that each integral in (2.2a) to (2.2c) may be expanded into two integrals in the form $J_{i1}+J_{i2}$, $i=a, b, c$, by setting

$$K(z,v)=K_1(z,v)+K_2(z,v)$$

$$=\frac{e^{-j\beta_0R_1(z,v)}}{R_1(z,v)}+\frac{e^{-j\beta_0R_2(z,v)}}{R_2(z,v)}, \tag{2.3a}$$

where

$$R_1(z, v)=((z-v)^2+a^2)^{\frac{1}{2}};\quad R_2(z, v)=((z+v)^2+a^2)^{\frac{1}{2}} \quad (2.3b)$$

and

$$v=z',\quad d-z',\quad d+z'. \quad (2.3c)$$

Since the point z, where the vector potential is evaluated, is on the surface of the upper half of antenna 1 between $z=0$ and $z=h$, the contributions to the total vector potential by the integrals in (2.2a) to (2.2b) differ widely. Although the distributions of the currents in the six halves of the three antennas are not all the same, they are sufficiently alike to have the same average order of magnitude *if made equal at the centers of the antennas*. Consequently, in determining the current in the *central unit*, the currents in all units may be assumed the same. Since the currents for $z<0$ are obtained from the currents for $z>0$ using (1.8a), the following expressions relate *all* currents:

$$I_2^s(d-z')\doteq I_1^s(z')\doteq I_2^s(z'+d);\quad (0\leqq z'\leqq h) \quad (2.4a)$$

$$-I_2^a(d-z')\doteq I_1^a(z')\doteq -I_2^a(z'+d);\quad (0\leqq z'\leqq h). \quad (2.4b)$$

With (2.4a, b), (2.1) becomes

$$\int_0^h I(z')K_c(z, z')dz'$$

$$=\frac{-j4\pi}{\zeta_0}[C_1\cos\beta_0 z+\tfrac{1}{2}V_{10}\sin\beta_0 z]:$$

$$(r=a;\quad 0\leqq z\leqq h). \quad (2.5)$$

When $V_{10}=V^s$, $I=I^s$, $C_1=C_1^s$, $K_c=K_c^s$; when $V_{10}=V^a$, $I=I^a$, $C_1=C_1^a$, $K_c=K_c^a$. The new kernel, $K_c(z, z')=K_{c1}(z, z')+K_{c2}(z, z')$, is defined as follows:

$$K_c(z, z')\equiv\left\{\begin{matrix}K_c^s(z, z')\\K_c^a(z, z')\end{matrix}\right\}\equiv K(z, z')$$

$$\pm[K(z, d-z')+K(z, d+z')] \quad (2.6)$$

with $K(z, v)$ defined as in (2.3a). Note that with (2.3b)

$$R_1(z, d-z')=((z-d+z')^2+a^2)^{\frac{1}{2}}=R_1(d-z, z'), \quad (2.7a)$$

$$R_1(z, d+z')=((z-d-z')^2+a^2)^{\frac{1}{2}}=R_2(d-z, z'), \quad (2.7b)$$

$$R_2(z, d-z')=((z+d-z')^2+a^2)^{\frac{1}{2}}=R_1(d+z, z'), \quad (2.7c)$$

$$R_2(z, d+z')=((z+d+z')^2+a^2)^{\frac{1}{2}}=R_2(d+z, z'). \quad (2.7d)$$

It follows that

$$K(z, d-z')+K(z, d+z')=K(d-z, z')+K(d+z, z') \quad (2.8)$$

so that

$$K_c(z, z')=K(z, z')\pm[K(d-z, z')+K(d+z, z')]. \quad (2.9)$$

This form of the kernel is convenient in the evaluation of the expansion parameter.

Since (2.5) is an integral equation like that for the single antenna,[3a,3b] the same formal solution is obtained with a new kernel. The current in the upper half of the central unit of the collinear array is given by (3) in reference 3b with $K_c(z, z')$ substituted for $K(z, z')$. Thus,

$$I_1(z)=\frac{j2\pi V}{\zeta_0\Psi_{Kc}}\left\{\frac{\sin\beta_0(h-z)+M_{c1}(z)/\Psi_{Kc}+\cdots}{\cos\beta_0 h+A_{c1}/\Psi_{Kc}+\cdots}\right\}. \quad (2.10)$$

Similarly, the impedance of the central unit is

$$Z_{0c}=\frac{-j\zeta_0\Psi_{Kc}}{2\pi}\left\{\frac{\cos\beta_0 h+A_{c1}/\Psi_{Kc}+\cdots}{\sin\beta_0 h+B_{c1}/\Psi_{Kc}+\cdots}\right\}. \quad (2.11)$$

Each of these formulas applies to the symmetrically

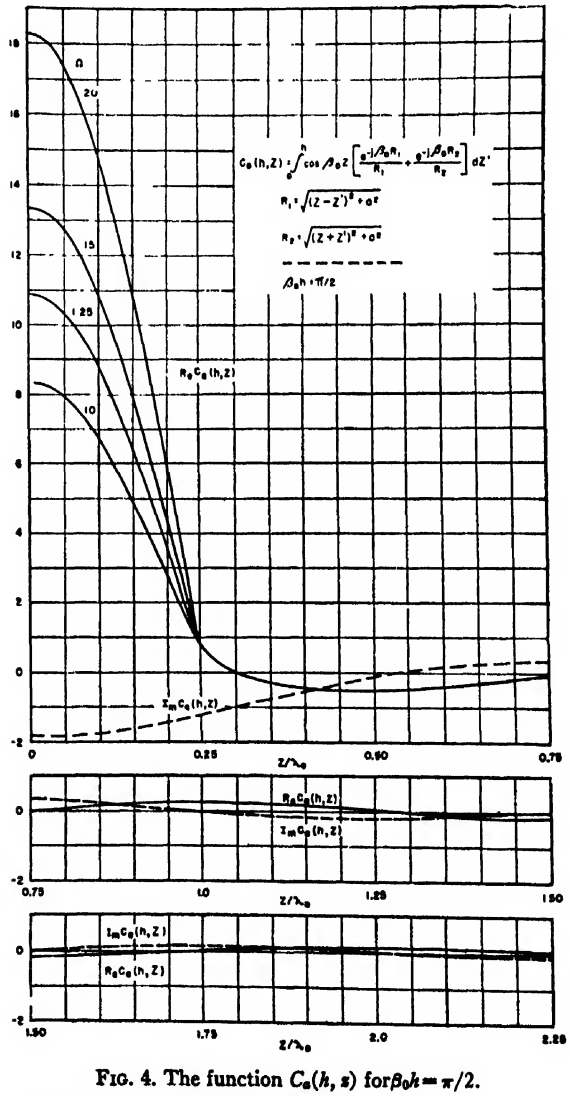

FIG. 4. The function $C_0(h, z)$ for $\beta_0 h=\pi/2$.

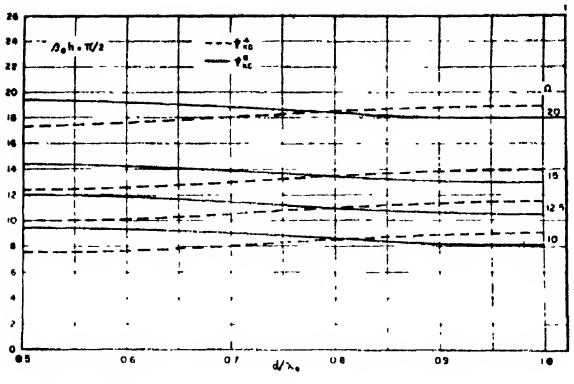

FIG. 5. The expansion parameters for the central unit in a three-element array.

driven array when a superscript s is affixed to V, I, M, B, A, Ψ and Z and the upper sign is used, and to the antisymmetrically driven array when the superscript a is affixed to these symbols and the lower sign is used. The quantities $M_{c1}(z)$, $B_{c1}=M_{1c}(0)$, and A_{c1} are the same as in reference 3 with $K_c(z, z')$ in (2.9) substituted for $K(z, z')$, and with Ψ_{Kc} replacing $\Psi=\Psi_{K1}$.

The expansion parameter Ψ_{Kc} is defined as is Ψ in reference 3. The steps include

$$\Psi_{Kc}(z)=\psi_{Kc}(z)/\sin\beta_0(h-z), \tag{2.12}$$

$$\psi_{Kc}(z)=\sin\beta_0 h\int_0^h \cos\beta_0 z' K_c(z, z')dz' - \cos\beta_0 h\int_0^h \sin\beta_0 z' K_c(z, z'^d dz'. \tag{2.13}$$

The integrals in (13) involve only the functions[4] $C_a(h, v)$ and $S_a(h, v)$ defined in references 3 and 4. Their introduction yields:

$$\psi_{Kc}(z)=\psi_1(z)\pm[\psi_1(d-z)+\psi_1(d+z)], \tag{2.14}$$

where

$$\psi_1(v)=C_a(h, v)\sin\beta_0 h-S_a(h, v)\cos\beta_0 h. \tag{2.15}$$

By far the most important case in practice is with $\beta_0 h=\pi/2$ for which

$$\psi_{Kc}(z)=C_a(h, z)\pm[C_a(h, d-z)+C_a(h, d+z)]; \quad h=\lambda_0/4. \tag{2.16}$$

The function of $C_a(h, z)$ for $\beta_0 h=\pi/2$ is given in Fig. 4. The function in (12) is:

$$\Psi_{Kc}(z)=\Psi_{K1}(z)\pm[\Psi_{K1}(d-z)+\Psi_{K1}(d+z)] \tag{2.17}$$

where $\Psi_{K1}(z)$ applies to the central unit when isolated.

Since the general behavior of $\Psi_{Kc}(z)$ as a function of z is like that of $\Psi_{K1}(z)$ for all possible values of d, the expansion parameter for the central unit may be defined as for the isolated antenna. Specifically,

$$\Psi_{Kc}=\begin{cases} |\Psi_{Kc}(0)|=|\Psi_{K1}(0)\pm 2\Psi_{K1}(d)| \\ \qquad\qquad \text{for} \quad \beta_0 h\leqq\pi/2 \\ |\Psi_{Kc}(h-\lambda_0/4)|=|\Psi_{K1}(h-\lambda_0/4) \\ \qquad \pm[\Psi_{K1}(d-h+\lambda_0/4) \\ \qquad +\Psi_{K1}(d+h-\lambda_0/4)]| \\ \qquad\qquad \text{for} \quad \beta_0 h\geqq\pi/2. \end{cases} \tag{2.18}$$

A superscript s is added to Ψ_{Kc} for $V=V^s$, and the upper signs are used; a superscript a is added for $V=-V^a$, and the lower signs are used. $\Psi_{Kc}{}^s$ and $\Psi_{Kc}{}^a$ are shown in Fig. 5.

It is clear from (2.18) that when the elements of the collinear array are driven in phase, current and impedance of the central unit are like those of an isolated antenna with a larger Ψ_{K1} and hence smaller radius. Alternatively, when the two outer units are driven 180 degrees out of phase with the central unit, this behaves like an isolated antenna with a smaller Ψ_{K1} and greater radius. This is true for $d/\lambda_0<0.8$.

The impedances Z^s and Z^a determined from (2.11) with appropriate superscripts s and a, and the corresponding currents $I_1{}^s(z)$ and $I_1{}^a(z)$ as given by (2.10) in terms of the driving voltage $V=V^s$ or $V=V^a$, are valid *only if the outer units are driven* so that the currents at their centers are equal to $I_1{}^s(0)$ in the symmetrical case, or to $-I_1{}^a(0)$ in the antisymmetrical case. Evidently, the problem of the central unit is not solved until $V_2{}^s=f^sV^s$ and $V_2{}^a=f^aV^a$ are known. They are determined in Sec. 3. Once f^s and f^a are known, a superposition of the solutions for which $V_2{}^s=V_2{}^a$ yields the solution of the array with parasitic outer elements. Since in this case

$$V^s/V^a=f^s/f^s=k, \tag{2.19a}$$

it follows that

$$\frac{1}{Z_{1\text{in}}}=Y_{1\text{in}} =\frac{I_1(0)}{V_{10}}=\frac{I_1{}^s(0)+I_1{}^a(0)}{V^s+V^a}=\frac{I_1{}^s(0)}{V^s(1+k^{-1})} +\frac{I_1{}^a(0)}{V^a(1+k)}=\frac{1}{Z_{0c}{}^s(1+k^{-1})}+\frac{1}{Z_{0c}{}^a(1+k)}. \tag{2.19b}$$

Solving for $Z_{1\text{in}}$ gives the input impedance of the three-element collinear array with the outer units parasitic.

$$Z_{1\text{in}}=\frac{2Z_{0c}{}^sZ_{0c}{}^a}{Z_{0c}{}^s+Z_{0c}{}^a}F_1=Z_{1\text{in}}{}'F_1, \tag{2.19c}$$

[4] The functions are:

$$C_a(h, z)=\int_0^h \cos\beta_0 z'\left[\frac{\exp(-j\beta_0 R_1)}{R_1}+\frac{\exp(-j\beta_0 R_2)}{R_2}\right]dz'$$

$$S_a(h, z)=\int_0^h \sin\beta_0 z'\left[\frac{\exp(-j\beta_0 R_1)}{R_1}+\frac{\exp(-j\beta_0 R_2)}{R_2}\right]dz'$$

$$R_1=((z-z')^2+a^2)^{\frac{1}{2}}; \quad R_2=((z+z')^2+a^2)^{\frac{1}{2}}.$$

where

$$F_1 \doteq 1+\frac{(Z_{0c}{}^s-Z_{0c}{}^a)(k-k^{-1})}{2Z_{0c}{}^s(1+k^{-1})+Z_{0c}{}^a(1+k)}. \quad (2.19d)$$

The determination of k is in Section 3. The numerical evaluation of Z_{11n} for $\beta_0 h=\pi/2$ is in Section 4.

The current in the central unit is given by

$$I(z)=I_1{}^s(z)+I_1{}^a(z) \quad (2.20)$$

where $I_1{}^s(z)$ is given by (2.10) with superscripts s and with $V=V^s=V_{10}/(1+k^{-1})$, and where $I_1{}^a(z)$ is given by (2.10) with superscripts a and with $V=V^a=V_{10}/(1+k)$. Once k is determined $I_1(z)$ may be calculated in terms of V_{10}, the actual driving voltage when the outer units are parasitic.

3. THREE-ELEMENT COLLINEAR ARRAY; GENERAL ANALYSIS OF OUTER ANTENNAS

The currents in the outer antennas cannot be determined so accurately as the currents in the central unit since they are not symmetrical with respect to the centers of these antennas. However, since it is not possible to center drive these units without the addition of unbalanced transmission lines, the only practically significant application of the theory as developed up to this point is with the outer units parasitic. Since in this case the currents in the parasites are not involved directly in the driving-point impedance, but only in f^s and f^a, and in obtaining the electromagnetic field of the array, it is adequate to determine approximate currents. For this purpose the principal assumption is that the current in each outer unit is composed of even and odd parts of which the odd is *not* large compared with the even. In general, this means that $\beta_0 h$ must not be near enough to π, 2π, $3\pi\cdots$ to make the odd part of the current the resonant part. When $\beta_0 h$ is near $\pi/2$ the even part of the current is resonant and the assumption is an excellent one.

The integral equation for the current in the halves of antenna 2 (Fig. 3) are

$$4\pi\nu_0 A(z_2)=\frac{-j4\pi}{\zeta_0}[C_1\cos\beta_0 z_2+C_2\sin\beta_0 z_2]; \quad (0\leqq z_2\leqq h), \quad (3.1a)$$

$$4\pi\nu_0 A(z_2)=\frac{-j4\pi}{\zeta_0}[C_1\cos\beta_0 z_2+C_4\sin\beta_0 z_2]; \quad (-h\leqq z_2\leqq 0), \quad (3.1b)$$

where

$$4\pi\nu_0 A(z_2)=\left(\int_{-h}^{h}+\int_{-d-h}^{-d+h}+\int_{-2d-h}^{-2d+h}\right)\times I(z_2')K_1(z_2, z_2')dz_2' \quad (3.2a)$$

with

$$K_1(z_2, z_2')=\frac{e^{-j\beta_0 R_1(z_2, z_2')}}{R_1(z_2, z_2')};$$

$$R_1(z_2, z_2')=((z_2-z_2')+a^2)^{\frac{1}{2}}. \quad (3.2b)$$

By setting $z'=d+z_2'$ in the second integral, $z_3'=2d+z_2'$ in the third integral and noting that

$$R_1(z_2, z'-d)=((d+z_2-z')^2+a^2)^{\frac{1}{2}}=R_1(d+z_2, z') \quad (3.3a)$$

$$R_1(z_2, z_3'-2d)=((2d+z_2-z_3')^2+a^2)^{\frac{1}{2}}=R_1(2d+z_2, z_3'). \quad (3.3b)$$

(3.2a) may be expressed as follows:

$$4\pi\nu_0 A(z_2)=\int_{-h}^{h}I_2(z_2')K_1(z_2, z_2')dz_2'+\int_{-h}^{h}I_1(z')K_1(d+z_2, z')dz'+\int_{-h}^{h}I_3(z_3')K_1(2d+z_2', z_3')dz_3'. \quad (3.4)$$

As a consequence of symmetry,

$$I_3(z_3')=I_2(-z_2'). \quad (3.5)$$

Since $I_1(z')$ is an even function of z' and symmetrical or antisymmetrical driving voltages are provided so that $I_1(z'=0)=\pm I_2(z_2'=0)$, a satisfactory approximation is

$$I_1(z')=\pm\tfrac{1}{2}[I_2(z_2')+I_2(-z_2')] \quad (3.6)$$

where the upper sign applies to the symmetrical, the lower sign to the antisymmetrical case. Substitution of (3.5) and (3.6) in (3.4) gives

$$4\pi\nu_0 A(z_2)=\int_0^h\{I_2(z_2')K_{1d}(z_2, z_2')+I_2(-z_2')K_{2d}(z_2, z_2')\}dz_2' \quad (3.7)$$

where

$$K_{1d}(z_2, z_2')\equiv K_1(z_2, z_2')\pm\tfrac{1}{2}[K_1(d+z_2, z_2')+K_2(d+z_2, z_2')]+K_2(2d+z_2, z_2') \quad (3.8a)$$

$$K_{2d}(z_2, z_2')\equiv K_2(z_2, z_2')\pm\tfrac{1}{2}[K_2(d+z_2, z_2')+K_1(d+z_2, z_2')]+K_1(2d+z_2, z_2'). \quad (3.8b)$$

The following notation is used:

$$K_1(u, z_2') \equiv \frac{e^{-j\beta_0 R_1(u, z_2')}}{R_1(u, z_2')};$$

$$K_2(u, z_2') \equiv \frac{e^{-j\beta_0 R_2(u, z_2')}}{R_2(u, z_2')}, \quad (3.9a)$$

$$R_1(u, z_2') \equiv ((u-z_2')^2+a^2)^{\frac{1}{2}};$$

$$R_2(u, z_2') = ((u+z_2')^2+a^2)^{\frac{1}{2}}. \quad (3.9b)$$

These formulas apply in the following two cases:

Symmetrical Case:

$$\left.\begin{aligned} &V_{10}=V^a; \quad V_{30}=V_{20}=V_2{}^a=f^aV^a; \\ &I_2(z_2')=I_2{}^a(z_2') \\ &K_{1d}(z_2, z_2') \text{ with upper sign} = K_{1d}{}^a(z_2, z_2'). \end{aligned}\right\}, \quad (3.10a)$$

Antisymmetrical Case:

$$\left.\begin{aligned} &V_{10}=V^a; \quad V_{30}=V_{20}=-V_2{}^a=-f^aV^a; \\ &I_2(z_2')=I_2{}^a(z_2') \\ &K_{1d}(z_2, z_2') \text{ with lower sign} = K_{1d}{}^a(z_2, z_2') \end{aligned}\right\}. \quad (3.10b)$$

The first step in the solution of (3.1a) with (3.7) is to resolve both sides into even and odd functions of z_2 and in this way obtain two equations, the one for the even part of $I_2(z_2)$, the other for the odd part. The conditions for the even parts of the vector potential and current are

$$A_{\text{even}}(z_2) = \tfrac{1}{2}[A(z_2)+A(-z_2)];$$

$$I_{\text{even}}(z_2) = \tfrac{1}{2}[I_2(z_2)+I_2(-z_2)] \quad (3.11a)$$

so that with (3.1a)

$$4\pi\nu_0 A_{\text{even}}(z_2) = \frac{-j4\pi}{\zeta_0}[C_{\text{even}} \cos\beta_0 z_2 + \tfrac{1}{2}V_{20} \sin\beta_0 z_2];$$

$$-h \leqq z_2 \leqq h) \quad (3.11b)$$

where $C_{\text{even}} = \frac{1}{2}(C_1+C_3)$ and $\frac{1}{2}V_{20} = \frac{1}{2}(C_2-C_4)$. The even part of the vector potential in the range $(-h \leqq z_2 \leqq 0)$ is obtained from $A_{\text{even}}(-z_2) = A_{\text{even}}(z_2)$.

The conditions for the odd part of the vector potential and current are

$$A_{\text{odd}}(z_2) = \tfrac{1}{2}[A(z_2)-A(-z_2)];$$

$$I_{\text{odd}}(z_2) = \tfrac{1}{2}[I_2(z_2)-I_2(-z_2)] \quad (3.12a)$$

so that with (1a)

$$4\pi\nu_0 A_{\text{odd}}(z_2) = \frac{-j4\pi}{\zeta_0} C_{\text{odd}} \sin\beta_0 z_2; \quad (-h \leqq z_2 \leqq h) \quad (3.12b)$$

where $C_{\text{odd}} = \frac{1}{2}(C_3+C_4)$ and $\frac{1}{2}(C_1-C_3)=0$ since $A_{\text{odd}}(-z_2) = A_{\text{odd}}(z_2) = 0$ at $z_2=0$. The odd vector potential in the range $(-h \leqq z_2 \leqq 0)$ is obtained from $A_{\text{odd}}(-z_2) = -A_{\text{odd}}(z_2)$.

The integrals and equations for the even and odd parts of the vector potential are obtained using (3.11a, b) and (3.12a, b). They are

$$4\pi\nu_0 A_{\text{even}}(z_2) = \int_0^h \{I_2(z_2')K_{1\text{even}}(z_2, z_2') + I_2(-z_2')K_{2\text{even}}(z_2, z_2')\}dz_2'$$

$$= \frac{-j4\pi}{\zeta_0}[C_{\text{even}} \cos\beta_0 z_2 + \tfrac{1}{2}V_{20} \sin\beta_0 |z_2|];$$

$$(-h \leqq z_2 \leqq h) \quad (3.13a')$$

$$4\pi\nu_0 A_{\text{odd}}(z_2) = \int_0^h \{I_2(z_2')K_{1\text{odd}}(z_2, z_2') + I_2(-z_2')K_{2\text{odd}}(z_2, z_2')\}dz_2$$

$$= \frac{-j4\pi}{\zeta_0} C_{\text{odd}} \sin\beta_0 z_2; \quad (-h \leqq z_2 \leqq h) \quad (3.13b)$$

where

$$K_{1\text{even}}(z_2, z_2') \equiv \tfrac{1}{2}[K_{1d}(z_2, z_2') + K_{1d}(-z_2, z_2')], \quad (3.14a)$$

$$K_{2\text{even}}(z_2, z_2') \equiv \tfrac{1}{2}[K_{2d}(z_2, z_2') + K_{2d}(-z_2, z_2')], \quad (3.14b)$$

$$K_{1\text{odd}}(z_2, z_2') \equiv \tfrac{1}{2}[K_{1d}(z_2, z_2') - K_{1d}(-z_2, z_2')], \quad (3.14c)$$

$$K_{2\text{odd}}(z_2, z_2') = \tfrac{1}{2}[K_{2d}(z_2, z_2') - K_{2d}(-z_2, z_2')]. \quad (3.14d)$$

In an asymmetrical geometrical arrangement like that of the outer elements in a collinear array, contributions to the even as well as the odd parts of the vector potential come from *both* even and odd parts of the currents in the three units. Consequently (3.13a) and (3.13b) cannot be solved directly for $I_{\text{even}}(z_2)$ and $I_{\text{odd}}(z_2)$. However, an approximate procedure is available. The current may be expanded into its even and odd parts by setting

$$I_2(z_2') = I_{\text{even}}(z_2') + I_{\text{odd}}(z_2');$$

$$I_2(-z_2') = I_{\text{even}}(z_2') - I_{\text{odd}}(z_2') \quad (3.15a)$$

where by definition

$$I_{\text{even}}(z_2') = \tfrac{1}{2}[I(z_2') + I_2(-z_2')] = I_{\text{even}}(-z_2'), \quad (3.15b)$$

$$I_{\text{odd}}(z_2') = \tfrac{1}{2}[I(z_2') - I_2(-z_2')] = -I_{\text{odd}}(-z_2'). \quad (3.15c)$$

If (3.15a) is substituted in (3.13a) and (3.13b), the

results are:

$$4\pi\nu_0 A_{\text{even}}(z_2)=\int_0^h \{I_{\text{even}}(z_2')[K_{1\text{even}}(z_2, z_2') + K_{2\text{even}}(z_2, z_2')]+I_{\text{odd}}(z_2')[K_{1\text{even}}(z_2, z_2') - K_{2\text{even}}(z_2, z_2')]\}dz_2' \quad (3.16a)$$

$$4\pi\nu_0 A_{\text{odd}}(z_2)=\int_0^h \{I_{\text{even}}(z_2')[K_{1\text{odd}}(z_2, z_2') + K_{2\text{odd}}(z_2, z_2')]+I_{\text{odd}}(z_2')[K_{1\text{odd}}(z_2, z_2') - K_{2\text{odd}}(z_2, z_2')]\}dz_2'. \quad (3.16b)$$

Let the following kernels be defined:

$$K_{\text{even}}(z_2, z_2')\equiv K_{1\text{even}}(z_2, z_2')+K_{2\text{even}}(z_2, z_2')=\tfrac{1}{2}[K_{1d}(z_2, z_2')+K_{2d}(z_2, z_2')+K_{1d}(-z_2, z_2')+K_{2d}(-z_2, z_2')]$$
$$=K_1(z_2, z_2')+K_2(z_2, z_2')\pm\tfrac{1}{2}[K_1(d+z_2, z_2')+K_2(d+z_2, z_2')+K_1(d-z_2, z_2')+K_2(d-z_2, z_2')]$$
$$+\tfrac{1}{2}[K_1(2d+z_2, z_2')+K_2(2d+z_2, z_2')+K_1(2d-z_2, z_2')+K_2(2d-z_2, z_2')] \quad (3.17a)$$

$$K_{e0}(z_2, z_2')\equiv K_{1\text{even}}(z_2, z_2')-K_{2\text{even}}(z_2, z_2')=\tfrac{1}{2}[K_{1d}(z_2, z_2')-K_{2d}(z_2, z_2')+K_{1d}(-z_2, z_2')-K_{2d}(-z_2, z_2')]$$
$$=-\tfrac{1}{2}[K_1(2d+z_2, z_2')-K_2(2d+z_2, z_2')+K_1(2d-z_2, z_2')-K_2(2d-z_2, z_2')] \quad (3.17b)$$

$$K_{0e}(z_2, z_2')\equiv K_{1\text{odd}}(z_2, z_2')+K_{2\text{odd}}(z_2, z_2')=\tfrac{1}{2}[K_{1d}(z_2, z_2')+K_{2d}(z_2, z_2')-K_{1d}(-z_2, z_2')-K_{2d}(z_2, z_2')]$$
$$=\pm\tfrac{1}{2}[K_1(d+z_2, z_2')+K_2(d+z_2, z_2')-K_1(d-z_2, z_2')-K_2(d-z_2, z_2')]$$
$$+\tfrac{1}{2}[K_1(2d+z_2, z_2')+K_2(2d+z_2, z_2')-K_1(2d-z_2, z_2')-K_2(2d-z_2, z_2')] \quad (3.17c)$$

$$K_{\text{odd}}(z_2, z_2')\equiv K_{1\text{odd}}(z_2, z_2')-K_{2\text{odd}}(z_2, z_2')=\tfrac{1}{2}[K_{1d}(z_2, z_2')-K_{2d}(z_2, z_2')-K_{1d}(-z_2, z_2')+K_{2d}(-z_2, z_2')]$$
$$=K_1(z_2, z_2')-K_2(z_2, z_2')-\tfrac{1}{2}[K_1(2d+z_2, z_2')-K_2(2d+z_2, z_2')]$$
$$+\tfrac{1}{2}[K_1(2d-z_2, z_2')-K_2(2d-z_2, z_2')]. \quad (3.17d)$$

Examination of (3.17b) as it appears in (3.16a) shows that it represents the contribution to the even part of the vector potential on antenna 2 by the odd parts of the currents in antenna 3. Since the odd currents involved are assumed to be relatively small, and in any case the distances are large, this term is negligible compared with the very much greater contribution from the large even currents in all three antennas. Since $R_1(2d\pm z_2, z_2')$ differs very much less from $R_2(2d\pm z_2, z_2')$ than does $R_1(z_2, z_2')$ from $R_2(z_2, z_2')$ it follows that the principal contributions to $K_{\text{odd}}(z_2, z_2')$ in (3.17d) are from the first two terms. That is,

$$K_{\text{odd}}(z_2, z_2')\doteq K_1(z_2, z_2')-K_2(z_2, z_2'). \quad (3.17e)$$

Neglecting the term in $K_{e0}(z_2, z_2')$, the two integral equations are:

$$4\pi\nu_0 A_{\text{even}}(z_2)=\int_0^h I_{\text{even}}(z_2')K_{\text{even}}(z_2, z_2')dz_2$$
$$=\frac{-j4\pi}{\zeta_0}[C_{\text{even}}\cos\beta_0 z_2+\tfrac{1}{2}V_{20}\sin\beta_0 z_2]; \quad (-h\leqq z_2\leqq h) \quad (3.18a)$$

$$4\pi\nu_0 A_{\text{odd}}(z_2)=\int_0^h I_{\text{even}}(z_2')K_{0e}(z_2, z_2')dz_2'$$
$$+\int_0^h I_{\text{odd}}(z_2')K_{\text{odd}}(z_2, z_2')dz_2'$$
$$=\frac{-j4\pi}{\zeta_0}C_{\text{odd}}\sin\beta_0 z_2; \quad (-h\leqq z_2\leqq h). \quad (3.18b)$$

Of these the first may be solved directly for $I_{\text{even}}(z_2)$; using this known value, the second equation may be solved for $I_{\text{odd}}(z_2)$. Note that the equations apply only in the symmetrical and antisymmetrical cases defined in (3.10a, b) but that the general case may be constructed by superposition.

The Eq. (3.18a) for the even part of the current is in exactly the same form as the equation for a single antenna. The solution may be written down directly in the form

$$I_{\text{even}}(z_2)=\frac{j2\pi V_{20}}{\zeta_0\Psi_{\text{even}}}\times\left\{\frac{\sin\beta_0(h-z_2)+M_{\text{even1}}(z_2)/\Psi_{\text{even}}+\cdots}{\cos\beta_0 h+A_{\text{even1}}/\Psi_{\text{even}}+\cdots}\right\}. \quad (3.19a)$$

The impedance is

$$Z_{\text{even}}=\frac{-j\zeta_0\Psi_{\text{even}}}{2\pi}\left\{\frac{\cos\beta_0 h+A_{\text{even1}}/\Psi_{\text{even}}+\cdots}{\sin\beta_0 h+B_{\text{even1}}/\Psi_{\text{even}}+\cdots}\right\}. \quad (3.19b)$$

For the symmetrical case a superscript s is added to I, Ψ, M, B, A, and Z, and V_{20} is replaced by V_2^s; for the antisymmetrical case a superscript a replaces the superscript s. The functions M, B, A, and Ψ are defined as for a single antenna but using a different kernel.

An important object in evaluating $I_{\text{even}}^s(z_2)$ and $I_{\text{odd}}^a(z_2)$ is to determine the factor f^s and f^a. They may be evaluated directly from (3.19a, b) as follows. Since the odd part of $I_2(z_2)$ necessarily is zero at $z_2=0$, the

entire current at this point is even. Hence, using (1.6) and (1.7),

Symmetrical case:

$$V_{20}=V_2{}^s=I_2{}^s(z_2=0)Z_{\text{even}}{}^s$$

$$=I_1{}^s(0)Z_{\text{even}}{}^s=\frac{V^s}{Z_{0c}{}^s}\cdot Z_{\text{even}}{}^s=f^sV^s. \quad (3.20a)$$

Therefore,

$$f^s=Z_{\text{even}}{}^s/Z_{0c}{}^s. \quad (3.20b)$$

Antisymmetrical case:

$$V_{20}=-V_2{}^a=I_2{}^a(z_2=0)Z_{\text{even}}{}^a$$

$$=-I_1{}^a(0)Z_{\text{even}}{}^a=\frac{-V^a}{Z_{0c}{}^a}Z_{\text{even}}{}^a=-f^aV^a. \quad (3.21a)$$

Therefore,

$$f^a=Z_{\text{even}}{}^a/Z_{0c}{}^a. \quad (3.21b)$$

$Z_{0c}{}^s$ and $Z_{0c}{}^a$ are given by (2.11) with appropriate superscripts. The complex factor k defined in (2.19a) is given by

$$k=f^a/f^s=\frac{Z_{\text{even}}{}^a}{Z_{\text{even}}{}^s}\cdot\frac{Z_{0c}{}^s}{Z_{0c}{}^a}. \quad (3.22)$$

It is this factor that is required in order to calculate the input impedance of the three-element array with the outer units parasitic using (2.19c).

The even part of the current in the outer antennas when these are parasitic is given by

$$I_{2\text{even}}(z_2)=I_{\text{even}}{}^s(z_2)-I_{\text{even}}{}^a(z_2) \quad (3.23a)$$

where $I_{\text{even}}{}^s(z_2)$ is obtained from (3.19a) with appropriate superscripts s and with $V_{20}=V_2{}^s$, and where $I_{\text{even}}{}^a(z_2)$ is given by (3.19a) with superscripts a and with $V_{20}=V_2{}^a$. Note that

$$V_2{}^a=V_2{}^s=f^sV^s=f^aV^a=V_{10}/2F_2 \quad (3.23b)$$

where

$$F_2\equiv(f^a+f^s)/2f^af^s. \quad (3.23c)$$

Thus,

$$I_{2\text{even}}(z_2)=\frac{j\pi V_{10}}{\zeta_0F_2}\left\{\frac{1}{\Psi_{\text{even}}{}^s}\left[\frac{\sin\beta_0(h-z_2)+M_{\text{even}1}{}^s(z_2)/\Psi_{\text{even}}{}^s+\cdots}{\cos\beta_0h+A_{\text{even}1}{}^s/\Psi_{\text{even}}{}^s+\cdots}\right]\right.$$

$$\left.-\frac{1}{\Psi_{\text{even}}{}^a}\left[\frac{\sin\beta_0(h-z_2)+M_{\text{even}1}{}^a(z_2)/\Psi_{\text{even}}{}^a+\cdots}{\cos\beta_0h+A_{\text{even}1}{}^a/\Psi_{\text{even}}{}^a+\cdots}\right]\right\}. \quad (3.23d)$$

$I_{2\text{even}}(z_2)$ does not differ greatly from $I_1(z)$ since both are even functions that are equal at the centers of all three antennas.

The odd part of the current in antenna 2 must be determined from (3.18b) using the known value of $I_{\text{even}}(z_2)$ obtained from the solution (3.19a) of (3.18a). Thus,

$$\int_0^h I_{\text{odd}}(z_2')K_{\text{odd}}(z_2,z_2')dz_2'$$

$$=\frac{-j4\pi}{\zeta_0}[C_{\text{odd}}\sin\beta_0z_2+U(z_2)];\quad(0\leqq z_2\leqq h) \quad (3.24a)$$

where

$$U(z_2)\equiv\frac{-j\zeta_0}{4\pi}\int_0^h I_{\text{even}}(z_2')K_{0e}(z_2,z_2')dz_2'. \quad (3.24b)$$

$K_{\text{odd}}(z_2,z_2')$ is given by (3.17e) and $K_{0e}(z_2,z_2')$ by (3.17c). The upper sign in (3.17c) applies to the symmetrical, the lower sign to the antisymmetrical case. Note that $K_{\text{odd}}(z_2,z_2')$ is the same for both. The evaluation of $I_{\text{odd}}(z_2)$ from (3.24a) is involved particularly when β_0h is near π since it then is a resonant-mode current whereas the even current is not. On the other hand, when β_0h is near $\pi/2$ the even distribution is resonant, the odd is not and, therefore, relatively small. Since the only practically important case, and at the same time the one for which an approximate evaluation of (3.24a) is readily carried out, is with $\beta_0h=\pi/2$, only this is considered.

The first step in the solution of (3.24a) is the simplification of the function $U(z_2)$. Since z_2 cannot exceed h, and $d\geqq 2h$ occurs in all distances R in $K_{0e}(z_2,z_2')$, the term a^2 in these distances is negligible. It follows that in the range $0\leqq z_2\leqq h$, $0\leqq z_2'\leqq h$, (3.17c) may be simplified into

$$K_{0e}(z_2,z_2')\doteq\pm\tfrac{1}{2}e^{-j\beta_0(d+z_2)}\left[\frac{e^{j\beta_0z_2'}}{d+z_2-z_2'}+\frac{e^{-j\beta_0z_2'}}{d+z_2+z_2'}\right]$$

$$\mp\tfrac{1}{2}e^{-j\beta_0(d-z_2)}\left[\frac{e^{j\beta_0z_2'}}{d-z_2-z_2'}+\frac{e^{-j\beta_0z_2'}}{d-z_2+z_2'}\right]$$

$$+\tfrac{1}{2}e^{-j\beta_0(3d+z_2)}\left[\frac{e^{j\beta_0z_2'}}{2d+z_2-z_2'}+\frac{e^{-j\beta_0z_2'}}{2d+z_2+z_2'}\right]$$

$$+\tfrac{1}{2}e^{-j\beta_0(2d-z_2)}\left[\frac{e^{j\beta_0z_2'}}{2d-z_2-z_2'}+\frac{e^{-j\beta_0z_2'}}{2d-z_2+z_2'}\right]. \quad (3.25)$$

As a next step in the simplification let z_2' be neglected in the denominators throughout. This is a good approximation for all values of z_2' in most of the terms, a poor approximation only in one term and then only when

$z_2=h$ and when z_2' approaches h. Since the current vanishes at h, an error here is of no great importance. Hence, setting $z_2'=0$ in the denominators, (3.25) reduces to

$$K_{0e}(z_2, z_2')=\left[\pm\frac{e^{-j\beta_0(d+z_2)}}{d+z_2}\mp\frac{e^{-j\beta_0(d-z_2)}}{d-z_2}+\frac{e^{-j\beta_0(2d+z_2)}}{2d+z_2}+\frac{e^{-j\beta_0(2d-z_2)}}{2d-z_2}\right]\cos\beta_0 z_2'. \quad (3.26)$$

Since with $\beta_0 h=\pi/2$, the even current is well approximated by

$$I_{\text{even}}(z_2)\equiv\frac{V}{Z_{0e}}\cos\beta_0 z_2' \quad (3.27)$$

the integral in (3.24b) may be evaluated directly using (3.26). It involves

$$\int_0^h \cos^2\beta_0 z_2' dz_2'=\pi/4\beta_0. \quad (3.28)$$

Accordingly,

$$U(z_2)\doteq\frac{j\zeta_0 V}{8Z_{0e}}\left\{\frac{\pm e^{-j\beta_0 d}}{\beta_0(d^2-z_2^2)}[z_2\cos\beta_0 z_2+jd\sin\beta_0 z_2]+\frac{e^{-j2\beta_0 d}}{\beta_0(4d^2-z^2)}[z_2\cos\beta_0 z_2+j2d\sin\beta_0 z_2]\right\}. \quad (3.29)$$

In the range $0\leqq\beta_0 z_2\leqq\pi/2$, the approximation $\beta_0 z_2\doteq\sin\beta_0 z_2$ is satisfactory except near $\beta_0 z_2=\pi/2$ where, however, the current vanishes and an error in $U(z_2)$ is immaterial. With this approximation,

$$U(z_2)\doteq\frac{\zeta_0 V}{8Z_{0e}\beta_0 d}F(z_2)\sin\beta_0 z_2\equiv\bar{U}(z_2)\sin\beta_0 z_2 \quad (3.30a)$$

where $\bar{U}(z_2)$ is defined by (3.30a) and where

$$F(z_2)=-\left\{\frac{\pm e^{-j\beta_0 d}}{(1-z_2^2/d^2)}\left[1-j\frac{\cos\beta_0 z_2}{\beta_0 d}\right]+\frac{e^{-j2\beta_0 d}}{(1-z_2^2/4d^2)}\left[1-j\frac{\cos\beta_0 z_2}{2\beta_0 d}\right]\right\}. \quad (3.30b)$$

Since $z_2/d\leqq\frac{1}{4}$, and $\beta_0 d\geqq\pi$, $F(z_2)$ does not vary rapidly. It follows that $U(z_2)$ varies approximately as $\sin\beta_0 z_2$. With (3.30a, b) the integral equation (3.24a) reduces to

$$\int_0^h I_{\text{odd}}(z_2')K_{\text{odd}}(z_2, z_2')dz_2'=\frac{-j4\pi}{\zeta_0}[C_{\text{odd}}+\bar{U}(z_2)]\sin\beta_0 z_2. \quad (3.31)$$

This integral equation can be solved for the current by

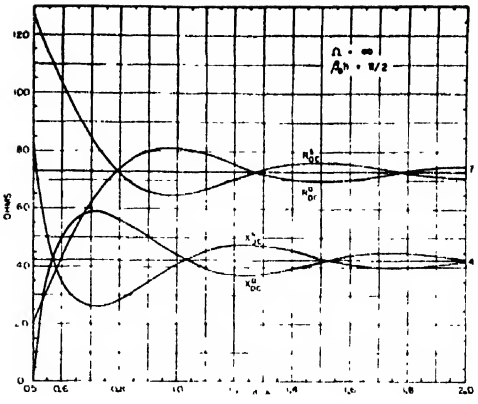

FIG. 6. Symmetrical and antisymmetrical impedances of the central unit in a three-antenna array.

the usual method of iteration. Let

$$I_{\text{odd}}(z_2')=I_{\text{odd}}(z_2)g(z_2, z_2') \quad (3.32)$$

where $g(z_2, z_2')$ is a distribution function that is chosen to make $I_{\text{odd}}(z_2)\Psi_{\text{odd}}(z_2)$ approximate closely the integral on the left in (3.31) with

$$\Psi_{\text{odd}}(z_2)=\int_0^h g(z_2, z_2')K_{\text{odd}}(z_2, z_2')dz_2'=\Psi_{\text{odd}}+\gamma_{\text{odd}}(z_2). \quad (3.33)$$

Ψ_{odd} is a mean constant value of the integral defined at a suitable reference point. With (3.32) and (3.33)

$$I_{\text{odd}}(z_2)=\frac{-j4\pi}{\zeta_0\Psi_{\text{odd}}}[C_{\text{odd}}+\bar{U}(z_2)]\sin\beta_0 z_2-\frac{1}{\Psi_{\text{odd}}}\left[I_{\text{odd}}(z_2)\gamma_{\text{odd}}(z_2)+\int_0^h[I_{\text{odd}}(z_2')-I_{\text{odd}}(z_2)g(z_2, z_2')]K_{\text{odd}}(z_2, z_2')dz_2'\right]. \quad (3.34)$$

By using the term in $\sin\beta_0 z_2$ as the zeroth-order current, and substituting this in the integrals, these may be evaluated assuming $\bar{U}(z_2)$ to be constant, and added to the zeroth-order current. This process of iteration can be repeated. The current then appears in the form

$$I_{\text{odd}}(z_2)=\frac{-j4\pi}{\zeta_0\Psi_{\text{odd}}}[C_{\text{odd}}+\bar{U}(z_2)]\times\left[\sin\beta_0 z_2+\frac{S_1(z_2)}{\Psi_{\text{odd}}}+\frac{S_2(z_2)}{\Psi_{\text{odd}}^2}+\cdots\right]. \quad (3.35)$$

The constant C_{odd} may be evaluated by requiring the current to vanish at $z_2=h$. Then

$$C_{\text{odd}}=-U(h) \quad (3.36)$$

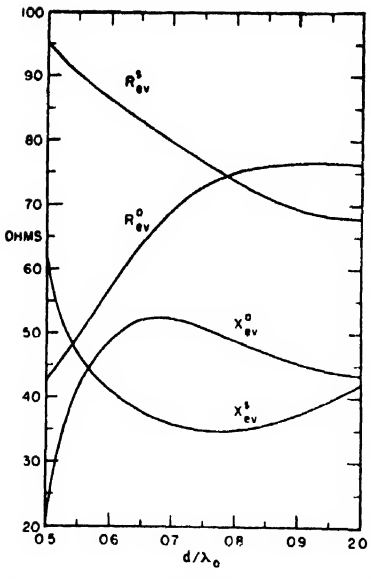

FIG. 7. Symmetrical and antisymmetrical impedances of the outer units in a three-element array.

so that

$$I_{\text{odd}}(z_2)=\frac{-j4\pi}{\zeta_0\Psi_{\text{odd}}}[U(z_2)-U(h)]\times\left[\sin\beta_0 z_2+\frac{S_1(z_2)}{\Psi_{\text{odd}}}+\frac{S_2(z_2)}{\Psi_{\text{odd}}^2}+\cdots\right]. \quad (3.37)$$

It follows from (3.30b) that with $\beta_0 h=\pi/2$, an approximate result is:

$$U(z_2)-U(h)\doteq\frac{j\zeta_0 VD(d)}{8Z_{0c}}\cos\beta_0 z_2, \quad (3.38a)$$

where

$$D(d)\equiv\frac{1}{\beta_0^2 d^2}\left[\pm\frac{e^{-j\beta_0 d}}{(1-h^2/d^2)}+\frac{e^{-j2\beta_0 d}}{2(1-h^2/4d^2)}\right]. \quad (3.38b)$$

Substitution of (3.38a) in (3.37) gives the following simple expressions for the zeroth-order odd currents in the outer units when $\beta_0 h=\pi/2$:

$$I_{\text{odd}^s}(z_2)=\frac{V^s}{Z_{0c^s}}\frac{\pi D^s(d)}{4\Psi_{\text{odd}}}\sin 2\beta_0 z_2 \quad (3.39a)$$

$$I_{\text{odd}^a}(z_2)=\frac{V^a}{Z_{0c^a}}\frac{\pi D^a(d)}{4\Psi_{\text{odd}}}\sin 2\beta_0 z_2 \quad (3.39b)$$

where $D^s(d)$ is (3.38b) with the upper sign and $D^a(d)$ is (3.38b) with the lower sign. Note that $V^s/Z_{0c^s}=I_1^s(0)$; $V^a/Z_{0c^a}=I_1^a(0)$. The odd part of the current in the outer units when these are parasitic is given by the sum of (3.39a) and (3.39b). Noting that as in (2.19b), $V^s=V_{10}/(1+k^{-1})$, $V^a=V_{10}/(1+k)$, it follows that

$$I_{2\text{odd}}(z_2)=I_{\text{odd}^s}(z_2)+I_{\text{odd}^a}(z_2)=\frac{V_{10}\pi}{4\Psi_{\text{odd}}}\left[\frac{D^s(d)}{Z_{0c^s}(1+k^{-1})}+\frac{D^a(d)}{Z_{0c^a}(1+k)}\right]\sin 2\beta_0 z_2;$$

$$(\beta_0 h=\pi/2). \quad (3.40)$$

The total current in the outer antennas is the sum of (3.40) and (3.23d) with $\beta_0 h=\pi/2$. Note that as the antenna is made thinner, i.e. $\Omega=2\ln(2h/a)$ increased, the odd current does not approach a value independent of Ω when $\beta_0 h=\pi/2$ as does the even current.

The final step in the complete evaluation of $I_{\text{odd}}(z_2)$ is the determination of Ψ_{odd} from (3.33). Since the zeroth-order distribution leads to a distribution function $g(z_2, z_2')=\sin 2\beta_0 z'/\sin 2\beta_0 z$ that does not permit the ready evaluation of Ψ_{odd}, the simpler procedure of assuming a sensibly uniform current and neglecting retardation is more convenient and adequate. This is equivalent to setting

$$\Psi_{\text{odd}}(z_2)=\int_0^h\left[\frac{1}{[(z_2'-z_2)^2+a^2]^{\frac{1}{2}}}-\frac{1}{[(z_2'+z_2)^2+a^2]^{\frac{1}{2}}}\right]dz_2'. \quad (3.41)$$

Since the odd current is most nearly constant near $z_2=h/2$ and this is its greatest value, it is a good approximation to choose the reference point for Ψ_{odd} at $z_2=h/2$. Thus

$$\Psi_{\text{odd}}=\int_{-h/2}^{h/2}\frac{du}{(u^2+a^2)^{\frac{1}{2}}}-\int_{h/2}^{3h/2}\frac{du}{(u^2+a^2)^{\frac{1}{2}}}=\ln\left(\frac{h^2}{3a^2}\right)=\Omega-2.5, \quad (3.42)$$

where $\Omega=2\ln(2h/a)$.

In this section general expressions have been obtained for the symmetrical and antisymmetrical components of the even current in the outer units of the three-element array. An approximate formula for the odd currents has been derived in the important special case, $\beta_0 h=\pi/2$. As a part of the determination of the even currents, relations between the three driving voltages were established which assure that the currents at the centers of all three units are equal in magnitude and either in-phase or 180 degrees out-of-phase as required by the conditions for the symmetrical and antisymmetrical cases. Thus, in Section 2 and this section the general formulas for the currents in collinear arrays are derived in the special case of the three-element array.

4. COLLINEAR ARRAY OF THREE HALF-WAVE DIPOLES

The most useful collinear array of three antennas consists of identical units each of electrical half-length $\beta_0 h = \pi/2$. The middle antenna No. 1 is center-driven from a balanced two-wire transmission line. As with the single antenna[1] this line may be replaced by an appropriate terminal-zone network with a slice generator. The two outer antennas, No. 2 and No. 3, are parasitic as shown in Fig. 2b.

The driving voltages for the three units are

$$V_{10} = V^s + V^a = V^s(1+k^{-1}) = V^a(1+k);$$

$$V_{20} = V_{30} = V_2{}^s - V_2{}^a = f^s V^s - f^a V^a = 0 \quad (4.1a)$$

where

$$k = \frac{f^a}{f^s}; \quad f^a = \frac{Z_{\text{even}}{}^a}{Z_{0c}{}^a}; \quad f^s = \frac{Z_{\text{even}}{}^s}{Z_{0c}{}^s}, \quad (4.1b)$$

and where Z_{even} is the impedance of each outer unit, Z_{0c} of the central unit. V^s is the driving voltage of the central unit when the other two are center-driven by voltages $V_3{}^s = V_2{}^s = f^s V^s$ such that the *currents* at the *centers* of all three units are equal and in phase. V^a is the driving voltage of the central unit when the two outer antennas are center-driven by voltages $V_3{}^a = V_2{}^a = f^a V^a$ such that the currents at the centers of the two outer units are equal to and in-phase with each other, but both equal to and 180 degrees out-of-phase with the current at $z=0$ in the central unit.

The first-order symmetrical and antisymmetrical currents in the central unit are given by (2.10) with $\beta_0 h = \pi/2$ and appropriate superscripts. Thus,

$$I_1{}^s(z) = \frac{j2\pi V^s}{\zeta_0 A_{c1}{}^s}[\cos\beta_0 z + M_{c1}{}^s(z)/\Psi_{Kc}{}^s];$$

$$(0 \leqq z \leqq h) \quad (4.2a)$$

$$I_1{}^a(z) = \frac{j2\pi V^a}{\zeta_0 A_{c1}{}^a}[\cos\beta_0 z + M_{c1}{}^a(z)/\Psi_{Kc}{}^a];$$

$$(0 \leqq z \leqq h). \quad (4.2b)$$

The total first-order current in the central unit when the outer units are parasitic is the sum of (4.2a) and (4.2b). With (4.1a, b) it is,

$$I_1(z) = I_1{}^s(z) + I_1{}^a(z) = \frac{j2\pi V_{10}}{\zeta_0}$$

$$\times\left\{\left[\frac{1}{A_{c1}{}^s(1+k^{-1})} + \frac{1}{A_{c1}{}^a(1+k)}\right]\cos\beta_0 z\right.$$

$$\left.+\left[\frac{M_{c1}{}^s(z)}{A_{c1}{}^s(1+k^{-1})\Psi_{K1}{}^s} + \frac{M_{c1}{}^a(z)}{A_{c1}{}^a(1+k)\Psi_{K1}{}^a}\right]\right\}. \quad (4.3)$$

The first-order symmetrical and antisymmetrical impedances of the central unit are

$$Z_{0c}{}^s = \frac{-j\zeta_0 A_{c1}{}^s}{2\pi}[1 + B_{c1}{}^s/\Psi_{Kc}{}^s]^{-1};$$

$$Z_{0c}{}^a = \frac{-j\zeta_0 A_{c1}{}^a}{2\pi}[1 + B_{c1}{}^a/\Psi_{Kc}{}^a]^{-1}. \quad (4.4a)$$

The first-order input impedance of the array when the outer units are parasitic is

$$Z_{1\text{in}} = \frac{-j\zeta_0}{2\pi}\left\{\left[\frac{1}{A_{c1}{}^s(1+k^{-1})} + \frac{1}{A_{c1}{}^a(1+k)}\right]\right.$$

$$\left.+\left[\frac{B_{c1}{}^s}{A_{c1}{}^s(1+k^{-1})\Psi_{K1}{}^s} + \frac{B_{c1}{}^a}{A_{c1}{}^a(1+k)\Psi_{K1}{}^a}\right]\right\}^{-1}. \quad (4.4b)$$

where

$$B_{c1}{}^s \equiv M_{c1}{}^s(0); \quad B_{c1}{}^a \equiv M_{c1}{}^a(0). \quad (4.4c)$$

For antennas that have a reasonably large value of h/a, $\Psi_{K1}{}^s$ and $\Psi_{K1}{}^a$ are sufficiently great to make the contributions by the $1/\Psi_{K1}$ terms in (2.2a, b), (2.3) and (2.4a, b) relatively small. When this is true the following expressions are satisfactory approximations:

$$I_1{}^s(z) \doteq \frac{V^s}{Z_{0c}{}^s}\cos\beta_0 z; \quad I_1{}^a(z) \doteq \frac{V^a}{Z_{0c}{}^a}\cos\beta_0 z;$$

$$I_1(z) = \frac{V_{10}}{Z_{1\text{in}}}\cos\beta_0 z \quad (4.5a)$$

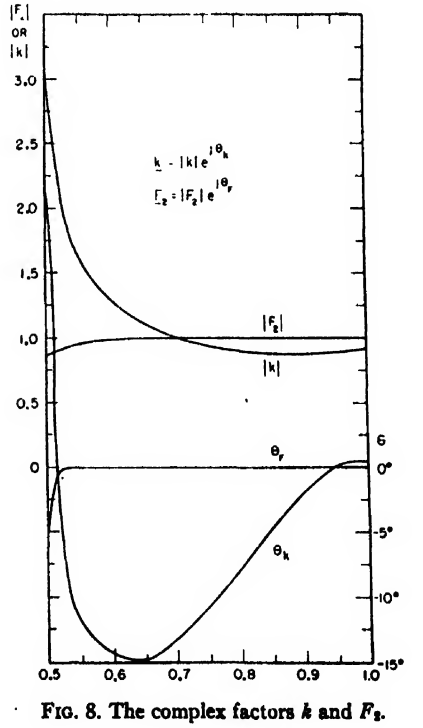

FIG. 8. The complex factors k and F_z.

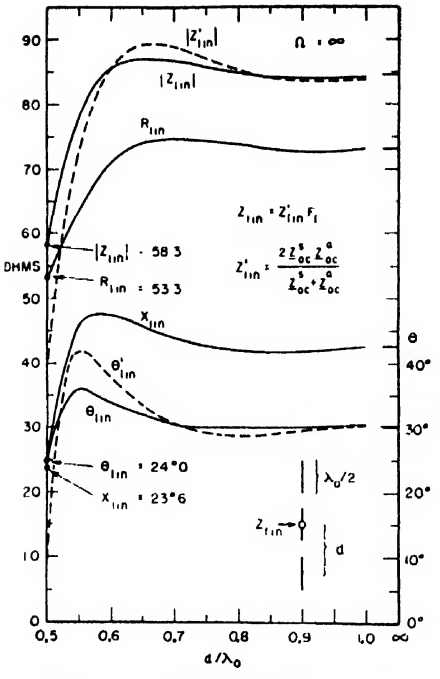

FIG. 9. Input impedance of antenna with two collinear parasites.

where

$$Z_{0c}{}^{s} \doteq \frac{-j\zeta_0 A_{c1}{}^{s}}{2\pi}; \quad Z_{0c}{}^{a} \doteq \frac{-j\zeta_0 A_{c1}{}^{a}}{2\pi} \tag{4.5b}$$

and where, using (2.19c, d),

$$Z_{1in} = \left[\frac{1}{Z_{0c}{}^{s}(1+k^{-1})} + \frac{1}{Z_{0c}{}^{a}(1+k)}\right]^{-1} = Z_{1in}{}' F_1 \tag{4.5c}$$

where

$$Z_{1in}{}' = \frac{2Z_{0c}{}^{s} Z_{0c}{}^{a}}{Z_{0c}{}^{s} + Z_{0c}{}^{a}};$$

$$F_1 = 1 + \frac{[Z_{0c}{}^{s} - Z_{0c}{}^{a}][k - k^{-1}]}{2[Z_{0c}{}^{s}(1+k^{-1}) + Z_{0c}{}^{a}(1+k)]}. \tag{4.5d}$$

It is seen from (4.5) that $I_1(z)$ and Z_{1in} involve only $A_{c1}{}^{s}$, $A_{c1}{}^{a}$, and k. As with the isolated antenna, the former are defined as follows when $\beta_0 h = \pi/2$:

$$A_{c1} \equiv F_{c1}(h) = -\int_{-h}^{h} \cos\beta_0 z' K_{c1}(h, z') dz'; \quad h = \lambda_0/4 \tag{4.6}$$

where

$$K_{c1}(h, z') = K_1(h, z') \pm [K_1(d-h, z') + K_1(d+h, z')]; \quad h = \lambda_0/4. \tag{4.7}$$

Using the integrals given in reference 4, (4.6) may be expressed as follows:

$$A_{c1} = -\{C_a(h, h) \pm [C_a(d-h, h) + C_a(d+h, h)]\}; \quad h = \lambda_0/4. \tag{4.8}$$

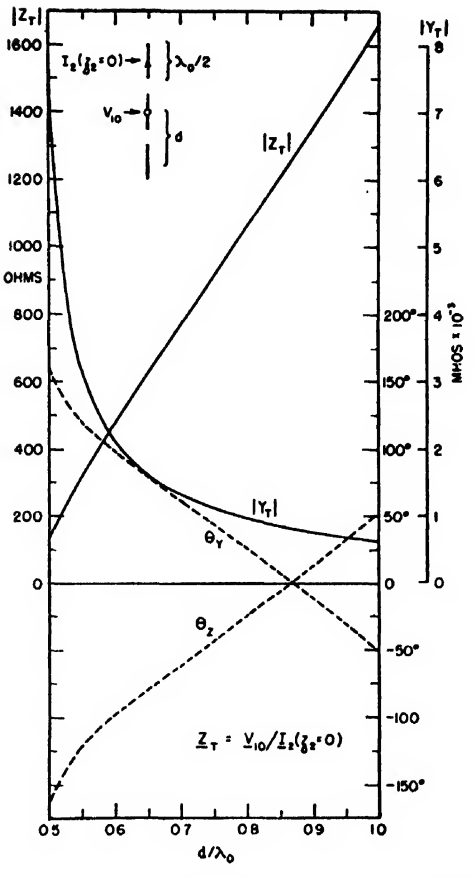

FIG. 10. Transfer impedance and admittance for antenna with two collinear parasites.

The upper sign requires a superscript s, the lower sign a superscript a on A_{c1}. It follows that

$$Z_{0c} = \frac{j\zeta_0}{2\pi}[C_a(h, h) \pm C_a(d-h, h) \pm C_a(d+h, h)]; \quad h = \lambda_0/4 \tag{4.9}$$

where the upper sign is for $Z_{0c}{}^{s}$, the lower sign for $Z_{0c}{}^{a}$. The symmetrical and antisymmetrical impedances of the three element array as given in (4.9) are in Fig. 6. The impedance $Z_{1in}{}'$ defined in (4.5c), which is the principal part of Z_{1in}, is shown in Fig. 9 together with Z_{1in}. Note that Z_{1in} reduces to $Z_{1in}{}'$ when d is sufficiently great so that $k \doteq 1$. It is not possible to determine Z_{1in} until k is available. This requires the evaluation of $Z_{even}{}^{s}$ and $Z_{even}{}^{a}$ in addition to $Z_{0c}{}^{s}$ and $Z_{0c}{}^{a}$.

The first-order symmetrical and antisymmetrical even currents in the outer units are given by (3.19a) with $\beta_0 h = \pi/2$. They are

$$I_{even}{}^{s}(z_2) = \frac{j2\pi V_2{}^{s}}{\zeta_0 A_{even1}{}^{s}} \times [\cos\beta_0 z_2 + M_{even1}{}^{s}(z_2)/\Psi_{even}{}^{s}] \tag{4.10a}$$

$$I_{\text{even}}{}^{a}(z_2)=\frac{j2\pi V_2{}^{a}}{\zeta_0 A_{\text{even1}}{}^{a}}$$

$$\times[\cos\beta_0 z_2+M_{\text{even1}}{}^{a}(z_2)/\Psi_{\text{even}}{}^{a}]. \quad (4.10b)$$

When the outer units are parasitic

$$V_2{}^{s}=V_2{}^{a}=f^{s}V^{s}=f^{a}V^{a}=V_{10}/2F_2;$$

$$F_2\equiv\frac{f^{a}+f^{s}}{2f^{a}f^{s}}=\frac{1}{2}\left[\frac{Z_{0c}{}^{s}}{Z_{\text{even}}{}^{s}}+\frac{Z_{0c}{}^{a}}{Z_{\text{even}}{}^{a}}\right] \quad (4.10c)$$

as in (3.23a) and the total current is given by,

$$I_{2\text{even}}(z_2)=I_{\text{even}}{}^{s}(z_2)-I_{\text{even}}{}^{a}(z_2)$$

$$=\frac{j\pi V_{10}}{\zeta_0 F_2}\left\{\left[\frac{1}{A_{\text{even1}}{}^{s}}-\frac{1}{A_{\text{even1}}{}^{a}}\right]\cos\beta_0 z_2\right.$$

$$\left.+\left[\frac{M_{\text{even1}}{}^{s}(z_2)}{A_{\text{even1}}{}^{s}\Psi_{\text{even}}{}^{s}}-\frac{M_{\text{even1}}{}^{a}(z_2)}{A_{\text{even1}}{}^{a}\Psi_{\text{even}}{}^{a}}\right]\right\};$$

$$\beta_0 h=\pi/2. \quad (4.11)$$

The first-order symmetrical and antisymmetrical impedances of the outer units are

$$Z_{\text{even}}{}^{s}=\frac{-j\zeta_0 A_{\text{even1}}{}^{s}}{2\pi}[1+B_{\text{even1}}{}^{s}/\Psi_{\text{even}}{}^{s}]^{-1};$$

$$Z_{\text{even}}{}^{a}=\frac{-j\zeta_0 A_{\text{even1}}{}^{a}}{2\pi}[1+B_{\text{even1}}{}^{a}/\Psi_{\text{even}}{}^{a}]^{-1}. \quad (4.12a)$$

The transfer impedance when the outer units are parasitic is

$$Z_T=\frac{-j\zeta_0 F_2}{\pi}\left\{\left[\frac{1}{A_{\text{even1}}{}^{s}}-\frac{1}{A_{\text{even1}}{}^{a}}\right]\right.$$

$$\left.+\left[\frac{B_{\text{even1}}{}^{s}}{A_{\text{even1}}{}^{s}\Psi_{\text{even}}{}^{s}}-\frac{B_{\text{even1}}{}^{a}}{A_{\text{even1}}{}^{a}\Psi_{\text{even}}{}^{a}}\right]\right\}^{-1} \quad (4.12b)$$

where

$$B_{\text{even1}}{}^{s}\equiv M_{\text{even1}}{}^{s}(0); \quad B_{\text{even1}}{}^{a}\equiv M_{\text{even1}}{}^{a}(0). \quad (4.12c)$$

For sufficiently great values of $\Psi_{\text{even}}{}^{s}$ and $\Psi_{\text{even}}{}^{a}$ the leading terms are good approximations. They are

$$I_{\text{even}}{}^{s}(z_2)\doteq\frac{V_2{}^{s}}{Z_{\text{even}}{}^{s}}\cos\beta_0 z_2;$$

$$I_{\text{even}}{}^{a}(z_2)\doteq\frac{V_2{}^{a}}{Z_{\text{even}}{}^{a}}\cos\beta_0 z_2;$$

$$I_{2\text{even}}(z_2)=\frac{V_{10}}{Z_T}\cos\beta_0 z_2 \quad (4.13a)$$

where

$$Z_{\text{even}}{}^{s}=\frac{-j\zeta_0 A_{\text{even1}}{}^{s}}{2\pi}; \quad Z_{\text{even}}{}^{a}=\frac{-j\zeta_0 A_{\text{even1}}{}^{a}}{2\pi}, \quad (4.13b)$$

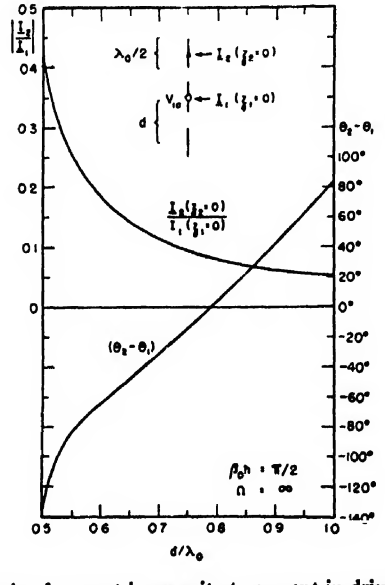

FIG. 11. Ratio of current in parasite to current in driven element.

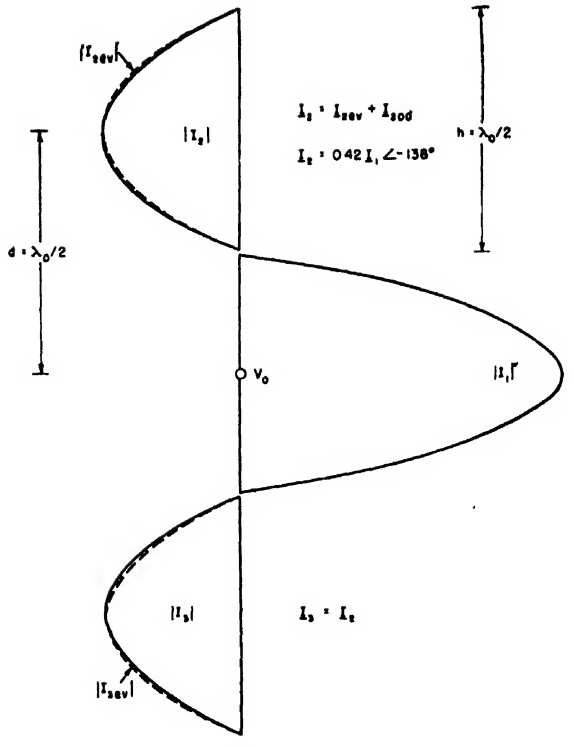

FIG. 12. Distributions of current on collinear array with outer elements parasitic.

$$Z_T = Z_T' F_2; \quad Z_T' \equiv \frac{2Z_{even^s} Z_{even^a}}{Z_{even^a} - Z_{even^s}};$$

$$F_2 \equiv \frac{1}{2}\left[\frac{Z_{0c^s}}{Z_{even^s}} + \frac{Z_{0c^a}}{Z_{even^a}}\right] \doteq 1. \quad (4.13c)$$

The ratio of currents at the centers of the outer parasitic units to the current at the center of the driven unit is given by

$$I_2(z_2=0)/I_1(0) = Z_{11n}/Z_T = \left|\frac{I_2(0)}{I_1(0)}\right| e^{j(\theta_2-\theta_1)}, \quad (4.14)$$

where Z_{11n} is given by (4.5c) and Z_T by (4.13b). It is shown later (Fig. 8) that the factor F_2 differs negligibly from unity as indicated in (4.13c) except when d/λ_0 is at or very near 0.5. As in (4.6), but with a different kernel,

$$A_{even1} = F_{even1}(h) = -\int_{-h}^{h} \cos\beta_0 z_2' K_{1even}(h, z_2') dz_2'$$

$$= -\int_0^h \cos\beta_0 z_2' K_{even}(h, z_2') dz_2' \quad (4.15)$$

where $K_{even}(h, z_2')$ is given by (2.17a) with $z_2 = h = \lambda_0/4$. Thus,

$$K_{even}(h, z_2) = K(h, z_2') \pm \tfrac{1}{2}[K(d-h, z_2') + K(d+h, z_2')] + \tfrac{1}{2}[K(2d-h, z_2') + K(2d+h, z_2')] \quad (4.16)$$

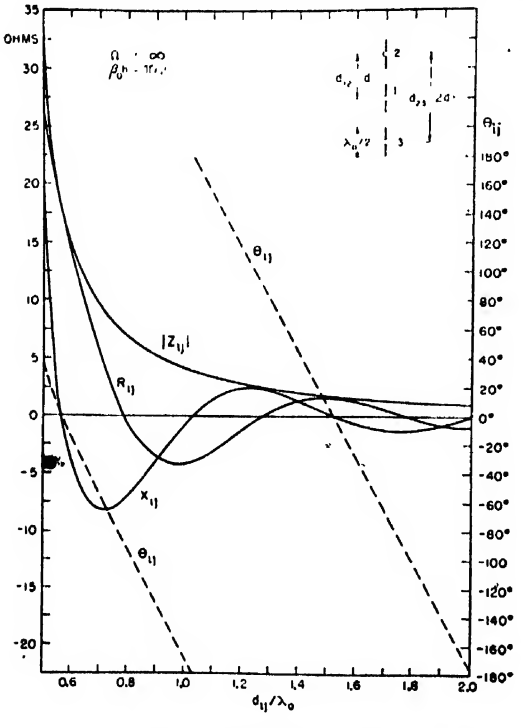

FIG. 13. Mutual impedance for collinear arrays.

where, as usual, $K \equiv K_1 + K_2$. With reference 4 the integrals in (4.13a) with (14.4) may be expressed as follows:

$$A_{even1} = -\{C_a(h, h) \pm \tfrac{1}{2}[C_a(d-h, h) + C_a(d+h, h)] + \tfrac{1}{2}[C_a(2d-h, h) + C_a(2d+h, h)]\}; \quad (h = \lambda_0/4). \quad (4.17)$$

The upper sign in (4.17) goes with a superscript s on A_{even1}, the lower sign with a superscript a. The corresponding impedances are

$$Z_{even} = \frac{j\zeta_0}{2\pi}\{C_a(h, h) \pm \tfrac{1}{2}[C_a(d-h, h) + C_a(d+h, h)] + \tfrac{1}{2}[C_a(2d-h, h) + C_a(2d+h, h)]\}; \quad h = \lambda_0/4, \quad (4.18)$$

where the upper sign is for Z_{even^s}, the lower sign for Z_{even^a}. They are in Fig. 7.

With Z_{even^s} and Z_{even^a} determined, the functions k, f^a and f^s defined in (4.1b) and the function F_2 defined in (4.5d) may be evaluated k and F_2 are in Fig. 8 in polar form. With k available and Z_{11n}' known, the approximate input impedance Z_{11n} (as defined in (4.5c)) may be evaluated. It is shown in Fig. 9 along with Z_{11n}' which it approaches as k approaches unity with increased d. With F_2 available the transfer impedance Z_T may be determined using its principal factor Z_T'. Z_T and Z_T' are in Fig. 10. Note that $Z_T \doteq Z_T'$ except when $d/\lambda_0 \doteq 0.5$, and even here the departure is small. The ratio of currents (4.14) is shown in Fig. 11 as a function of d/λ_0 and the distribution in Fig. 12 for $d = \lambda_0/2$. Note that when $d = \lambda_0/2$ the currents in the parasites are nearly opposite in phase to the current in the central unit.

The general equations for the three-element array in which the outer units are always identical are

$$V_{10} = I_{10}Z_{s1} + I_{20}Z_{12} + I_{30}Z_{13} = I_{10}Z_{s1} + 2I_{20}Z_{12} \quad (4.19a)$$

$$V_{20} = I_{10}Z_{21} + I_{20}Z_{s2} + I_{30}Z_{23} = I_{10}Z_{12} + I_{20}(Z_{s2} + Z_{23}). \quad (4.19b)$$

When the units are symmetrically driven,

$$V^s = I_{10}(Z_{s1} + 2Z_{12}), \quad (4.20a)$$

$$V_2^s = I_{10}(Z_{s2} + Z_{12} + Z_{23}). \quad (4.20b)$$

When the units are antisymmetrically driven,

$$V^a = I_{10}(Z_{s1} - 2Z_{12}), \quad (4.21a)$$

$$V_2^a = -I_{10}(Z_{s2} - Z_{12} + Z_{23}). \quad (4.21b)$$

Comparison with (9) and (18) shows that when $\beta_0 h = \pi/2$ these approximate expressions for the symmetrical and antisymmetrical impedances are consistent with the following definitions:

$$Z_{s1} \doteq Z_{s2} \doteq (j\zeta_0/2\pi) C_a(h, h), \tag{4.22a}$$

$$Z_{12} = Z_{13} \doteq \frac{j\zeta_0}{2\pi}\frac{1}{2}[C_a(d-h, h) + C_a(d+h, h)], \tag{4.22b}$$

$$Z_{23} \doteq \frac{j\zeta_0}{2\pi}\frac{1}{2}[C_a(2d-h, h) + C_a(2d+h, h)]. \tag{4.22c}$$

The functions Z_{12} and Z_{23} may be obtained from Fig. 13. It may be concluded that in general, when $\beta_0 h = \pi/2$, the zeroth-order self-impedance of each of N collinear antennas is

$$Z_{s1} = \cdots Z_{sN} \doteq \frac{j\zeta_0}{2\pi} C_a(h, h) = 73.13 + j42.5 \text{ ohms}. \tag{4.23a}$$

Similarly the zeroth-order mutual impedances between two collinear antennas numbered m and n and separated a distance $(n-m)d$ between centers, is

$$Z_{mn} \doteq \frac{j\zeta_0}{2\pi}\frac{1}{2}\{C_a[(n-m)d-h, h] + C_a[(n-m)d+h, h]\}. \tag{4.23b}$$

For collinear elements that are *not* near $\beta_0 h = \pi/2$ in electrical half-length the self- and mutual impedances cannot be expressed in this simple form. Only when $\beta_0 h = \pi/2$ and the identical antennas are sufficiently thin so that Ψ_{even^s} and Ψ_{even^a} are large compared with unity are the simple relations (4.22a, b, c) and (4.23a, b) moderately good approximations. In general, if the antennas are sufficiently thin so that (4.23a) is a good approximaion, it may be assumed that (4.23b) is an even better approximation. Tables of the several zeroth-order impedances involved in the three-element collinear array are in Table I.

The odd currents in the parasitic elements are evaluated in Section 3 when $\beta_0 h = \pi/2$. The approximate expression given in (3.40) is

$$I_{2odd}(z_2) = \frac{V_{10}}{\Psi_{odd}} K \sin 2\beta_0 z_2 \tag{4.24a}$$

where

$$K \equiv \frac{\pi}{4}\left[\frac{D^s(d)}{Z_{0c^s}(1+k^{-1})} + \frac{D^a(d)}{Z_{0c^a}(1+k)}\right] \tag{4.24b}$$

where $D^s(d)$ and $D^a(d)$ are given by (3.38b) respectively with the upper and lower sign, and where k is defined in (4.22). It is now readily verified that with $\beta_0 h = \pi/2$ the odd part of the current in the parasites

1.8	-3.60 $-j$ 3.92	$-$ .184 $-j1.16$	72.5 $+j42.2$	1310 $+j$ 266
1.9	-4.12 $-j$ 2.24	$-$ .805 $-j$ .704	72.7 $+j42.1$	1280 $+j$ 782
2.0	-4.16 $-j$ .725	$-$ .958 $+j$ .017	73.2 $+j42.8$	1020 $+j1290$

$Z_{s1} = Z_{s2} = Z_{s3} = 73.1 + j42.5$

is quite small compared with the even parts. Thus, when $\beta_0 d = \pi$, $h/d = \frac{1}{2}$,

$$D^s(d) = \frac{1}{\pi^2}\left(-\frac{4}{3} + \frac{8}{15}\right) = -0.08, \tag{4.25a}$$

$$D^a(d) = \frac{1}{\pi^2}\left(\frac{4}{3} + \frac{8}{15}\right) 0.19. \tag{4.25b}$$

Also,

$$Z_{0c^s}(1+k^{-1}) = 196.9\underline{/28°.3}; \qquad Z_{0c^a}(1+k) = 82.7\underline{/22.2°}. \tag{4.26}$$

With these values,

$$K \doteq 1.56\times 10^{-3}\underline{/-21°} \tag{4.27}$$

so that with $\Omega = 12.5$, $\Psi_{odd} = 10$,

$$I_{odd}(z_2) = 1.56\times 10^{-4} V_{10} e^{-j21°} \sin 2\beta_0 z_2. \tag{4.28}$$

The corresponding value for the even current with $\beta_0 d = \pi$ is obtained from (4.13a) with $Z_T = 137.7\underline{/-162°}$.

$$I_{even}(z_2) = \frac{V_{10}}{Z_T}\cos\beta_0 z_2 = 72.8\times 10^{-4} V_{10} e^{j162°}\cos\beta_0 z_2. \tag{4.29}$$

Combining (4.28) with (4.29) gives

$$I_2(z_2) = 72.8\times 10^{-4} V_{10} e^{j162°} \times [\cos\beta_0 z_2 - e^{-j3°} 0.022 \sin 2\beta_0 z_2]. \tag{4.30}$$

It is seen from (4.30) that the amplitude of the odd current is only 2 percent of the amplitude of the even current for $\Omega = 12.5$. For thicker antennas the odd currents are relatively greater. The current in (4.30) is shown in Fig. 12 together with the current in the central unit.

5. THE CENTER-DRIVEN COLLINEAR ARRAY WITH THE PHASE-REVERSING STUBS

It is shown in Section 4 that the currents in the two outer units of a three-element collinear array are nearly *opposite* in direction and equal in magnitude to the current in the central unit if the distance between adjacent ends of the elements is very small. The electromagnetic field of such a distribution of current is characterized by large maxima both along the plane bisecting the antenna and along symmetrical cones in the hemispheres. Between these maxima are deep minima. Whereas such a pattern is useful for certain applications, it is undesirable when a field is required that has a large amplitude only in the central plane. It is known that such a field is maintained by a collinear array if the currents are all about equal and in phase. Such a distribution can be maintained in the antennas if each unit is center-driven but, in practice, this involves long transmission lines in non-neutral planes. A better way is to drive only the central unit and to excite the outer units by coupling networks that connect the adjacent ends of the several units. The function of such networks is to *reverse the phase* of the currents in the outer antennas.

A simple phase-reversing network is a high-impedance, transmission-line stub. In Fig. 14a a three-element array is shown with two *phase-reversing stubs* constructed of low loss two-wire line. *If properly adjusted* in length, the transmission-line impedance of each stub to *equal and opposite currents* is very great.

The approximate determination of the current and impedance of the array in Fig. 14a may be carried out as for the array with parasitic elements. The analysis is resolved into two parts the superposition of which yields the desired result. These are (1) the symmetrical part with all three units individually center-driven by slice generators with voltages that maintain equal currents in phase at the centers of the antennas, and (2), the antisymmetrical part in which the driving voltages are so chosen that the currents at the centers of the outer antennas are reversed. These two parts are considered in turn and combined later.

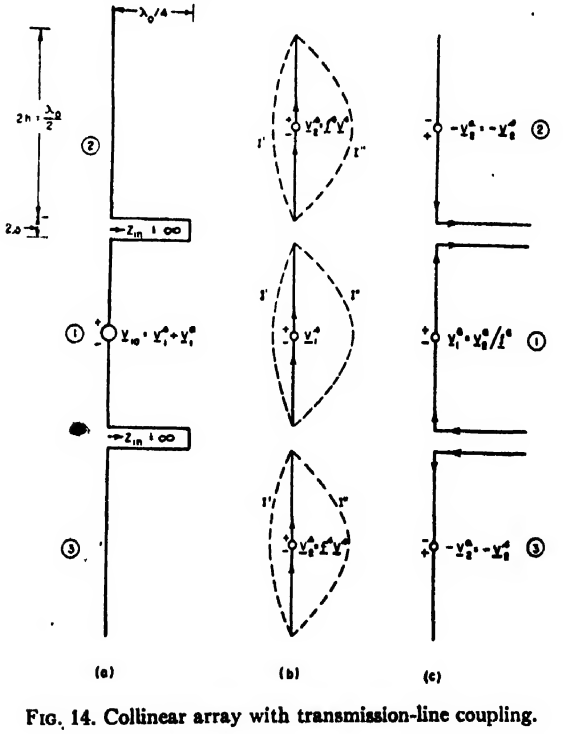

FIG. 14. Collinear array with transmission-line coupling.

The Symmetrical Problem

Let the voltages required to maintain equal currents at the centers of all three units, $I_1^s(0)=I_2^s(z_2=0)=I_3^s(z_3=0)$, be represented as in (3.20a)

$$V_{10}=V_1^s=V^s;\quad V_{30}=V_{20}=V_2^s=f^sV^s. \tag{5.1}$$

It is shown readily that f^s in (5.1) is effectively the same function as in (3.20b) even though the array differs from that involved in Section 3 by the presence of the stubs. Since the currents that enter the stubs from the attached antennas are essentially equal and opposite, and since the stubs are adjusted to offer an extremely high impedance to equal and opposite currents, the currents actually existing at the ends of the antennas where they are connected to the stubs are very small. This does not mean that transmission-line currents all along the stubs are as small as the input currents. Actually, the distribution of transmission-line currents on the high-impedance stubs is approximately sinusoidal with a small amplitude at the input end and a large amplitube in the terminating bridge. However, with closely spaced good conductors the ohmic losses in the stubs and the radiation losses from them are insignificant compared with radiation from the array as a whole, and they contribute nothing to the far-zone field. Indeed, there can be no significant change in either the input impedance of the array or the distribution of current in the three antennas if the stubs are removed as in Fig. 14b, leaving the circuit already analyzed in Section 4 where it constitutes the symmetrical part of the collinear array with parasitic outer units. The symmetrical current $I_1^s(z)$ in the central unit is given by (4.2a) or (4.5a); the symmetrical impedance Z_{0c}^s of the central unit is given by (4.9a) and graphically in Fig. 6. The currents in the outer units are well approximated by (4.10a) or (4.13a) since the odd components of current are negligible in determining the far-zone field of the array. The approximate currents are

$$I_1^s(z)=(V^s/Z_{0c}^s)\cos\beta_0 z \tag{5.2a}$$

$$I_3^s(z_3)=I_2^s(z_2)=(V_2^s/Z_{even}^s)\cos\beta_0 z_2$$
$$=(V^sf^s/Z_{even}^s)\cos\beta_0 z_2=I_1^s(z) \tag{5.2b}$$

where Z_{0c}^s is in (4.9a), Z_{even}^s is in (4.18a), and $f^s=Z_{even}^s/Z_{0c}^s$.

The Antisymmetrical Problem

Let the driving voltages required to maintain the currents $I_3^a(z_3=0)=I_2^a(z_2=0)=-I_1^a(0)$ in the array in Fig. 14a be represented as in (3.21a):

$$V_{10}=V_1^a=V^a;\quad V_{30}=V_{20}=-V_2^a=-f^aV^a. \tag{5.3}$$

The function f^a in (3) is *not* the same as in (3.21b). Since the currents in the two parallel conductors of the phase-reversing stubs are nearly equal and codirectional, these two conductors are always at the same potential at opposite points. Therefore, the terminating bridge may be removed (or replaced by an equivalent open end) without significant effect. Thus, the solution of the antisymmetrical problem of Fig. 14a reduces to the analysis of Fig. 14c. Unfortunately, this presents an intricate problem in a quantitative sense except for conductors of very small radius. Nevertheless, much valuable information on the general nature of the distribution of current and the operation of the array, and even a fair estimate of the impedance can be acquired from a rough quantitative investigation.

It has been shown[6] for parallel antennas that the current in an antenna that is coupled to another is determined in *major outline* by the dimensions of the antenna itself even if the coupling is quite close. Therefore, the first step in the study of Fig. 14c is directed toward the behavior *when isolated* of each of the three antennas with its attached half of the now open stub. It is reasonable to assume that the effects of the right-angled bends in the conductors can, at most, lead to a small quantitative modification, but not to essential changes in the distributions of current and charge. This is indicated from the study of the V-antenna.[6] Accordingly, the distributions of current in antennas 1 and 2 of Fig. 14c must be approximately the distributions in the same conductors when these are straightened as in Fig. 15. This makes the central unit equivalent to a center-driven antenna of electrical half-length $\beta_0 h=\pi$. The distribution of current on such an antenna is reproduced in Fig. 15f, and transferred to the bent antenna in Fig. 15e as an approximation. The impedance is simply

$$Z_{0c}^a=Z_0(\beta_0 h=\pi)\equiv Z_\pi \tag{5.4}$$

The bent antenna 2 in Fig. 15a may be approximated by the asymmetrically driven straight antenna in Fig. 15b. The analysis of this[7] has shown that in solving for the current in either half, this half may be assumed to be erected on an infinite, perfectly conducting plane and driven by a slice generator with appropriate voltage. For the upper half with an electrical length $\beta_0 h=\pi/2$ and an impedance $\frac{1}{2}Z_0(\beta_0 h=\pi/2)\equiv(Z_{\pi/2})/2$ the driving voltage is

$$V_{\pi/2}\equiv -V_2^aZ_{\pi/2}/(Z_\pi+Z_{\pi/2}); \tag{5.5a}$$

for the lower half (which has an electrical length $\beta_0 h=\pi$ and an impedance $\frac{1}{2}Z_0(\beta_0 h=\pi)\equiv(Z_\pi)/2$) the driving voltage is

$$V_\pi=-V_2^aZ_\pi/(Z_{\pi/2}+Z_\pi). \tag{5.5b}$$

Since the two antennas are in series, the resultant driving voltage is $-V^a$ as assumed in (5.3). The impedance is

$$Z_2^a=\tfrac{1}{2}(Z_\pi+Z_{\pi/2}). \tag{5.6}$$

The distributions of current on the two dissimilar parts of the outer antennas are shown in Fig. 15c, d with phases referred to $-V_2^a$. It is assumed that these distributions for isolated straight asymmetrical antennas approximate the distributions on the bent antenna in Fig. 15a.

With approximate distributions of current in the three antennas of Fig. 14c determined under the assumption that they are isolated, it remains to evaluate the effect of their interaction. An estimate of this may be obtained as follows. The most closely coupled parts of antennas 1 and 2 are the parallel ends at right angles to the axis of the array. These parts carry co-directional currents. It is known that the effect upon a given isolated antenna of a closely spaced parallel antenna with equal co-directional current is to increase the expansion parameter somewhat. That is, $\Psi_{\pi 1}$ for two symmetrically driven, parallel antennas is greater than Ψ_{K1} for the isolated antenna if b/λ_0 is small. For close

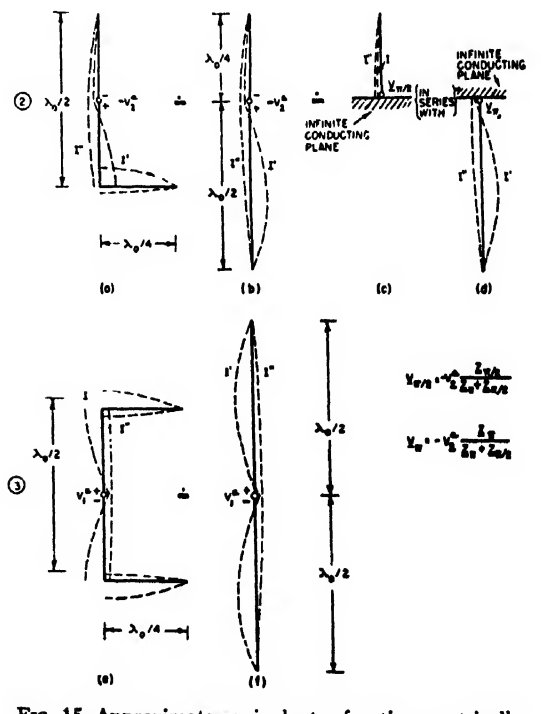

FIG. 15. Approximate equivalents of antisymmetrically driven antennas in three-element collinear array.

[7] R. King, "Asymmetrically driven antennas and the sleeve dipole," Cruft Laboratory Technical Report No. 93, (December, 1949). Proc. I.R.E. 38, 1154–1164 (1950).

spacing this increase is of the order of magnitude of 3 to 6. For thick antennas with $\Omega=2\ln(2h/a)$ not very large, the percentage change in Ψ_{K1} is great; for very thin wires it is quite small. The collinear parts of antennas 1 and 2 carry currents that are practically equal and opposite. It has been shown in Section 2 that a coupled antenna carrying an equal and opposite currents reduces the expansion parameter approximately in the same proportion as it is increased when the currents are co-directional. Thus, antenna 1 in the proximity of antennas 2 and 3 in Fig. 14c behaves roughly like a straight isolated antenna of the same length of conductor which has outer halves that are effectively of smaller radius, inner halves that are effectively of greater radius than when isolated. The same reasoning applies to the outer antennas.

To summarize, it is evident that a good estimate of the distribution of current and of the driving-point impedance of the three-element collinear array in Fig. 14a may be obtained by superimposing the solution of the symmetrically driven array in Fig. 14b upon the solution of the antisymmetrically driven array in Fig. 14c. In this latter, the currents in the central unit are like that in Fig. 15f. The resultant current is the algebraic sum of these symmetrical and antisymmetrical currents. In addition, there is the transmission-line distribution of equal and opposite currents on the stubs with large amplitude in the connecting bridges. Evidently, the method applied to the three-element array may be extended to any number of units. Note that the approximations involved improve as the value of $\Omega=2\ln(2h/a)$ increases.

Since the amplitude of the current in an antenna of electrical half-length $\beta_0 h=\pi$ is very much smaller than in an antenna for which $\beta_0 h=\pi/2$ when both are driven by the same voltage (for $\Omega=20$ the ratio of maximum currents is roughly 1 to 12), and since the antisymmetrically driven array in Fig. 15c corresponds roughly to elements with $\beta_0 h=\pi$, whereas the symmetrically driven array in Fig. 15b corresponds roughly to elements with $\beta_0 h=\pi/2$, it follows that even for moderately large ratios h/a, the predominating currents are the symmetrical currents of Fig. 14b as given in (5.1). *It is primarily these currents that determine the far-zone electromagnetic field.* Note that they are co-directional in the several units. That is, the phase-reversing stubs have, indeed, effectively reversed the *significantly radiating currents* in the outer units. Note that additional currents are maintained both on the stubs and on the antennas, but their principal role is to maintain the desired co-directional currents on the antennas while contributing negligibly to the radiation field either because they are small (viz., additional currents on antennas and co-directional currents on stubs) or, if large, because they are equal, opposite, and close together (as with the transmission-line currents on the stubs).

The driving-point admittance of the central unit and, hence, of the entire array is formally like (2.19b), viz.,

$$Y_{in}=\frac{I_1(0)}{V_{10}}=\frac{I_1^e(0)+I_1^a(0)}{V^e+V^a}$$

$$=\frac{1}{Z_{0c}^e(1+k^{-1})}+\frac{1}{Z_{0c}^a(1+k)}, \quad (5.7)$$

where Z_{0c}^e is given by (4.9a) and is plotted in Fig. 6, $Z_{0c}^a=Z_\pi$, and k is defined by

$$k\equiv\frac{f^a}{f^e};\quad f^a=\frac{Z_2^a}{Z_{0c}^a}=\frac{Z_\pi+Z_{\pi/2}}{2Z_\pi};\quad f^e=\frac{Z_2^e}{Z_{0c}^e}=\frac{Z_{\text{even}}^e}{Z_{0c}^e} \quad (5.8)$$

where Z_{even}^e is given by (4.18a) and is plotted in Fig. 7. If the separation b of the conductors of the transmission-line stubs is very small, $d/\lambda_0\doteq 0.5$. For this value $Z_{0c}^e\doteq 126+j83$, $Z_{\text{even}}^e\doteq 95+j62$; $f^e\doteq 0.75$. For sufficiently thin antennas, $|Z_\pi|\gg|Z_{\pi/2}|$ so that $f^a\doteq 0.5$. Hence $k\doteq\frac{2}{3}$. With this value,

$$Z_{in}=\frac{1}{Y_{in}}=\frac{Z_{0c}^e Z_\pi(1+\frac{2}{3})(1+\frac{3}{2})}{Z_{0c}^e(1+\frac{3}{2})+Z_\pi(1+\frac{2}{3})}. \quad (5.9)$$

Since for thin antennas, $|Z_\pi|\gg|Z_{0c}^e|$, it follows that

$$Z_{in}\doteq Z_{0c}^e(1+\tfrac{3}{2})=2.5Z_{0c}^e=2.5(126+j83)$$

$$=315+j207. \quad (5.10)$$

This value corresponds to $73.1+j42.5$ for a single unit. More accurate numerical results may be obtained for specific values of Z_π and $Z_{\pi/2}$ if desired. Other values of d/λ_0 may be used provided the spacing b of the stub wires satisfies $\beta_0 b\ll 1$.

Although the investigation of the three-element center-driven collinear array with phase-reversing stubs is not rigorous, it does provide an excellent picture of the several components of current and their distributions. Moreover, it justifies the conventional practice of assuming currents in the elements of the array co-directional, and sinusoidally distributed with equal amplitude in determining radiation-field patterns with $\beta_0 h=\pi/2$. That is, the dominant, symmetrical distribution in Fig. 14b approximates the distribution

$$I_s\doteq I_0\cos\beta_0 z_i;\quad i=1,2,3 \quad (5.11)$$

where z_i is measured from the center of antenna i.

The advantages of the collinear array with phase-reversing stubs over the same antennas with each element center-driven from a transmission line are clear. In the first place, it is much simpler from the constructional point of view. In the second place, it provides a far-zone field that is determined entirely by currents in the antennas and not by currents in the feeding lines. While it is true that the stub sections of line have unbalanced currents, it has been shown that these are

small compared with the principal currents on the antennas. Moreover, the stubs are of fixed and relatively short length so that contributions from small unbalanced currents in them are both negligible and determinate. Since individual transmission lines usually are long, and unbalanced currents in them may be large if the over-all electrical length of the line and attached metal at the generator-end happen to be self-resonant, their contribution to the far-zone field is neither determinate nor is it usually small.

Beam Oscillations in an F-M Cyclotron*

T. TEICHMANN
Princeton University, Princeton, New Jersey
(Received May 8, 1950)

This paper considers the radial and vertical oscillations of a synchro-cyclotron beam. It is found that various oscillations of substantially constant or increasing amplitude may occur in certain regions of the field, in which there are angular or other asymmetries, though only one possible oscillation (that at $n\simeq\frac{1}{4}$) can occur in a field that is cylindrically and vertically symmetric. The conditions for the various oscillations, and their behavior, are discussed.

I. INTRODUCTION

THE aim of this paper is to give a general discussion of various oscillations of a cyclotron beam which are induced (or permitted) by the particular shape or angular inhomogeneity of the magnetic field.[1]

The calculation is given only for small oscillations (i.e., oscillations of amplitude small compared to the radius of the beam) and depends on the adiabatic approximation, i.e., on the smallness of the fractional gain of energy of the beam over the period of several oscillations. The discussion is substantially non-relativistic, but can easily be extended to small relativistic energies.

II. NOTATION

One thus considers the motion of a particle of charge e, mass m, and energy $E=mv^2/2$, in a temporally constant magnetic field with cylindrical components (H_r, H_θ, H_z). Because of the particular design of cyclotrons, it is possible to find a median plane (usually parallel to and midway between the pole faces of the magnet) and a perpendicular axis, such that the field may be represented in good approximation by the cylindrical-components $(0, 0, H_n)(H_n=\text{constant})$. This plane and axis are then taken as the basis for a cylindrical coordinate system to describe the position of the particles (r, θ, z) and the spatial variation of the field. If the field were exactly $(0, 0, H_n)$ and the particle were set moving in the median plane, the subsequent motion would be of constant angular frequency

$$w_n=eH_n/mc \tag{2.1}$$

in a circle of radius

$$r_n=v/w_n. \tag{2.2}$$

In practice, because of the field variation, and possible angular inhomogeneities, the motion will be almost periodic (instead of strictly periodic) and may be regarded as uniform circular motion with superposed vertical and radial oscillations about the instantaneous equilibrium orbit (to be denoted by "i.o." in the following). The accelerating field of the dees will, of course, gradually increase the velocity v, and hence the i.o., but over a large portion of the particles path in the synchro-cyclotron this increment is relatively small over several periods of the oscillations considered, and the i.o. radius r_n may be regarded as constant in the region of any particular oscillation. If the oscillations about the equilibrium have a very large period, this (adiabatic) approximation loses its validity (see below).

It is convenient to refer all quantities to the i.o. and to introduce the new (non-dimensional) coordinates,

$$x=(r-r_n)/r_n \tag{2.3}$$

$$y=z/r_n, \tag{2.4}$$

and the velocity v_n of motion in the i.o. with angular velocity w_n,

$$v_n=-r_nw_n. \tag{2.5}$$

The magnetic field $\mathbf{H}=(H_r, H_\theta, H_z)$ is then most conveniently written in the form

$$\mathbf{H}=H_n(R, Q, Z) \tag{2.6}$$

(where $R\simeq0$, $Q\simeq0$, $Z\simeq1$). The (non-dimensional) components R, Q, Z, may be expanded in double Taylor series in x, y about any equilibrium radius r_n, and in Fourier series in θ. Carrying the Taylor series up to second-degree terms (i.e., using a parabolic approximation)

$$R=R_0+R_xx+R_yy+\tfrac{1}{2}R_{xx}x^2+R_{xy}xy+\tfrac{1}{2}R_{yy}y^2 \tag{2.7}$$

* This work was assisted in part by the joint program of the ONR and AEC.

[1] The discussion is thus an extension to other regions of the field of considerations given by Hamilton and Lipkin (unpublished) for $n\simeq\frac{1}{4}$.

and Q, Z may be expressed in the same way. Further,

$$R_y=\sum_{-\infty}^{+\infty} R_y{}^k e^{ik\theta}, \text{ etc.} \tag{2.8}$$

Note that H_n is a parameter which is regarded as constant over the domain of any oscillation, but which varies from i.o. to i.o. (as r_n increases). The normalization is so chosen that

$$Z_0=1+\sum_{k\neq 0} Z_0{}^k e^{ik\theta}. \tag{2.9}$$

Because of the electromagnetic equations curl$\mathbf{H}=0$, and div$\mathbf{H}=0$, and possible symmetries, the coefficients defined above satisfy certain linear equations which are listed in the Appendix, and used in the remainder of this paper. The most important of these relations are the following:

$$\int_{-\pi}^{\pi} Q d\theta=0, \text{ implying } Q_\alpha{}^0=0, \text{ for all } \alpha=x, y \text{ etc.} \tag{2.10}$$

$$R_y=Z_x \tag{2.11}$$

$$R_{xy}=Z_{xx} \tag{2.12}$$

$$R_{yy}=Z_{xy}. \tag{2.13}$$

If the vertical component of the field is symmetric about the median plane, one has the additional relations

$$Z_y=Z_{xy}=R_{yy}=0. \tag{2.14}$$

The usual definition

$$n=-d\log H_z/d\log r \tag{2.15}$$

is also slightly modified here to apply only to the angularly symmetric part of H_z, i.e.,

$$Z_x{}^0=-nZ_0{}^0=-n \tag{2.16}$$

and hence,

$$Z_{xx}{}^0=(n^2+n-n'), \quad n'=dn/dx. \tag{2.17}$$

III. SUMMARY OF RESULTS

It is found that approximately periodic oscillations about the i.o. can occur only in the neighborhood of certain particular values of n, and that the possibility of developing an appreciable amplitude then depends not only on the shape of the field, but also on the initial phase ψ_n which is in general determined both by the field shape and by the initial displacement of the particle from the i.o., and its velocity. When they do occur, these oscillations have the form†

$$A(\theta)\cos(c\theta+\phi) \tag{3.1}$$

where $\theta\simeq w_n t$ is the path length, and $A(\theta)$ is a slowly varying function of θ. Only the cases in which $A(\theta)$ can remain substantially constant, or increase, are of practical interest.

(i) There are only two oscillations which can occur if the field is cylindrically symmetric, the most important of these being a coupled radial-vertical oscillation which occurs near $n\simeq\frac{1}{3}$, and is fully discussed in reference 1. If X and Y are the amplitudes of the oscillations of x and y (i.e., the ratios of the amplitudes of the radial and vertical oscillations to the i.o. radius r_n), then

$$4X^2+Y^2=\text{constant}, \tag{3.2}$$

so that the oscillations are substantially limited by their initial values, though a radial deviation will turn into a vertical one in the course of time and conversely.

(ii) The other possible oscillations (except at $n\simeq\frac{1}{3}, \frac{1}{5}$) depend on the presence of fundamental or second harmonic terms in the Fourier expansions of R, Q and Z. Proceeding systematically in the direction of increasing n, there is first a purely vertical oscillation at $n\simeq\frac{1}{2}$. For small θ the amplitude has the form

$$Y=Y_0/(1-Y_0|C|\cos u\cdot\theta), \tag{3.3}$$

Y_0 being the initial amplitude (deviation from i.o.), and C a certain linear combination of first Fourier coefficients [see Eq. (5.4)]. Since Y_0, $|C|$ are positive by definition, unpleasant oscillations are only likely if $\cos u>0$.

(iii) At $n\simeq\frac{1}{4}$ a purely vertical oscillation may again occur, though of rather different form, to wit,

$$Y=Y_0\exp(|D|\cos u\cdot\theta) \tag{3.4}$$

for small θ. D is substantially the fundamental Fourier coefficient of Z_z, i.e., of dH_z/dr. Here again nasty oscillations may occur if $\cos u>0$.

(iv) At $n\simeq 9/25$ coupled radial-vertical oscillations may occur both if certain fundamental Fourier coefficients and/or if certain second harmonics are present in the field, though if both types of terms are present together the equations are rather too complicated to be solved in an informative manner. In each separate case the amplitudes satisfy relations of the type

$$|M|X^2\pm|L|Y^2=\text{constant}, \tag{3.5}$$

the quantities L and M being linear combinations of the Fourier coefficients involved. If the plus sign obtains, the oscillations are unlikely to become obtrusive, since they are substantially limited by their initial values, though coupling from radial to vertical oscillation, or the converse, may give rise to trouble, especially if L and M differ widely in magnitude. If the minus sign obtains, on the other hand, the oscillations may grow very large, since it then turns out that X and Y may be represented approximately by hyperbolic functions of θ [see Eq. (5.24)ff].

(v) When $n\simeq 4/9$ there is again the possibility of a purely vertical oscillation, of similar form to that at $n\simeq\frac{1}{3}$, the only difference being that the coefficient C

† The frequencies of the oscillations discussed below are respectively, $w_n(1-n)^{\frac{1}{2}}$ and $w_n(n)^{\frac{1}{2}}$ for the radial and vertical oscillations.

now depends on the second harmonics in the field components.

(vi) At $n\simeq\frac{1}{2}$ there is the possibility of a coupled oscillation if the field is not vertically symmetric about the median plane, quite apart from any angular inhomogeneity. The amplitudes satisfy the relation

$$X^2+Y^2=\text{constant}, \tag{3.6}$$

so that the oscillations are not likely to be troublesome. For small θ, X and Y are themselves approximately periodic in θ with period

$$2\pi/B\cos u. \tag{3.7}$$

Proceeding to larger values of n, one finds that oscillations may occur for those values of $1-n$ for which oscillations occur at n (as above), with the difference that the roles of radial and vertical oscillations are interchanged. It is not of interest to discuss these further, except to remark that the oscillation at $n\simeq\frac{4}{5}$, which is the analog of that at $n\simeq\frac{1}{5}$, here depends on the existence of an asymmetry about the median plane [by virtue of (2.13)], and hence may be avoided in practice.

The upshot of these considerations is that by careful design of the vertical and cylindrical symmetry of the field it is possible to get rid of all the oscillations of the beam, except that at $n\simeq\frac{1}{5}$, which is by its nature generally of limited amplitude.

IV. EQUATION OF MOTION OF THE BEAM (PARTICLES)‡

The motion of a particle of charge e and mass m, in a magnetic field (H_r, H_θ, H_z) is determined by the equations

$$\dot{v}_r=\ddot{r}-r\dot{\theta}^2=(e/mc)(v_\theta H_z-v_z H_\theta) \tag{4.1}$$

$$\dot{v}_\theta=r\ddot{\theta}+2\dot{r}\dot{\theta}=(e/mc)(v_z H_r-v_r H_z)+\text{accelerating force} \tag{4.2}$$

$$\dot{v}_z=\ddot{z}=(e/mc)(v_r H_\theta-v_\theta H_r). \tag{4.3}$$

Instead of Eq. (4.2) it is more convenient to use

$$v^2=v_r^2+v_\theta^2+v_z^2 \tag{4.4}$$

which is essentially the energy integral. The effect of the accelerating force is to change v as the motion progresses, and the adiabatic approximation is permissible provided that this change is relatively small during the time of one radial or vertical oscillation, whichever is the larger; a small relative change per revolution of the particle is not enough. Consequently the method below should not be taken too seriously for n near 0 or 1, unless the fractional increase in energy is exceedingly small at these values.

In terms of the quantities w_n, r_n, and the new variables x, y, the equations of motion become

$$\ddot{x}=w_n(v_\theta Z/r-\dot{y}Q)+v_\theta^2/rr_n \tag{4.5}$$

$$\ddot{y}=w_n(\dot{x}Q-v_\theta R/r) \tag{4.6}$$

and (4.4) (since $v_r=r_n\dot{x}$, $v_\theta=r\dot{\theta}$, $v_z=r_n\dot{y}$). It is now convenient to introduce the new variable $\vartheta=w_n t$. In view of the smallness of the oscillations and the adiabatic principle, $\vartheta\simeq\theta$. Actually they are related by $\vartheta/\theta=w_n/\theta$, and $w_n/\theta\simeq 1$. In the following it will be assumed that $\vartheta=\theta$. x' then denotes $dx/d\theta$, etc. It is also convenient to write

$$v^2=v_n^2(1+\epsilon) \tag{4.7}$$

(i.e., the total energy $mv^2/2=$energy of rotation in an idealized i.o. $mv_n^2/2$+additional energy $\epsilon mv_n^2/2$ due to the fact that oscillations occur and that the i.o. is idealized). Due to the assumed smallness of the oscillations ϵ is a small quantity; thus

$$v_\theta\simeq v_n(1+\tfrac{1}{2}\epsilon-\tfrac{1}{2}x'^2-\tfrac{1}{2}y'^2) \tag{4.8}$$

up to terms of the second degree. Equations (4.5) and (4.6) then become, respectively,

$$x''+(1-n)x=F=-(1+\tfrac{1}{2}\epsilon-\tfrac{1}{2}x'^2-\tfrac{1}{2}y'^2)(Z_0+(Z_x-n)x+Z_y y+\tfrac{1}{2}Z_{xx}x^2+\cdots)-y'(Q_0+Q_x x+Q_y y+\cdots)+1+\epsilon+x^2-x'^2-y'^2 \tag{4.9}$$

$$y''+ny=G=x'(Q_0+Q_x x+Q_y y+\cdots)+(1+\tfrac{1}{2}\epsilon-\tfrac{1}{2}x'^2-\tfrac{1}{2}y'^2)(R_0+R_x x+(R_y-n)y+\tfrac{1}{2}R_{xx}x^2+\cdots) \tag{4.10}$$

using some of the results of Section II. It is possible to eliminate the constant terms on the right of Eqs. (4.9) and (4.10) by a slight definition of the i.o. [*viz.*, replacing r_n by $r_n+\epsilon/2(1-n)$ eliminates the constant term in (3.9) to first order, while raising the equilibrium plane by an amount $\sim r_n R_0^0/n$ gets rid of the constant term in (4.10)]. It will be assumed that this has been done, and that only the non-constant terms in F and G need be considered. For the sake of simplicity let

$$a=(1-n)^{\frac{1}{2}},\quad b=(n)^{\frac{1}{2}}. \tag{4.11}$$

If $F\equiv 0$, $G\equiv 0$, equations (4.9) and (4.10) have the solutions[2]

$$x=X\sin(a\theta+\phi) \tag{4.12}$$

$$y=Y\sin(b\theta+\psi), \tag{4.13}$$

X, Y, ϕ, and ψ being suitable constants. Since F and G are not constant, but involve x, y, and θ in a complicated way, the solutions may still be written in the same form, but with X, Y, ϕ, and ψ taken as functions of θ. Imposing the additional conditions

$$x'=aX\cos(a\theta+\phi) \tag{4.14}$$

$$y'=bY\cos(b\theta+\psi), \tag{4.15}$$

‡ The first part of this section is a summary of portions of reference 1 in which a more detailed discussion is given.

[2] See A. Kryloff and N. Bogoliuboff, *Non-Linear Mechanics*, Princeton University Press, 1943 for further details of this method.

one finds that $X(\theta)$, $Y(\theta)$ satisfy the first-order differential equations

$$X' = F\cdot\cos(a\theta+\phi)/a \tag{4.16}$$

$$Y' = G\cdot\cos(b\theta+\psi)/b. \tag{4.17}$$

The right-hand sides of these equations are small, and almost periodic in θ, so that in general, the average of X', Y' over several periods of the motion will be zero or negligible. This will not be the case if there are secular (θ-independent) or almost secular (very long period) terms in the right-hand sides. In this case X' or Y' or both will be of constant sign over many periods of the oscillations, and X, Y may become appreciable despite insignificant initial values. In this approximation, therefore, appreciable oscillations may arise for those values of a and b for which secular terms appear in the right-hand sides of Eqs. (4.16) and (4.17).

In terms of the original equations (4.9) and (4.10) the interpretation of these oscillations is somewhat as follows. The beam has in first approximation two modes of oscillation, a radial mode with frequency $w_r = w_n(1-n)^{\frac{1}{2}}$, and a vertical mode with frequency $w_z = w_n(n)^{\frac{1}{2}}$. The equations of motion are linear in this approximation, and thus the amplitude of the oscillations will be constant and determined by their initial values. In higher approximation, the equations of motion contain complicated non-linear terms (F, G) which may cause suppression of the oscillations due to interference, and will generally prevent any increase in the amplitudes, if not actively decreasing them. For certain particular values of n, however, these non-linear terms give rise to a species of subharmonic resonance, so that the initial oscillations of the beam may increase in amplitude.

It is to be noted that ϕ and ψ also satisfy first-order differential equations, similar in form to (4.16) and (4.17). If one is interested mainly in the amplitudes of individual oscillations, these phase variations will not play a significant role. On the other hand, if the motion is to be traced through from one region of oscillation to another, phase changes will be important, because of their effect on the initial values, and the equations for ϕ' and ψ' may have to be discussed in a similar way to that in which (4.16) and (4.17) are dealt with below. This is, however, not required in the sequel.

V. POSSIBLE OSCILLATIONS

This section is devoted to the task of finding for what values of a and b (i.e., of n) secular terms may arise in $F\cos(a\theta+\phi)$ and $G\cos(b\theta+\psi)$, and to discussing briefly the corresponding oscillations. The calculation is, of course, only carried out up to second-degree terms, and since it is straightforward, though tedious, no details of the first part of the computation are given here.

Since a and b are symmetric about $n=\frac{1}{2}$, and F, G both contain terms of substantially the same type, it is easy to see that any oscillation which occurs for $n=\frac{1}{2}-j$ will also occur for $n=\frac{1}{2}+j$, with the roles of x and y interchanged. Because of this, and also because the beam is usually extracted well before $n=\frac{1}{2}$, only the oscillations in the range $0<n\leqslant\frac{1}{2}$ are discussed here.

Inspection of F and G shows that in this range secular terms may arise from sines or cosines with the following arguments: (i) $(a-2b)\theta$, $n\simeq\frac{1}{5}$; (ii) $(1-3b)\theta$, $n\simeq\frac{1}{9}$; (iii) $(1-2b)\theta$, $n\simeq\frac{1}{4}$; (iv) $(1-2a-b)\theta$, $(2-a-2b)\theta$, $n\simeq 9/25$; (v) $(2-3b)\theta$, $n\simeq 4/9$; (vi) $(a-b)\theta$, $n\simeq\frac{1}{2}$. The corresponding amplitudes X and Y then satisfy equations as follows.

(i) $n\simeq\frac{1}{5}$, $a\simeq 2b$

In this case one finds the coupled oscillations

$$\left.\begin{aligned} X' &= -KY^2\cos p \\ Y' &= 4KXY\cos p \end{aligned}\right\}. \tag{5.1}$$

Here

$$16K = (5)^{\frac{1}{2}}Z_{xx}{}^0 = (5)^{\frac{1}{2}}(6/25-n') \tag{5.2}$$

$p=(a-2b)\theta+u$, and u, the initial phase, depends only on the initial phases of the two individual oscillations, ϕ_0 and ψ_0, $u=\phi_0-2\psi_0$. It follows from (5.1) that $4X^2+Y^2=$constant. These oscillations are dealt with *in extenso* in reference 1, and therefore will not be discussed further here, though similar oscillations are considered in more detail in (iv) below.

(ii) $n\simeq\frac{1}{9}$, $1\simeq 3b$

Here there is only a vertical oscillation, satisfying the equation

$$Y' = |C|\,Y^2\cos p \tag{5.3}$$

$$C = \int_{-\pi}^{\pi}(9Z_{xy}-R_0)e^{i\theta}d\theta/48\pi \tag{5.4}$$

$$p=(1-3b)\theta+u,\ u=-3\psi_0+\text{phase } C.$$

Thus,

$$Y = Y_0/(1-Y_0|C|\cdot\int_0^{\theta}\cos p\cdot d\theta). \tag{5.5}$$

Noting that $(1-3b)\theta\simeq 0$, and choosing the origin of θ at the point where $1=3b$, p may be approximated by

$$p = u-3\theta^2db/d\theta = u-9g^2\theta^2\pi/2 \tag{5.6}$$

$$\pi g^2 = (dn/dr)(dr/d\theta) = n'\cdot\Delta E/4(1-n)E\cdot\pi,$$

i.e.,

$$g^2 = \frac{1}{\pi}\cdot\frac{dn}{dr}\frac{dr}{d\theta} = \frac{n'}{4\pi^2(1-n)}\cdot\frac{\Delta E}{E}. \tag{5.7}$$

ΔE = energy per revolution of the beam, E = total energy. (See Appendix I.)

Thus,

$$\int_0^{\theta}\cos p\cdot d\theta = (\cos u\cdot\mathfrak{C}(3g\theta)+\sin u\cdot\mathfrak{S}(3g\theta))/3g, \tag{5.8}$$

where

$$\mathcal{C}(\theta)=\int_0^\theta \cos\frac{\pi}{2}\theta^2 d\theta, \quad \mathcal{S}(\theta)=\int_0^\theta \sin\frac{\pi}{2}\theta^2\cdot d\theta \quad (5.9)$$

are the usual Fresnel functions.

The behavior of the oscillations thus depends both on the magnitude of C and on the initial phase u. In order to examine the behavior more closely, one assumes that $g^2\theta^2$ is small enough not only for (5.6) to be valid, but also to permit the right-hand side of (5.8) to be replaced by $|C|\cos u\cdot\theta$, so that

$$Y=Y_0/(1-Y_0|C|\cos u\cdot\theta). \quad (5.10)$$

Since Y and $|C|$ are positive, increasing oscillations can only occur for

$$\cos u>0. \quad (5.11)$$

This approximation also defines a limiting value of the path length θ

$$\theta_1=1/Y_0|C|\cos u \quad (5.12)$$

beyond which the method is not valid, despite the smallness of $g^2\theta^2$. A similar, though rather more complicated effect may also take place in the approximation (5.8).

(iii) $n\simeq\frac{1}{4}$, $1\simeq 2b$

Here again there is only a vertical oscillation, the amplitude of which satisfies the equation

$$Y'=|D|Y\cos p \quad (5.13)$$

$$D=\int_{-\pi}^{\pi} Z_x e^{i\theta}d\theta/2\pi \quad (5.14)$$

$$p=(1-2b)\theta+u,\ u=-2\psi_0+\text{phase}(1/D).$$

Thus

$$Y=Y_0\exp(|D|\int_0^\theta \cos p d\theta). \quad (5.15)$$

Proceeding as in (ii)

$$p=u-2\pi g^2\theta^2 \quad (5.16)$$

and hence

$$Y=Y_0\exp(|D|(\cos u\cdot\mathcal{C}(2g\theta)+\sin u\cdot\mathcal{S}(2g\theta))/2g). \quad (5.17)$$

For small enough $g^2\theta^2$, one has

$$Y\simeq Y_0\exp(|D|\cos u\cdot\theta). \quad (5.18)$$

If $\cos u>0$, Y will increase approximately exponentially, with "time constant" $1/w_n|D|\cos u$, and thus, if conditions are favorable, very disturbing oscillations may arise in this region. It is interesting to remark, parenthetically, that there was strong evidence of this type of oscillation in the Princeton cyclotron: the edges of the dees were found to be strongly radioactive in the region $n\simeq\frac{1}{4}$, indicating that the beam was vertically splayed out in this region.

(iv) $n\simeq 9/25$, $2a-b\simeq 1$ and/or $a+2b\simeq 2$

In this case there are coupled oscillations satisfying the equations

$$X'=|L|XY\cos p+|N|Y^2\cos q$$
$$Y'=|M|X^2\cos p^*+|P|XY\cos q^* \quad (5.19)$$

$$L=\int_{-\pi}^{\pi}(5Z_{xy}+3iQ_x)e^{i\theta}d\theta/32\pi$$
$$M=\int_{-\pi}^{\pi}(25R_{xx}+16R_0)e^{i\theta}d\theta/240\pi \quad (5.20)$$

$$N=\int_{-\pi}^{\pi}(25Z_{yy}+30iQ_y+9Z_0)e^{2i\theta}d\theta/320\pi$$
$$P=\int_{-\pi}^{\pi}(5Z_{xx}+4iQ_y)e^{2i\theta}d\theta/24\pi \quad (5.21)$$

$$p=(1-2a+b)\theta+u, \qquad p^*=(1-2a+b)\theta+u^*$$
$$q=(2-a-2b)\theta+s, \qquad q^*=(2-a-2b)\theta+s^*$$
$$u=-2\phi_0+\psi_0+\text{phase}L,\ u^*=-2\phi_0+\psi_0+\text{phase}M$$
$$s=-\phi_0-2\psi_0+\text{phase}N\ \ s^*=-\phi_0-2\psi_0+\text{phase}P$$

The first terms on the right arise from the fundamental Fourier coefficients, and correspond to the near vanishing of $1-2a+b$, while the second terms come from the second harmonics, and correspond to the smallness of $2-a-2b$.

Equations (5.19) are pretty complicated even when the approximation $p=p^*=q=q^*=0$ is made. However, an indication of the sort of thing that happens is given by taking $N=P=0$ (absence of higher harmonics in the field), and placing $u=u^*$. This latter assumption may make it necessary to replace $|M|$ by $-|M|$, to obtain a reasonable representation of what happens if u and u^* differ widely. The equations then become [see (i)]

$$X'=|L|XY\cos p$$
$$Y'=\pm|M|X^2\cos p. \quad (5.22)$$

If the plus sign obtains,

$$(X^2/|L|)-(Y^2/|M|)=k^2, \quad (5.23)$$

and one may put

$$X=k(|L|)^{\frac{1}{2}}\sec(W-W_0),$$
$$Y=k(|M|)^{\frac{1}{2}}\tan(W-W_0) \quad (5.24)$$

whence W satisfies the differential equation

$$W'=-k|L|(|M|)^{\frac{1}{2}}\cos p. \quad (5.25)$$

For small enough θ,

$$W-W_0\simeq -k|L|(|M|)^{\frac{1}{2}}\cos u\cdot\theta. \quad (5.26)$$

Because of (5.24) one again obtains a limiting value for

the angular path length θ

$$\theta_1 = \pi/2k|L|(|M|)^{\frac{1}{2}}\cos u. \tag{5.27}$$

It is clear that in this case both the radial and vertical oscillations may reach uncomfortably large amplitudes, unless their initial values are both zero. This is not so however if the minus sign applies in Eqs. (5.22); the equations then obtained are the analog of (5.1), with the roles of X and Y interchanged. (5.23) is replaced by

$$(X^2/|L|)+(Y^2/|M|)=k^2 \tag{5.28}$$

and one writes

$$X=k(|L|)^{\frac{1}{2}}\sin(W-W_0), \qquad Y=k(|M|)^{\frac{1}{2}}\cos(W-W_0). \tag{5.29}$$

W satisfies the equation

$$W'=k|L|(|M|)^{\frac{1}{2}}\cdot\sin(W-W_0)\cdot\cos p \tag{5.30}$$

so that

$$W-W_0=\arctan\exp\int_0^\theta k|L|(|M|)^{\frac{1}{2}}\cos p\,d\theta \tag{5.31}$$

or, for small θ,

$$W-W_0\simeq\arctan\exp k|L|(|M|)^{\frac{1}{2}}\cos u\cdot\theta. \tag{5.32}$$

Here the combined amplitudes are limited by their initial values, though disturbing oscillations may still occur, due to coupling between the radial and vertical modes, if L and M differ widely in magnitude. Similar results are obtained if there are only second harmonics in the field, *viz.*, $L=M=0$, N, $P\neq 0$.

(v) $n\simeq 4/9$, $2\simeq 3b$

The vertical oscillation has the same form as that occurring at $n\simeq\frac{1}{9}$, except that the coefficient C now depends on the corresponding second harmonics in the field components. [See (ii).]

(vi) $n\simeq\frac{1}{2}$, $a\simeq b$

Using the normalization described following (4.10), the coupled oscillations satisfy the equations

$$\begin{aligned} X' &= BY\cos p \\ Y' &= -BX\cos p \\ B &= Z_y^0/\sqrt{2} \\ p &= (a-b)\theta+u, \quad u=\phi_0-\psi_0. \end{aligned} \tag{5.33}$$

In general $B=0$, since the vertical component of the field is usually symmetric about the plane in which $R_0^0=\int_0^{2\pi}R_0 d\theta/2\pi=0$. The redefinition of coordinates involved in attaining this state of affairs may however distort the median "plane" into slightly conical form (deviation $\sim r_n R_0^0/n$) so that then B is not zero. Equation (5.33) yields the relation

$$X^2+Y^2=k^2B. \tag{5.34}$$

Writing

$$X=k(B)^{\frac{1}{2}}\sin(W-W_0), \quad Y=k(B)^{\frac{1}{2}}\cos(W-W_0) \tag{5.35}$$

one finds

$$W'=B\cos p \tag{5.36}$$

so that, proceeding in the usual way,

$$W-W_0=2^{\frac{1}{2}}B[\cos u\cdot\mathcal{C}(g\theta/2^{\frac{1}{2}})+\sin u\cdot\mathcal{S}(g\theta/2^{\frac{1}{2}})]/g. \tag{5.37}$$

For sufficiently small θ,

$$W-W_0\simeq B\cos u\cdot\theta. \tag{5.38}$$

Thus X and Y are themselves approximately periodic with period

$$2\pi/B\cos u. \tag{5.39}$$

The amplitudes are here again limited by their initial values.

VI. GENERAL REMARKS

The discussion of the previous section was concerned chiefly with the possibility and behavior of self-maintaining or increasing oscillations. It is also fitting to make some brief comments about the oscillations in general, i.e., when the particular cases of Section V do not obtain.

Since in this case the oscillations are small, and (by hypothesis) not self-maintaining, it is sufficient to consider the differential equations (4.9) and (4.10) only up to first-degree terms, *viz.*,

$$x''+a^2x=-(Z_x-n)x-Z_y y-(Z_0-1)-Q_0 y' \tag{6.1}$$

$$y''+b^2y=(R_y-n)y+R_x x+(R_0-R_0^0)+Q_0 x'. \tag{6.2}$$

The coefficients on the right are in general Fourier series in θ with period 2π. Because of this, these equations are closely related to the Mathieu equations: alternatively, attempting to solve these equations by Laplace transforms leads to a set of difference equations. Unless something fairly specific is known about the magnitudes of the Fourier coefficients, there is not much to be gained by pursuing such a mathematically detailed treatment further, all the more in view of the many preceding approximations. Brief consideration will thus only be given to the approximate solution of the system (6.1) and (6.2).

Because of the form of the differential operator on the left, terms containing (say) $\cos k\theta$ on the right will yield similar terms with a multiplicative factor $1/(a^2-k^2)$, $1/(b^2-k^2)$, respectively. Hence only the first few terms need be considered in the Fourier series on the right, at least in an approximate treatment. Incidentally, the values of n for which alarming oscillations may occur may be found in this way (successive substitutions), by placing $x=X\sin a\theta$, $y=Y\sin b\theta$ on the right, and looking for those values of a, b for which some of the a^2-k^2, b^2-k^2 reduce to zero. Second-order terms should also be considered in this case.

It is not difficult to see that even in the absence of an initial deviation there will be a forced oscillation due to

the cylindrical asymmetry of the field, of the form

$$x = -Z_0^1 \cos\theta/n \tag{6.3}$$

$$y = R_0^1 \cos\theta/(1-n^*) \tag{6.4}$$

(if only fundamentals are present in the field). The "oscillations" (6.3), (6.4) denote, respectively, a displacement of the center of the i.o. by an amount $Z_0^1 r_n/n$, and a tilting of its plane by an angle $\sim R_0^1/(1-n)$. If higher harmonics are present the interpretation is no longer so simple: the i.o. is no longer a circle, nor even a plane curve, though it will generally be fairly close to the more idealized i.o. as initially defined. In higher approximation, not only will higher Fourier components appear in x and y but also small constant terms which may be removed by further renormalization of the original i.o. radius r_n, and the i.o. plane [see (4.10)f]; these latter correspond to the fact that any "excess" energy of the beam is shared between the various modes (*viz.*, the rotational, as well as the two vibrational modes).

Inspection of (6.1) and (6.2) shows that if the beam contains some components of its normal modes to start with, it will also contain terms of the type $\sin(k+a)\theta$, etc. In general, if the more exact equations of motion are considered, the deviations from equilibrium have the form

$$\sum_k \sum_l \sum_m A_{klm} \sin[(k+la+mb)\theta+\phi_{klm}] \tag{6.5}$$

so that the motion is generally not even approximately periodic. In special cases when $la+mb$ is an integer, the deviation becomes approximately periodic and much larger; these cases correspond to the oscillations considered in Section V.

APPENDIX I. CHANGE OF RADIUS WITH PATH LENGTH

The radius of the equilibrium orbit given by

$$r = (mc/e)(v/H),$$

H being the vertical component of the field, so that the relation between the increments is

$$(\Delta r/r) = (\Delta v/v) - (\Delta H/H).$$

Since the energy

$$E = mv^2/2$$
$$(\Delta v/v) = (\Delta E/2E),$$

while by definition of n

$$(\Delta H/H) = -n(\Delta r/r).$$

Thus

$$(\Delta r/r) = (\Delta E/2(1-n)E).$$

Taking E to be the increment in energy per revolution (i.e., the energy gained from the r-f field of the dees per revolution) one finds for the average rate of increase of radius per angular path length

$$dr/d\theta = (r \cdot \Delta E/4\pi(1-n)E).$$

APPENDIX II. DESCRIPTION OF THE FIELD

Using the definition (2.6) of the field, and the electromagnetic equations $\mathrm{curl}\mathbf{H}=0$, $\mathrm{div}\mathbf{H}=0$, one has

$$\frac{\partial Z}{\partial\theta} - (1+x)\frac{\partial Q}{\partial y} = 0 \qquad Q + (1+x)\frac{\partial Q}{\partial x} - \frac{\partial R}{\partial\theta} = 0$$

$$\frac{\partial Z}{\partial x} - \frac{\partial R}{\partial y} = 0 \qquad R + (1+x)\frac{\partial R}{\partial x} + \frac{\partial Q}{\partial\theta} + (1+x)\frac{\partial Z}{\partial y} = 0.$$

Inserting the Eqs. (2.7) and (2.8), i.e., the expansions of R, Q, Z, in Taylor series in x, y and Fourier series in θ, and equating coefficients, one finds the following relations, which prove useful in specific calculations:

$$\begin{aligned}
Z_x^k &= R_y^k & ikZ_0^k &= Q_y^k \\
Z_{xy}^k &= R_{yy}^k & ikZ_x^k &= Q_y^k + Q_{xy}^k \\
Z_{xx}^k &= R_{xy}^k & ikZ_y^k &= Q_{yy}^k \\
ikR_0^k &= Q_0^k + Q_x^k & -ikQ_0^k &= R_0^k + R_x^k + Z_y^k \\
ikR_x^k &= Q_{xx}^k + 2Q_x^k & -ikQ_x^k &= R_{xx}^k + 2R_x^k + Z_y^k \\
& & -ikQ_y^k &= R_y^k + R_{xy}^k + Z_{yy}^k.
\end{aligned}$$

Taking $k=0$ these equations show that

$$\int_{-\pi}^{\pi} Q d\theta = 0,$$

which must of course be the case in the absence of a vertical component of the magnetizing current.

The author is indebted to Drs. P. C. Gugelot and H. J. Lipkin for helpful discussions and suggestions.

On the Theory of Dislocations*

JOHN LEE BOGDANOFF
Department of Civil Engineering, Columbia University, New York, New York
(Received May 12, 1950)

If, in a multiply-connected elastic solid, discontinuities are permitted across a stationary barrier in either the strain or its first derivatives or both, dislocations of a more general type than encountered in classical theory are possible. A number of these more general dislocations have been obtained for states of plane and anti-plane strain in a hollow right circular cylinder when the surface of discontinuity is a single stationary plane barrier. Some of the dislocations found possess the characteristic that although the strain is continuous across the barrier the displacement discontinuity is *not* one which would be possible in a rigid body. Examination of the conditions for the uniqueness of solution of the boundary value problems of elasticity reveals that when dislocations of the more general type are admitted appropriate data must be given at each point on the specified barrier in addition to the usual information.

Notation

r, θ, z: Cylindrical coordinates.
$\sigma_\theta, \tau_{r\theta}, \tau_{rz}, \sigma_r, \tau_{\theta z}, \sigma_z$: Components of stress tensor.
$e_{rr}, e_{r\theta}, e_{rz}, e_{\theta\theta}, e_{\theta z}, e_{zz}$: Components of strain tensor.
u_r, u_θ, u_z: Displacement components.
ω_z: z component of rotation.
E: Young's modulus.
σ: Poisson's ratio.

I. INTRODUCTION

In the classical theory of dislocations in a multiply-connected body, Weingarten's theorem[1] plays a fundamental role. According to it, the displacement of the matter immediately on one side of a barrier with respect to the matter on the other side is one which would be possible in a rigid body. Inherent in the proof of this theorem is the assumption that the strain is continuous of class $C^{(2)}$ throughout. We now ask the following question: If discontinuities in the strain or its first derivatives or both are permitted across a stationary barrier, what new displacement discontinuities are allowed? It must be expected in this case that the displacement discontinuity cannot be represented by a displacement possible in a rigid body. The existence of dislocations of a more general type than those of classical theory has been suggested by Goodier.[2]

The six dislocations of classical theory possible in a hollow right circular cylinder are known and have been described in detail by Volterra.[3] In particular there are three in plane strain and one in anti-plane strain. We shall seek dislocations of the less restricted type in the same body for states of plane and anti-plane strain when there is a single plane barrier Ω.

If the strain is discontinuous across Ω, it follows that discontinuities also exist across the same surface in the stress components. It is known[4] however, that in the absence of body forces equilibrium requires the traction on a stationary surface of discontinuity to be continuous across it. Hence, we are restricted to have discontinuities only in those components of the stress which do not enter the expression for the traction on Ω. Because of this condition, it is convenient in what follows to work directly with the stresses.

II. STATEMENT OF PROBLEM

We consider the equilibrium of a hollow right circular cylinder of isotropic elastic material in which there are no body forces. Let the z axis of a cylindrical coordinate system (r, θ, z) coincide with the axis of the cylinder, and let the surface of discontinuity Ω be the intersection of the half-plane $\theta=0$ with the cylinder. The angular coordinate is restricted by

$$0 \leq \theta \leq 2\pi. \tag{2.01}$$

In order to obtain dislocations of the more general type we must seek stress systems in which the stresses or their derivatives or both are discontinuous across Ω. Further, these stresses must satisfy both the differential equations of equilibrium and the compatibility equations; and the traction on Ω must be continuous across this surface.

The procedure followed in obtaining appropriate stress systems is the same for both the anti-plane strain and plane strain problems. First, we assume that at least one of the components of traction on the barrier is expressed by means of functions that are continuous of class $C^{(2)}$ in the simply-connected region formed by introducing Ω and continuous across this surface. Next,

* As used in the present paper, the term dislocation means a state of strain in a multiply-connected elastic solid in which the displacement is discontinuous across one or more barriers. However, this term has a different meaning in theories concerning the plasticity of matter. For a definition of this second meaning and for a discussion of the uses of the dislocations defined above in plastic theories, the reader should consult the references given at the end of Chapter 2 in the book, *The Inelastic Behavior of Engineering Materials and Structures*, A. M. Freudenthal (John Wiley and Sons, Inc., New York, 1950).

using this assumption, stresses are derived (in which discontinuities may exist) that satisfy the differential equations of equilibrium and compatibility relations. Finally, after rejecting those systems that either are continuous of class $C^{(2)}$ throughout the cylinder or have discontinuities which do not meet the requirements of continuous traction on crossing Ω, the displacements are determined. Any remaining stress systems that have discontinuities in displacement across the barrier, constitute dislocations of the desired type.

The barrier is at $\theta=0$ in what follows. To secure complete freedom in choosing the angular position, corresponding dislocations are needed also for Ω at $\theta=\pi/2$. Since the procedures are identical for both positions, we shall indicate only the initial step when the barrier is in the second position. It will be recalled that, in the case of dislocations in classical theory, the position of the barrier is immaterial.

3. ANTI-PLANE STRAIN

In a state of plane strain, the stress components, σ_r, σ_θ, σ_z and $\tau_{r\theta}$ are functions of r and θ while τ_{rz} and $\tau_{\theta z}$ vanish. In a state of anti-plane strain, the converse is true. Then, the differential equations of equilibrium require the existence of a function $\varphi(r,\theta)$ such that

$$\tau_{rz}=r^{-1}\partial\varphi/\partial\theta, \quad \tau_{\theta z}=-\partial\varphi/\partial r; \tag{3.01}$$

and the compatibility relations require

$$(\partial^2/\partial r^2+r^{-1}\partial/\partial r+r^{-2}\partial^2/\partial\theta^2)\varphi\equiv\nabla^2\varphi=d_0\,(\text{const.}), \tag{3.02}$$

where φ is a continuous function of class $C^{(2)}$ in the simply-connected cylinder. For continuity of traction on Ω, we must have

$$\Delta\tau_{\theta z}\equiv\tau_{\theta z}\,|_{\theta=2\pi}-\tau_{\theta z}\,|_{\theta=0}=0. \tag{3.03}$$

Let us now assume that $\tau_{\theta z}$ is expressed by

$$-(\tau_{\theta z})_n=\xi_n(r)\theta\sin n\theta+\eta_n(r)\cos n\theta+\eta_0(r) \tag{3.04}$$

where n is an integer, $\xi_n(r)$, $\eta_n(r)$, and $\eta_0(r)$ are continuous functions of class $C^{(2)}$, and

$$0\leq\theta\leq 2\pi.$$

Equation (3.03) is satisfied by this assumption.

The stress function φ_n we seek must satisfy (3.02) and

$$\partial\varphi_n/\partial r=\xi_n(r)\theta\sin n\theta+\eta_n(r)\cos n\theta+\eta_0(r). \tag{3.05}$$

The function φ which satisfies these equations is

$$\varphi\equiv\sum_{n=1}^{\infty}\varphi_n=\sum_{n=1}^{\infty}a_nr^n(\theta\sin n\theta-\log r\cos n\theta)+\sum_{n=1}^{\infty}b_nr^{-n}(\theta\sin n\theta+\log r\cos n\theta)$$
$$+L(\theta^2-\log^2 r)+\sum_{n=1}^{\infty}(c_nr^n+d_nr^{-n})\cos n\theta+a_0+b_0\log r+c_0\theta+\frac{d_0r^2}{4}. \tag{3.06}$$

The terms on the last line of this equation give stresses that are continuous of class $C^{(2)}$ throughout the cylinder. Hence, they are of no interest to us, except for noting that the term $b_0\log r$ represents a dislocation of classical theory of order 3.[8] The stresses for the remaining terms are

$$\left.\begin{aligned}\tau_{rz}&=\sum_{n=1}^{\infty}a_nr^{n-1}[n\theta\cos n\theta+(n\log r+1)\sin n\theta]\\&\quad+\sum_{n=1}^{\infty}b_nr^{-n-1}[n\theta\cos n\theta\\&\quad-(n\log r-1)\sin n\theta]+L\theta r^{-1},\\\tau_{\theta z}&=-\sum_{n=1}^{\infty}a_nr^{n-1}[n\theta\sin n\theta-(n\log r+1)\cos n\theta]\\&\quad+\sum_{n=1}^{\infty}b_nr^{-n-1}[n\theta\sin n\theta\\&\quad+(n\log r-1)\cos n\theta]+Lr^{-1}\log r.\end{aligned}\right\} \tag{3.07}$$

The components of displacement u_r, u_θ, u_z are related to the strains e_{rz}, $e_{\theta z}$ and the stresses τ_{rz}, $\tau_{\theta z}$ by the following expressions

$$\left.\begin{aligned}2\tau_{rz}(1+\sigma)/E&=e_{rz}=\partial u_r/\partial z+\partial u_z/\partial r,\\2\tau_{\theta z}(1+\sigma)/E&=e_{\theta z}=r^{-1}\partial u_z/\partial\theta+\partial u_\theta/\partial z,\end{aligned}\right\} \tag{3.08}$$

where σ is Poisson's ratio and E is Young's modulus. The displacements corresponding to (3.07) are

$$\left.\begin{aligned}u_r&=0,\\u_\theta&=0,\\u_z&=2(1+\sigma)E^{-1}\{\sum_{n=1}^{\infty}a_nr^n(\theta\cos n\theta+\log r\sin n\theta)\\&\quad-\sum_{n=1}^{\infty}b_nr^{-n}(\theta\cos n\theta-\log r\sin n\theta)+L\theta\log r\},\end{aligned}\right\} \tag{3.09}$$

the terms which represent the displacement of the cylinder as a rigid body being omitted.

Inspection of (3.07) and (3.09) shows that τ_{rz} and u_z are discontinuous across Ω, and $\tau_{\theta z}$, u_r, and u_θ are not. Therefore, (3.07) represent dislocations of the desired

type. The discontinuities have the forms

$$\left.\begin{aligned}\Delta\tau_{rz}&\equiv\tau_{rz}\big|_{\theta=2\pi}-\tau_{rz}\big|_{\theta=0}\\&=2\pi\Big[\sum_{n=1}^{\infty}n(a_nr^{n-1}+b_nr^{-n-1})+Lr^{-1}\Big],\\\Delta u_z&\equiv u_z\big|_{\theta=2\pi}-u_z\big|_{\theta=0}=4\pi(1+\sigma)E^{-1}\\&\quad\times\Big[\sum_{n=1}^{\infty}(a_nr^n-b_nr^{-n})+L\log r\Big].\end{aligned}\right\}\tag{3.10}$$

We also note that the stress system given by $L(\theta^2-\log^2 r)$ has a resultant force acting on a cylindrical surface which encloses the z axis.

Equation (3.04) may be altered to place Ω at $\theta=\pi/2$ by assuming

$$-(\tau_{\theta z})_n=\xi_n(r)\theta\cos n\theta+\eta_n(r)\sin n\theta+\eta_0(r).\tag{3.11}$$

4. PLANE STRAIN

We assume that the displacements u_r and u_θ are functions of r and θ only while u_z is zero. The strain components e_{rz}, $e_{\theta z}$, e_{zz} vanish throughout the cylinder; and the formulas connecting the strains, displacements and stresses are

$$\left.\begin{aligned}e_{rr}&=\partial u_r/\partial r=(\sigma_r-\sigma'\sigma_\theta)/E',\\e_{r\theta}&=\partial u_\theta/\partial r-r^{-1}u_\theta+r^{-1}\partial u_r/\partial\theta\\&=2(1+\sigma')\tau_{r\theta}/E',\\e_{\theta\theta}&=r^{-1}\partial u_\theta/\partial\theta+r^{-1}u_r=(\sigma_\theta-\sigma'\sigma_r)/E',\end{aligned}\right\}\tag{4.01}$$

and

$$\sigma_z=\sigma'(\sigma_r+\sigma_\theta)\tag{4.02}$$

where $\sigma'=\sigma/1-\sigma$, $E'=E/1-\sigma^2$. Then the differential equations of equilibrium are the conditions for the existence of a function $\chi(r,\theta)$ such that

$$\sigma_r=\frac{\partial\chi}{r\partial r}+\frac{\partial^2\chi}{r^2\partial\theta^2},\quad\tau_{r\theta}=-\frac{\partial}{\partial r}\left(\frac{\partial\chi}{r\partial\theta}\right),\quad\sigma_\theta=\frac{\partial^2\chi}{\partial r^2},\tag{4.03}$$

where Airy's stress function χ is a continuous function of class $C^{(2)}$ in the simply-connected region. The compatibility relations require that χ be biharmonic:

$$\nabla^4\chi=0.\tag{4.04}$$

The requirement of continuity of traction on crossing Ω is expressed by

$$\left.\begin{aligned}\Delta\tau_{r\theta}&\equiv\tau_{r\theta}\big|_{\theta=2\pi}-\tau_{r\theta}\big|_{\theta=0}=0,\\\Delta\sigma_\theta&\equiv\sigma_\theta\big|_{\theta=2\pi}-\sigma_\theta\big|_{\theta=0}=0.\end{aligned}\right\}\tag{4.05}$$

We assume first that $\tau_{r\theta}$ and σ_θ are given by the real and imaginary parts of expressions of the type

$$(\tau_{r\theta})_n=f_n(r)e^{in\theta},\quad(\sigma_\theta)_n=g_n(r)e^{in\theta},\tag{4.06}$$

where $f_n(r)$ and $g_n(r)$ are continuous functions of class $C^{(2)}$ and n is an integer including zero. Clearly, these expressions satisfy (4.05).

We must now determine stresses $(\sigma_r)_n$, $(\tau_{r\theta})_n$, and $(\sigma_\theta)_n$ that satisfy the differential equations of equilibrium, the compatibility equations, and (4.06); in the process, we must not exclude those stress systems for which $(\sigma_r)_n$ is discontinuous. These requirements are fulfilled provided the stresses are derived from an Airy stress function χ_n which satisfies

$$-\frac{\partial}{\partial r}\left(\frac{\partial\chi_n}{r\partial\theta}\right)=f_n(r)e^{in\theta},\quad\frac{\partial^2\chi_n}{\partial r^2}=g_n(r)e^{in\theta},$$

$$\nabla^4\chi_n=0.\tag{4.07}$$

Upon integrating these equations, we obtain

$$\begin{aligned}\chi=\sum_{n=1}^{\infty}\chi_n&=A_0r^2+B_0r^2(\log r-1)+C_0\log r+D_0\theta\\&\quad+(A_1r+B_1r^{-1}+B\theta r+C_1r^3+D_1r\log r)e^{i\theta}\\&\quad+\sum_{n=2}^{\infty}(A_nr^n+B_nr^{-n}+C_nr^{n+2}+D_nr^{-n+2})e^{in\theta}\\&\quad+L(\theta^2-\log^2 r)re^{i\theta}.\end{aligned}\tag{4.08}$$

The stresses corresponding to the terms of the first three lines of (4.08) are continuous of class $C^{(2)}$ throughout the cylinder.[5] Therefore, the only function of immediate interest is

$$L(\theta^2-\log^2 r)re^{i\theta}.\tag{4.09}$$

We note in passing that the classical dislocations of orders 1, 2 and 6[5] are given by $Dr\log r\sin\theta$, $D'r\log r\cos\theta$, $B_0r^2\log r$.

The stresses for the real and imaginary parts of (4.09) are respectively

$$\left.\begin{aligned}\sigma_r&=2L_2r^{-1}[(1-\log r)\cos\theta-2\theta\sin\theta],\\\tau_{r\theta}&=-2L_2r^{-1}\log r\sin\theta,\\\sigma_\theta&=-2L_2r^{-1}(1+\log r)\cos\theta,\end{aligned}\right\}\tag{4.10}$$

and

$$\left.\begin{aligned}\sigma_r&=2L_1r^{-1}[(1-\log r)\sin\theta+2\theta\cos\theta],\\\tau_{r\theta}&=2L_1r^{-1}\log r\cos\theta,\\\sigma_\theta&=-2L_1r^{-1}(1+\log r)\sin\theta.\end{aligned}\right\}\tag{4.11}$$

Examination of these formulas reveals that in (4.10) all the stresses (and hence the strains) are continuous across Ω, but $\partial\sigma_r/\partial\theta$ is discontinuous; while in (4.11), σ_r and $\partial\sigma_r/\partial r$ are discontinuous across the same surface, the discontinuity in σ_r being

$$\Delta\sigma_r\equiv\sigma_r\big|_{\theta=2\pi}-\sigma_r\big|_{\theta=0}=8\pi L_1r^{-1}.\tag{4.12}$$

Both stress systems have a resultant force acting on a cylindrical surface enclosing the z axis.

The displacements corresponding to (4.10) and (4.11)

[5] These three lines constitute the stress function given by J. H. Michell in "On the direct determination of stress in an elastic solid," Proc. London Math. Soc. 31, 100–124 (1900).

are given by

$$\left.\begin{aligned} E'u_r &= L_2\{[2(1+\sigma')\log r-(1-\sigma')\log^2 r]\cos\theta \\ &\quad +[(1-\sigma')\theta^2-4\theta\log r]\sin\theta\}, \\ E'u_\theta &= L_2\{[(1-\sigma')\theta^2-4\sigma'\theta-2(1-\sigma') \\ &\quad -4\theta\log r]\cos\theta+(1-\sigma') \\ &\quad \times[\log^2 r-2(1+\theta)]\sin\theta\}, \end{aligned}\right\} \quad (4.13)$$

and

$$\left.\begin{aligned} E'u_r &= L_1\{[4\theta\log r-(1-\sigma')\theta^2]\cos\theta \\ &\quad +[2(1+\sigma')\log r-(1-\sigma')\log^2 r]\sin\theta\}, \\ E'u_\theta &= L_1\{(1-\sigma')[2(1+\theta)-\log^2 r]\cos\theta \\ &\quad +[(1-\sigma')\theta^2-4\sigma'\theta-2(1-\sigma') \\ &\quad -4\theta\log r]\sin\theta\}, \end{aligned}\right\} \quad (4.14)$$

where the rigid body terms have been omitted. The discontinuities in displacement across Ω are

$$\Delta u_r=\text{const.},\quad \Delta u_\theta=\text{const.}-8\pi L_2\log r/E', \quad (4.15)$$

$$\Delta u_r=\text{const.}+8\pi L_1\log r/E',\quad \Delta u_\theta=\text{const.}, \quad (4.16)$$

respectively, where $\Delta u_r\equiv u_r\big|_{\theta=2\pi}-u_r\big|_{\theta=0}$ and $\Delta u_\theta\equiv u_\theta\big|_{\theta=2\pi}-u_\theta\big|_{\theta=0}$. Since the displacements have discontinuities on crossing Ω involving $\log r$ the stress systems (4.10) and (4.11) represent dislocations of the general type.

When Ω is at $\theta=\pi/2$, the roles of the real and imaginary parts of (4.09) are interchanged.

The stress function (4.09) was obtained on the assumption that $\tau_{r\theta}$ and σ_θ have the forms given by (4.06); obviously this is not the only starting point. However, rather than assume other forms for these stress components and proceed as before, it is convenient at this point to make use of information already obtained. We recall that both $\chi_1=r\varphi_1\sin\theta+\varphi_2$ and $\chi_2=r\varphi_1\cos\theta+\varphi_2$, where φ_1 and φ_2 are harmonic functions, are solutions of $\nabla^4\chi=0$. For φ_1 and φ_2 we choose the function given by the first two lines of (3.06). Thus,

$$\begin{aligned} \chi_1 &= \sum_{n=1}^{\infty}[A_n r^{n+1}(\theta\sin n\theta-\log r\cos n\theta) \\ &\quad +B_n r^{-n+1}(\theta\sin n\theta+\log r\cos n\theta)]\sin\theta \\ &\quad +\sum_{n=1}^{\infty}[C_n r^n(\theta\sin n\theta-\log r\cos n\theta) \\ &\quad +D_n r^{-n}(\theta\sin n\theta+\log r\cos n\theta)] \\ &\quad +L_1(\theta^2-\log^2 r)r\sin\theta+G_1(\theta^2-\log^2 r) \end{aligned} \quad (4.17)$$

and

$$\begin{aligned} \chi_2 &= \sum_{n=1}^{\infty}[A_n' r^{n+1}(\theta\sin n\theta-\log r\cos n\theta) \\ &\quad +B_n' r^{-n+1}(\theta\sin n\theta+\log r\cos n\theta)]\cos\theta \\ &\quad +\sum_{n=1}^{\infty}[C_n' r^n(\theta\sin n\theta-\log r\cos n\theta) \\ &\quad +D_n' r^{-n}(\theta\sin n\theta+\log r\cos n\theta)] \\ &\quad +L_2(\theta^2-\log^2 r)r\cos\theta+G_2(\theta^2-\log^2 r). \end{aligned} \quad (4.18)$$

The requirement that the traction on Ω be continuous across this surface can be met by setting

$$C_n=D_n=G_1=0,\quad (n=1, 2, \cdots); \quad (4.19)$$

and

$$\left.\begin{aligned} C_n' &= -A_{n-1}'\frac{n-1}{n}, \quad (n=2, 3, \cdots), \\ D_n' &= -B_{n+1}\frac{n+1}{n}, \quad (n=1, 2, \cdots), \\ G_2 &= -B_1. \end{aligned}\right\} \quad (4.20)$$

With these equations, we find that the stresses corresponding to (4.17) and (4.18) are

$$\left.\begin{aligned} 2\sigma_r &= \sum_{n=1}^{\infty}A_n r^{n-1}\{-(2n-3)\sin(n-1)\theta+(2n+1)\sin(n+1)\theta-n(n-3)\theta\cos(n-1)\theta+n(n+1)\theta\cos(n+1)\theta \\ &\quad -\log r[-n(n-3)\sin(n-1)\theta+n(n+1)\sin(n+1)\theta]\}+\sum_{n=1}^{\infty}B_n r^{-n-1}\{-(2n-1)\sin(n-1)\theta \\ &\quad +(2n+3)\sin(n+1)\theta-n(n-1)\theta\cos(n-1)\theta+n(n+3)\theta\cos(n+1)\theta+\log r[n(n-1)\sin(n-1)\theta \\ &\quad -n(n+3)\sin(n+1)\theta]\}+4L_1 r^{-1}[(1-\log r)\sin\theta+2\theta\cos\theta], \\ 2\tau_{r\theta} &= \sum_{n=1}^{\infty}A_n r^{n-1}\{(2n-1)\cos(n-1)\theta-(2n+1)\cos(n+1)\theta-n(n-1)\theta\sin(n-1)\theta+n(n+1)\theta\sin(n+1)\theta \\ &\quad +\log r[n(n-1)\cos(n-1)\theta-n(n+1)\cos(n+1)\theta]\}+\sum_{n=1}^{\infty}B_n r^{-n-1}\{(2n-1)\cos(n-1)\theta \\ &\quad +(2n+1)\cos(n+1)\theta-n(n-1)\theta\sin(n-1)\theta+n(n+1)\theta\sin(n+1)\theta \\ &\quad +\log r[-n(n-1)\cos(n-1)\theta+n(n+1)\cos(n+1)\theta]\}+4L_1 r^{-1}(1+\log r)\sin\theta, \\ 2\sigma_\theta &= \sum_{n=1}^{\infty}A_n r^{n-1}\{(2n+1)[\sin(n-1)\theta-\sin(n+1)\theta]+n(n+1)\theta[\cos(n-1)\theta \\ &\quad -\cos(n+1)\theta]+n(n+1)\log r[\cos(n-1)\theta-\cos(n+1)\theta]\} \\ &\quad +\sum_{n=1}^{\infty}B_n r^{-n-1}\{(2n-1)[\sin(n-1)\theta-\sin(n+1)\theta]+n(n-1)\theta[\cos(n-1)\theta-\cos(n+1)\theta] \\ &\quad -n(n-1)\log r[\sin(n-1)\theta-\sin(n+1)\theta]\}-4L_1 r^{-1}(1+\log r)\sin\theta; \end{aligned}\right\} \quad (4.21)$$

and

$$
\left.
\begin{aligned}
2\sigma_r = &\sum_{n=1}^{\infty} A_n' r^{n-1}\Big\{(2n-3)\cos(n-1)\theta - \frac{(n-1)(2n+1)}{n+1}\cos(n+1)\theta - n(n-3)\theta\sin(n-1)\theta \\
&+ n(n-1)\theta\sin(n+1)\theta - \log r[n(n-3)\cos(n-1)\theta - n(n-1)\cos(n+1)\theta]\Big\} \\
&+ \sum_{n=2}^{\infty} B_n' r^{-n-1}\Big\{-\frac{(n+1)(2n-1)}{n-1}\cos(n-1)\theta + (2n+3)\cos(n+1)\theta + n(n+1)\theta\sin(n-1)\theta \\
&- n(n+3)\theta\sin(n+1)\theta + \log r[n(n+1)\cos(n-1)\theta - n(n+3)\cos(n+1)\theta]\Big\} \\
&+ B_1' r^{-2}[5\cos 2\theta - 1 - 4\theta\sin\theta + 2\log r(1-2\cos 2\theta)] + 4L_2 r^{-1}[\cos\theta - 2\theta\sin\theta - \log r\cos\theta], \\
2\tau_{r\theta} = &-\sum_{n=1}^{\infty} A_n' r^{n-1}\Big\{(2n-1)\sin(n-1)\theta - \frac{(n-1)(2n+1)}{n+1}\sin(n+1)\theta + n(n-1)\theta[\cos(n-1)\theta - \cos(n+1)\theta] \\
&+ n(n-1)\log r[\sin(n-1)\theta - \sin(n+1)\theta]\Big\} - \sum_{n=1}^{\infty} B_n' r^{-n-1}\Big\{\frac{(n+1)(2n-1)}{n-1}\sin(n-1)\theta \\
&- (2n+1)\sin(n+1)\theta + n(n+1)\theta[\cos(n-1)\theta - \cos(n+1)\theta] - n(n+1)\log r[\sin(n-1)\theta \\
&- \sin(n+1)\theta]\Big\} + B_1' r^{-2}[\sin 2\theta - 2\theta(1-\cos 2\theta) + 2(1-\log r)\sin 2\theta] - 4L_2 r^{-1}\sin\theta, \\
2\sigma_\theta = &\sum_{n=1}^{\infty} A_n' r^{n-1}\Big\{-(2n+1)\cos(n-1)\theta - \frac{(n-1)(2n+1)}{n+1}\cos(n+1)\theta + n(n+1)\theta\sin(n-1)\theta \\
&- n(n-1)\theta\sin(n+1)\theta - \log r[n(n+1)\cos(n-1)\theta - n(n-1)\cos(n+1)\theta]\Big\} \\
&+ \sum_{n=2}^{\infty} B_n' r^{-n-1}\Big\{\frac{(n+1)(2n-1)}{n-1}\cos(n-1)\theta - (2n-1)\cos(n+1)\theta - n(n+1)\theta\sin(n-1)\theta \\
&+ n(n-1)\theta\sin(n+1)\theta - \log r[n(n+1)\cos(n-1)\theta - n(n-1)\cos(n+1)\theta]\Big\} \\
&+ B_1' r^{-2}[1 - \cos 2\theta - 2\log r] - 4L_2 r^{-1}(1+\log r)\cos\theta,
\end{aligned}
\right\} \quad (4.22)
$$

respectively. By means of (4.01), the displacements can be found for these stress systems. The discontinuities in the stresses and the displacements across Ω are

$$
\left.
\begin{aligned}
&\Delta\sigma_r = 4\pi[\sum_{n=1}^{\infty} n(A_n r^{n-1} + B_n r^{-n-1}) + 2L_1 r^{-1}], \\
&E'\Delta u_r = 4\pi[\sum_{n=1}^{\infty}(A_n r^n - B_n r^{-n}) + 2L_1\log r], \\
&\Delta\sigma_\theta = \Delta\tau_{r\theta} = \Delta u_\theta = 0;
\end{aligned}
\right\} \quad (4.23)
$$

and

$$
\left.
\begin{aligned}
E'\Delta u_\theta = 4\pi[&-\sum_{n=1}^{\infty} A_n' r^n + \sum_{n=2}^{\infty} B_n' r^{-n} \\
&+ B_1' r^{-1} + 2L_2\log r], \\
&\Delta u_r = \Delta\sigma_r = \Delta\tau_{r\theta} = \Delta\sigma_\theta = 0.
\end{aligned}
\right\} \quad (4.24)
$$

Equations (4.21) and (4.22) thus represent general dislocations.

As before, χ_1 and χ_2 may be suitably altered to place the barrier at $\theta = \pi/2$.

5. DISCUSSION

After the first draft of this paper was prepared, Mann[6] published an article in which many of the stress functions obtained above were given. In addition, she also solved several boundary value problems (of interest in connection with slip theories of plasticity) for states of plane and anti-plane strain in a hollow cylinder, and she indicated a general procedure for dealing with such problems. There is no need then for additional discussion of these aspects of the solutions.

It was not noticed in reference 6, however, that it is possible to divide the dislocation in the plane strain problem into two distinct classes, and those stress functions involving $(\theta^2 - \log^2 r)$, i.e.

$$L_2(\theta^2 - \log^2 r)r\cos\theta, \quad L_1(\theta^2 - \log^2 r)r\sin\theta, \quad (4.09a)$$

$$L(\theta^2 - \log^2 r) \quad (3.06a)$$

were not found. As these two points are of some importance, we shall comment on them and then conclude with a remark on the requirements for uniqueness of solution of boundary value problems involving a sta-

[6] E. H. Mann, "An elastic theory of dislocations," Proc. Royal Soc. A199, No. 1058, 376-394 (1949).

tionary barrier across which the strains or their derivatives are discontinuous.

In a course of the proof of Weingarten's theorem, we find by means of Cesaro's theorem[7] that for the plane strain problem

$$\left.\begin{aligned}\Delta u_r^{(1)} &= \Delta u_r^{(0)} + \int_{r_0}^{r_1} \Delta e_{rr} dr,\\ \Delta u_\theta^{(1)} &= \Delta u_\theta^{(0)} + (r_1 - r_0)\Delta\omega_z^{(0)} + \int_{r_0}^{r_1} \{\Delta e_{r\theta}/2\\ &\quad - (r_1 - r)[\Delta\partial e_{r\theta}/2\partial r - \Delta(\partial e_{rr}/r\partial\theta)]\} dr\end{aligned}\right\} \quad (5.01)$$

where it has been assumed that the strains are continuous of class $C^{(2)}$ and satisfy the compatibility relations in the simply-connected cylinder, r_0 and r_1 are any two points on Ω, and ω_z is the z component of the rotation. As the traction on Ω must be continuous across this surface,

$$\Delta e_{r\theta} = \Delta(\partial e_{r\theta}/\partial r) = 0, \quad (5.02)$$

for an isotropic solid. Hence, (5.01) becomes

$$\left.\begin{aligned}\Delta u_r^{(1)} &= \Delta u_r^{(0)} + \int_{r_0}^{r_1} \Delta e_{rr} dr,\\ \Delta u_\theta^{(1)} &= \Delta u_\theta^{(0)} + (r_1 - r_0)\Delta\omega_z^{(0)}\\ &\quad + \int_{r_0}^{r_1} (r_1 - r)\Delta(\partial e_{rr}/r\partial\theta) dr.\end{aligned}\right\} \quad (5.03)$$

In the classical dislocation theory, the strains are continuous of class $C^{(2)}$ throughout the body. The integrals on the right-hand side of (5.03) therefore vanish, and the displacement discontinuity has the form predicted by Weingarten's theorem.

Two possibilities arise in the case of dislocations of the general type. First, if we assume that the strains (and hence the stresses) are continuous across Ω, $\Delta e_{rr} = 0$, but discontinuities in displacement can still exist provided that $\Delta(\partial e_{rr}/\partial\theta) = 0$; in this case

$$\begin{aligned}\Delta u_r^{(1)} &= \Delta u_r^{(0)},\\ \Delta u_\theta^{(1)} &= \Delta u_\theta^{(0)} + (r_1 - r_0)\Delta\omega_z^{(0)}\\ &\quad + \int_{r_0}^{r_1} (r_1 - r)\Delta(\partial e_{rr}/r\partial\theta) dr.\end{aligned} \quad (5.04)$$

Second, if we assume that $\Delta e_{rr} \neq 0$ and $\Delta(\partial e_{rr}/\partial\theta) = 0$, the displacement discontinuity across Ω is

$$\begin{aligned}\Delta u_r^{(1)} &= \Delta u_r^{(0)} + \int_{r_0}^{r_1} \Delta e_{rr} dr,\\ \Delta u_\theta^{(1)} &= \Delta u_\theta^{(0)} + (r_1 - r_0)\Delta\omega_z^{(0)}.\end{aligned} \quad (5.05)$$

Thus, there is a division of the general dislocations belonging to the plane strain problem considered in this paper into two classes. In the class given by (5.04), the strains and u_r are continuous across Ω and u_θ is discontinuous; and Δe_{rr}, $\Delta e_{\theta\theta}$, and Δu_r are not zero while $\Delta e_{r\theta}$ and Δu_θ are zero in the class expressed by (5.05), assuming $\Delta u_r^{(0)} = \Delta u_\theta^{(0)} = \Delta\omega_z^{(0)} = 0$, of course.

The dislocations belonging to the class represented by (5.05), i.e. (4.22), reveal an omission in a proof of Weingarten's theorem given in reference 2. In the course of this proof, it is stated that if the strains are continuous across a barrier, which is a surface of discontinuity in displacement, the only possible displacement discontinuity is one that might take place in a rigid body. The stresses, and hence the strains, are continuous across Ω in the dislocations of (4.22), but the displacement discontinuity cannot be represented by the displacement of a rigid body. Hence, we must assume that the strains, together with at least their first derivatives, are continuous across a barrier in order to establish the theorem.

Equations (4.21) represent all the dislocations of the two classes needed to represent specified discontinuities in u_θ and u_r, respectively. For, by assigning appropriate values to the coefficients in these equations, it is seen, from (4.23) and (4.24), that we can express any given discontinuity in u_θ and u_r which is an analytic function of r every where except for possible singularities at $r = 0$ and $r = \infty$. The importance of having the terms of the form (4.09a) is that they are required in order to provide the logrithmic singularity in displacement discontinuity at the axis of the cylinder.

When the solid is not isotropic, the division into two classes of the dislocations in this plane strain problem is not usually possible.

In the anti-plane strain problem considered, there is only one class of general dislocations. The second of equations (3.10) shows that (3.07) provides all dislocations required to represent any specified discontinuity in u_z. The term (3.06a) provides the logrithmic singularity in Δu_z at $r = 0$.

When general dislocations are admitted, the theorems on uniqueness of solution require modification. In addition to the usual quantities, we must now specify at each point on Ω either the traction or the displacement discontinuity or an appropriate combination of the components of each. With the dislocations of classical theory, we recall that we only need specify either the resultant force and couple acting on the barrier or the six constants of the displacement discontinuity or a suitable combination of these quantities. The location and shape of the barrier must also be given when dealing with general dislocations, whereas this information does not have to be supplied in classical theory.

The author wishes to acknowledge that the stress functions given in Eqs. (3.06a) and (4.09a) were disclosed to him by R. D. Mindlin. The author also wishes to thank Prof. Mindlin for helpful discussions during the course of this study.

A Microwave Study of the High Pressure Arc

J. D. Cobine, E. P. Cleary,* and W. C. Gray†
General Electric Research Laboratory, Schenectady, New York
(Received April 26, 1950)

The impedance of an atmospheric pressure d.c. arc was measured at 1000 mc/sec. by means of a coaxial line and standing wave detector. The reactance and resistance of the arc, an essentially lumped load at the end of the line, increase with length of arc. The resistance decreases with increasing current and is approximately the same as the d.c. "resistance." The reactance is capacitive and nearly independent of current. Air, argon, and helium were studied at currents from 1–4 amp. d.c. arc current.

INTRODUCTION

THE following research was initiated in order to determine the possibilities of using microwave techniques to investigate high pressure heavy-current arcs. Measurements made with microwaves would be expected to indicate the actual electron conditions, since only electrons can respond to such high frequencies. The d.c. arc was studied as a lumped load at the end of a coaxial line. An r-f generator and measuring equipment with a 10-cm wave-length was used to study the discharge. The use of cavities and a 3-cm wave-length equipment was found to be unsatisfactory because of the high value of electron density in the high pressure arc.

APPARATUS

The arc chamber, shown schematically in Fig. 1, was arranged so that the arc burned as a section of the inner conductor of the coaxial line. Because of the necessity for water-cooled tungsten electrodes and in order to confine the position of the arc foot-points, the arc was placed ½ wave-length from the shorted end of the line to produce the effect of a short circuit at one electrode surface. It was believed that by keeping the arc length less than 0.1λ the condition of a pure lumped load would be rather closely approached. The shorted end assembly permits changes in the arc length. The arc chamber was mounted vertically and a stabilizing flow of gas was provided by means of three gas inlets set to give a spiral flow of gas around the arc column and exhaust through outlet ports at the top of the device. The fixed electrode assembly had a quarter-wave choke stub to permit direct connection to the d.c. and to admit cooling water. A tuned choke was used with a tapered adapter to connect by a flexible conductor to the microwave generator.

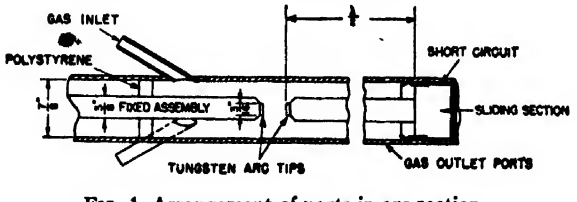

FIG. 1. Arrangement of parts in arc section.

A portion of the outer conductor below the arc chamber consisted of a slotted section for standing wave measurements.

The experimental arrangement is shown in Fig. 2. The microwave generator was an AN/APT5 Radar Set (Carpet Jamming Transmitter) set at 30 cm wave-length, unmodulated, and at minimum power output (~0.1 watt). The attenuator was a length of lossy line having an attenuation at 1000 mc/sec. of 11 db. The arc was maintained by the laboratory d.c. supply with a ballast inductance L and a current controlling resistance R in series. The standing wave measurements were made by means of a crystal detector and microammeter with the slotted line section.

EXPERIMENTAL RESULTS

The impedance, reactance, and resistance of the arc at a 30 cm wave-length were determined by calculation from standing wave data in the usual way with due regard for the reactance of the gap without the arc. It was found that each of these quantities increase with arc length and the resistance decreases with increasing d.c. current in the range 1 to 4 amperes. The arc reactance was found to be capacitive.

Figure 3 shows the resistance of arcs in air for currents from 1 to 4 amperes. A d.c. "resistance," obtained by dividing the d.c. arc voltage by the current, is included. This resistance, except for the longer lengths, is seen to be of the same order of magnitude as the r-f value and has the same trend. It is probable that the rapid decrease in R at short lengths (less than 0.25 cm) is due to the constriction that occurs in the column near electrodes and to the presence of some metal vapor in that

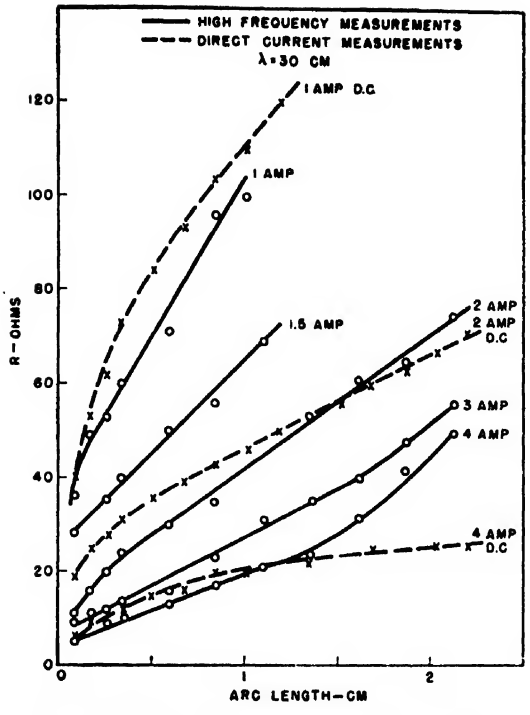

FIG. 3. Resistance characteristics of d.c. arcs in air.

legion. The upward trend of the r-f resistance of the ronger gap lengths may be due to the presence of hot ionized gas flowing along the half-wave section of the upper electrode. This would introduce losses in that section, increasing the measured value. The fact that this trend is most pronounced at the higher current is in agreement with this concept.

The arc consists of three zones of markedly different characteristics. At the cathode is a positive ion space-charge zone having a d.c. voltage drop of the order of the ionization potential of the gas. At the anode is an electron space charge zone that may have a voltage drop as high as the ionization potential of the gas. Both of these space-charge zones are of the order of a few mean free paths ($\sim 10^{-4}-10^{-5}$ cm) thick and the current density[1] at each is of the order of 50,000 amp./cm². Between these small zones is the column, which is of essentially uniform current density, except for constrictions near the ends where space charge zones develop. The current density for the low current arc column is approximately uniform along the column and is of the order of 10 amp./cm². The column gradient is uniform and relatively low. It is evident that a "resistance" obtained by dividing the total arc drop by the current might be considerably different from that measured by the r-f. The entire r-f resistance might be assumed to reside in the column. In this case, the d.c. column resistance is obtained by subtracting a reasonable maximum value of anode plus cathode voltage drops (15+15) from the total voltage and dividing by

[1] J. D. Cobine and C. J. Gallagher, Phys. Rev. 74, 1524 (1948).

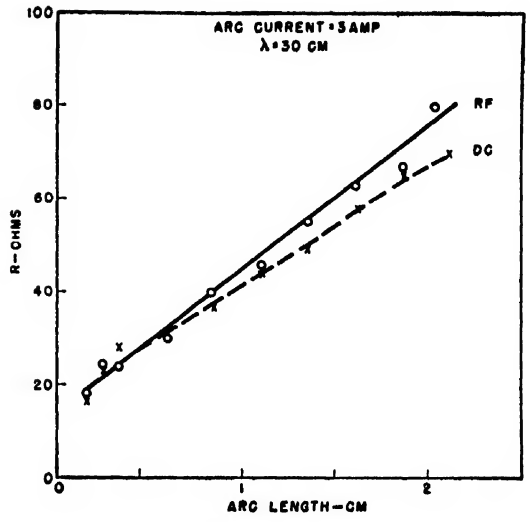

FIG. 4. Resistance characteristics of d.c. arcs in helium.

the current. The resulting resistance curves are not as good in absolute value as those shown in Fig. 3, except for 2 amperes where r-f and d.c. values are very nearly the same throughout most of the range in length studies. However, the slopes of the d.c. resistance *vs.* length curves thus obtained were nearly the same as for the high frequency curves over most of the range. The greatest error here may be in assuming the anode drop to have its maximum value; actually, it may have been only a few volts. Few really reliable values of anode drop have been measured for the high pressure arc.

The r-f resistances of arcs in helium and argon are shown in Figs. 4 and 5. The helium characteristic does not curve upwards at the longer gaps as does that for

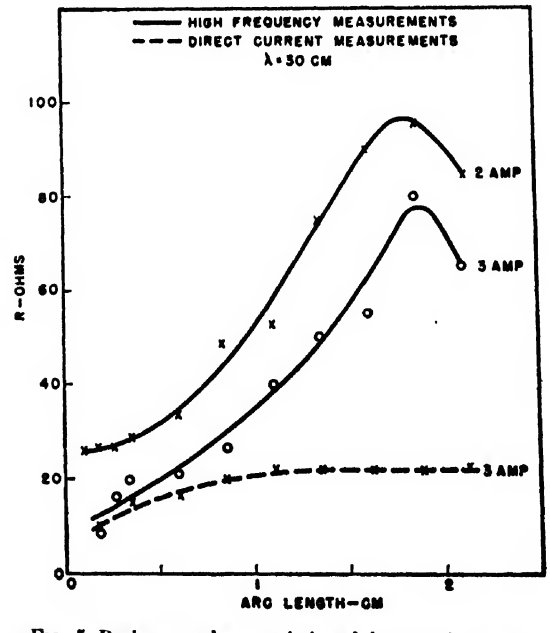

FIG. 5. Resistance characteristics of d.c. arcs in argon.

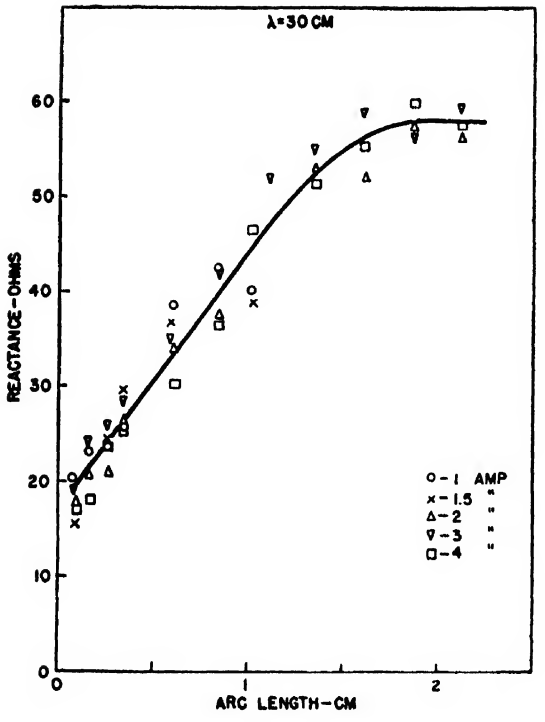

FIG. 6. High frequency reactance of d.c. arcs in air.

air. This might be the result of a lower temperature column of different size and more rapidly cooled residual gas than was true for air. The argon characteristic exhibits a definite maximum that was present in all the runs taken. There is no obvious explanation for this nor for the marked departure of the d.c. resistance from the r-f at the longer gap lengths.

The effects of arc current and gap length on the reactance of the d.c. arc in air are shown in Fig. 6. The reactance is capacitive. It is evident that arc current has very little effect on the reactance measured. Probably the principal effect in the straight line portion is due to the increase in column diameter as current is increased. There seems to be a systematic trend at the longer gap length for each current where the data indicate a departure from linearity; in fact, there may be a maximum near the end for each current. This departure occurs at increasingly greater gap lengths as the current is increased. There is no obvious explanation for this at present. The reactances for helium, air, and argon are compared in Fig. 7 for a 3-ampere arc. The general characteristics are the same for each gas. A definite maximum appears in the curves for helium and argon.

COMPARISON WITH THEORY

The fact that an atmospheric pressure arc in the low current range studied exhibits a capacitive reactance at high frequencies may be shown to be in agreement with the analysis of discharge admittance made by Everhart and Brown.[2] According to their analysis, a high conductivity discharge will have a capacitive reactance when the ratio

$$\gamma=\omega/\nu_c\leqq 0.25,$$

where ω is the angular frequency of the r-f and ν_c is the collision frequency of the electrons. The collision frequency is the ratio of the average velocity of the electrons to their mean free path. The average velocity may be taken as the average thermal velocity $\bar{c}$ of the electrons. If the arc temperature is assumed to be 6000°K, the value of $\bar{c}$ is 4.8×10^7 cm/sec. The probability of collision for electrons[3] of about this energy is 30 for N_2 and 20 for O_2. The gases in a high pressure arc column have a rather high degree of dissociation so that Brode's data are not strictly applicable. However, there seem to be no data for the probability of collision in atomic nitrogen or oxygen. Using the value for N_2 and correcting to 760 mm and 6000°K gives an electron mean free path $L_e=9.65\times10^{-4}$. Then

$$\nu_c=\bar{c}/L_e=4.8\times10^7/9.65\times10^{-4}=4.97\times10^{10}.$$

For an r-f frequency of 10^9 c.p.s. this gives

$$\gamma=2\pi10^9/4.97\times10^{10}=0.126.$$

Thus the conditions for a capacitive reactance are satisfied, provided the discharge is of high conductivity. The high frequency conductivity of the plasma can be calculated from the analysis of Margenau[4] as follows. The quantity $x_1(=m(\omega L_e)^2/2kT$, Reference 4, Eq. 20)

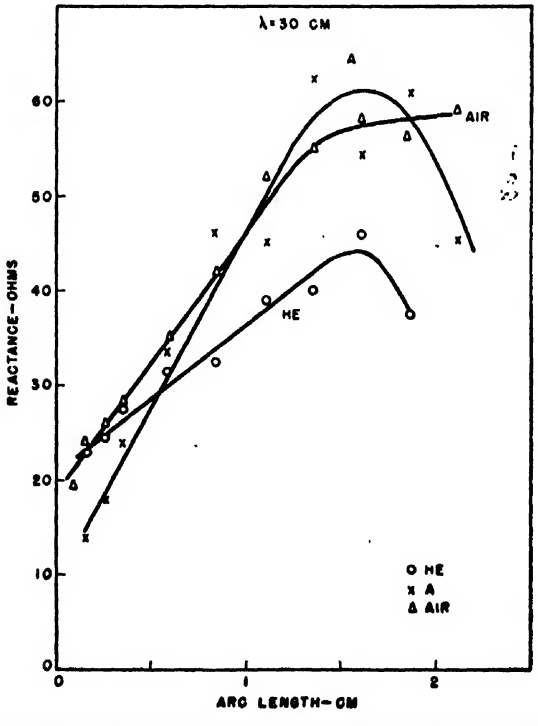

FIG. 7. High frequency reactance of 3-ampere d.c. arcs in helium, argon, and air.

[2] E. Everhart and S. C. Brown, Phys. Rev. 76, 839 (1949).

[3] R. B. Brode, Rev. Mod. Phys. 5, 257 (1933).

[4] H. Margenau, Phys. Rev. 69, 508 (1946).

has the value 2.02×10^{-3} when the above value of L_e is used and the electrons are assumed in thermal equilibrium at 6000°K. Thus the limiting values of $K_2=1$ and $K_1=\frac{1}{2}\pi^{\frac{1}{2}}$ may be used. The complex conductivity then becomes

$$\sigma=(ne^2/\omega m)[(4x_1^{\frac{1}{2}}/3\pi^{\frac{1}{2}})-j(2x_1/3)].$$

This may be compared with the free space susceptance by dividing by $\omega\epsilon_0$. Substituting the numerical values gives

$$\sigma/\omega\epsilon_0=8.62\times10^{-12}n-j1.09\times10^{-12}n.$$

If n is assumed to be of the order of 10^{14} for the high pressure arc[5]

$$\sigma/\omega\epsilon_0=8.62\times10^{2}-j1.09\times10^{2}.$$

Therefore the value of the Everhart and Brown constant η ($=|\sigma_{\omega 0}|/\omega\epsilon_0$) is of the order of 1000 and the discharge lies in the capacitive zone of their Fig. 2. Thus, the arc appears to be an example of a discharge having a positive susceptance, although the imaginary part of the complex conductivity is negative. Similar conditions were found at lower pressures by Everhart and Brown.[2] Their theory seems to agree with the observed results even though it was derived for a sinusoidal distribution of electrons along the arc, whereas in the arc the distribution is essentially uniform. A considerable discrepancy exists between the observed and theoretical values of conductivity which is not understood.

ACKNOWLEDGMENTS

Mr. R. H. Johnston took much of the data included in this paper. The coaxial line approach was suggested by Dr. M. D. Fiske of this Laboratory. Helpful suggestions were made by Professor Sanborn C. Brown of M.I.T. and by R. A. Dehn and Dr. C. J. Gallagher of this Laboratory.

A Relationship between Resistance and Temperature of Thermistors

G. Bosson, F. Gutmann, and L. M. Simmons
The New South Wales University of Technology, Sydney, Australia

(Received May 22, 1950)

The equation $\log R=A+B/(T+\theta)$ for the resistance R of a thermistor at T°K is proposed. Least square analyses of the most precise resistance-temperature data available for three different thermistor materials show that the equation is a considerable improvement over its predecessors; the standard relative errors of fit are 0.4 percent, 0.17 percent, and 0.91 percent.

THE $1/T$ law for thermistors

$$\log R=A+B/T \qquad (1)$$

derived from consideration of the free energy of an electron gas,[1] is known to be only approximate, since plots of $\log R$ *versus* $1/T$ yield bowed lines. By assuming that the slopes of these plots increase linearly with temperature, Becker, Green, and Pearson[2] proposed the following improved relationship, to which we shall refer as the B.G.P. law:

$$\log R=\log A-C\log T+B/2.303T. \qquad (2)$$

We have carried out a least square analysis of this law, using data kindly supplied by Bell Telephone Laboratories relating to the Western Electric Thermistor Material No. 1, the precision being: temperatures ±0.02°K, resistances ±0.02 percent. The results, shown in Table I, indicate clearly that considerable deviations occur between the resistances calculated from the B.G.P. law (R_b) and those observed (R_0).

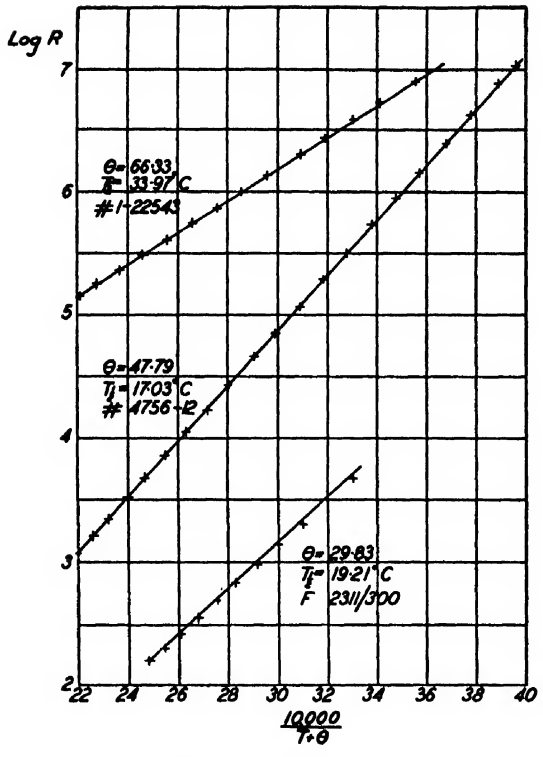

FIG. 1. Plots of log$R$ *versus* $10^4/(T+\theta)$ for three different thermistor materials.

The following empirical law is now proposed:

$$\log R = A + \frac{B}{T+\theta}. \qquad (3)$$

It indicates a linear relationship between log$R$ and $1/(T+\theta)$, and this is shown in Fig. 1 to hold for the three thermistor materials investigated, viz. Western Electric Material No. 1, Western Electric Zinc Ferrite No. 1-22543, and Standard Telephones and Cables, Ltd. Thermistor Type F2311/300. The values for θ were obtained by least square analyses of data supplied by Bell Telephone Laboratories, N. J., and Standard Telephones and Cables Ltd., London. These results are shown in Table II, which further demonstrates that Eq. (3) permits the resistance of a thermistor to be predicted from its temperature sufficiently closely for all but the most precise work.

A High Intensity Short Duration Spark Light Source*,**

J. A. Fitzpatrick, J. C. Hubbard, and W. J. Thaler
Department of Physics, Catholic University of America, Washington, D. C.
(Received May 25, 1950)

The spark described here provides a high intensity light source, whose effective duration approaches 10^{-7} second. The light intensity is nine hundred times greater than that obtained using RG8U cable cut for 10^{-7} second duration discharge. The cable described here is coaxial with silver conductors fired on the dielectric, a compound of barium titanate. The gain in light intensity is apparently due to both the higher capacity of the barium titanate cable and its very low characteristic impedance.

A COAXIAL cable compounded of barium titanate provides a spark light of both high intensity and short duration. This is accomplished by applying the method employed by Beams *et al.*[1] to a cable of low characteristic impedance. Since the velocity of propagation of the discharge wave is low, a short length of cable, 16.5 cm is used. The cable is cylindrical, the outside conducting surface having a diameter of five centimeters and the inside a diameter of two and one-half centimeters, with the dielectric forming the body of the cable.

The discharge producing the light is confined to a small hole made with a number 80 drill, 0.013-inch diameter and 4-mm long drilled in a piece of unfired soapstone, Fig. 1. For some applications a triggering gap is fitted in series with the light producing gap to discharge the cable at a specific time.

The dielectric constant of the material forming the cable has been measured at frequencies up to 250 megacycles. A General Radio Impedance Bridge was used for the low frequency measurement at 1000 c.p.s. For the higher frequencies resort was had to using the cable as a shorted and open end transmission line, and observing the resonance frequencies indicated on a grid dip meter connected as a generator to the sending end of the line. For a short circuited line the impedance presented to the generator is zero for an infinitely short line, becoming an increasing inductive reactance as the line is lengthened until the impedance becomes infinitely great for a value of $2\pi l/\lambda=\pi/2$ when l, the length of the cable, equals one quarter wave-length in the dielectric. Since the length l of the cable was fixed at 16.5 cm, the frequency of the generator was varied between a range of 2 to 250 megacycles and the frequencies of resonance or maximum impedance observed as the patterns of standing waves on the line were established. Knowing the frequency and wave-length, the velocity of propagation was determined as well as the dielectric constant. The values shown in Table I were obtained for both an open and short circuited line.

The characteristic impedance of the line is a function of the dielectric constant. Since a cable will discharge in a square wave of current if terminated in its characteristic impedance, it is desirable to make such a termination. We see from Table I that it is impossible to assign a fixed value to the characteristic impedance which will satisfy all the frequencies present in the discharge. The terminal impedance corresponding to the lowest value of the dielectric constant is 1.5 ohms while the value for the highest is 1.2 ohms. The writers have inserted various resistors of between one and two ohms in series with the gap but were unable to observe any effects on shadowgraphs made of progressive ultrasonic waves such as shown in Figs. 2–4, even when terminating resistors were eliminated. It is believed that the resistance of the fittings of the spark head as well as some resistance presented by the spark gap are close enough to the characteristic impedance of the cable to allow the omission of a resistor in series with the gap.

The duration of light produced by the barium titanate cable has been compared with a section RG8U cable cut for 10^{-7} second discharge, approximately 9½-meters long. Both discharges were made in confined gaps. Figure 5 shows a cathode ray oscilloscope trace and a five megacycle time marking signal superimposed on the discharge. These traces were made with a photo-

multiplier tube and synchronoscope combination.*** The following comparative data are obtained.

	RG8U Cable	$BaTiO_3$ Cable
Over-all light duration	7×10^{-7} sec.	12×10^{-7} sec.
Decay time, peak to $1/e$ peak	1.9×10^{-7} sec.	2×10^{-7} sec.
Rise time, zero to peak	1×10^{-7} sec.	1×10^{-7} sec.
Fifty percent of peak limits	1.5×10^{-7} sec.	1.8×10^{-7} sec.

The series of spark shadowgraphs shown in Figs. 2, 3, and 4 show the approach to a resolution limit as the frequency of the progressive ultrasonic waves is increased from three to nine megacycles. A quartz crystal having a fundamental frequency of one megacycle was driven at 3, 7, and 9 times its fundamental frequency to obtain these shadowgraphs. The method used was that devised by Hubbard, Zartman, and Larkin.[2]

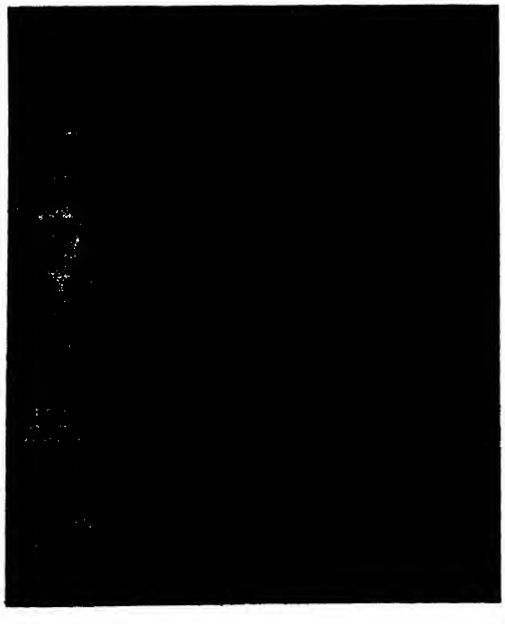

FIG. 2. Shadowgraph of 3.0 Mc progressive ultrasonic wave in water. The scale shown is in cm. Water temperature—25°C.

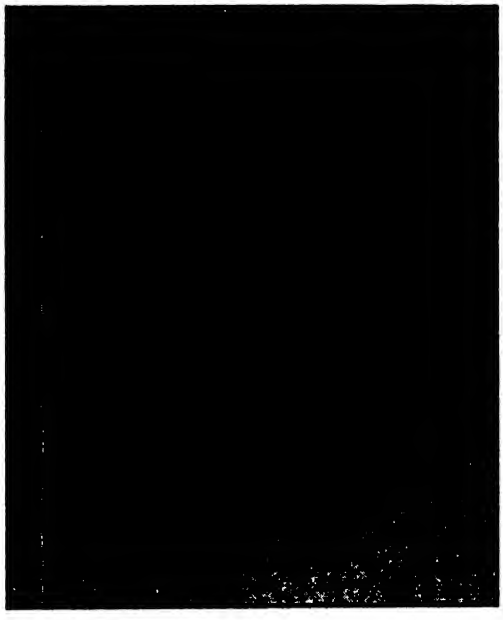

FIG. 3. Shadowgraph of 7.0 Mc progressive waves in water. Note that definition is not as good as that shown in Fig. 1. See also caption in Fig. 4.

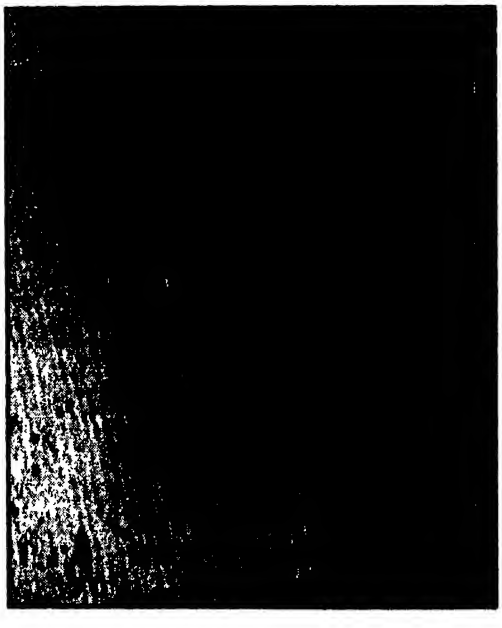

FIG. 4. Shadowgraph of 9 Mc progressive wave in water. The wave pattern here is not very distinct indicating that the acoustic wave has moved an appreciable part of a wave-length during the period of illumination. A diminution of the sound intensity is seen in the short distance covered by this picture. The marginal spacing is in mm.

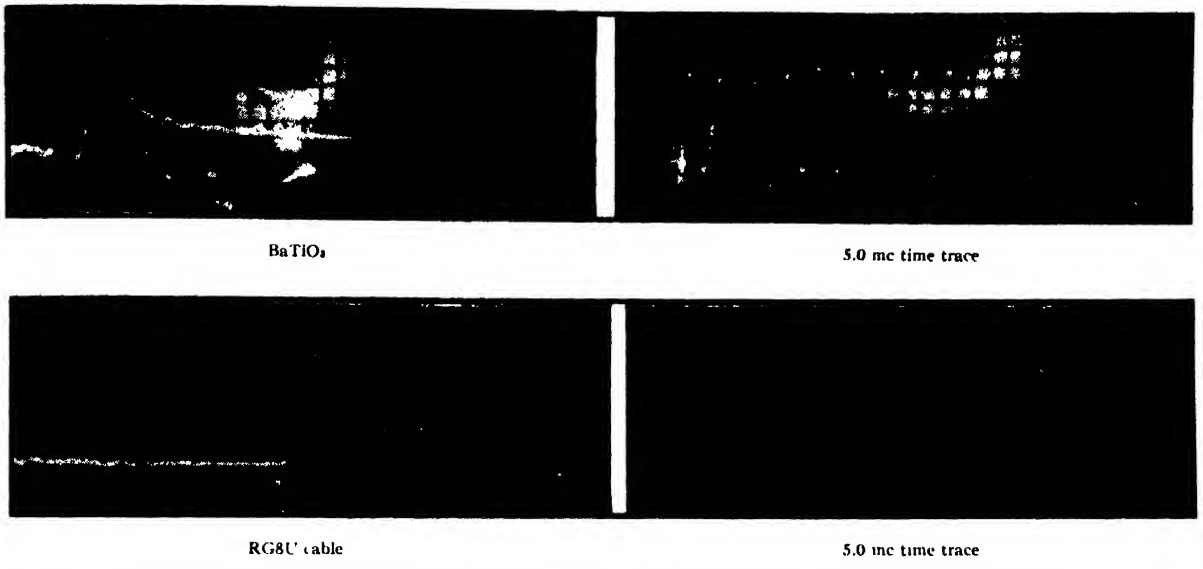

FIG. 5. Photograph of cathode-ray oscilloscope traces of light from spark sources as a function of time. The time scale is given by the sinusoidal traces on the right of frequency 5 Mc/sec.

Comparative light intensities have been made by discharging both the RG8U cable and the $BaTiO_3$ cable through the same spark electrodes and allowing the divergent light to fall on the sensitive plate of a photomultiplier tube the output of which was coupled to a ballistic galvanometer. To obtain the same deflection from the galvanometer as was obtained from discharging the RG8U cable at a fixed distance it was necessary to move the barium titanate light source to 30 times the distance from the photo-cell, thus indicating a light intensity nine hundred times as great as that produced by the RG8U cable. It is possible to obtain good spark photographs on lantern slide plates four feet away from the barium titanate divergent light source. Apparently the nine-hundred fold gain in light intensity is due to the elimination of the loss inherent in the fifty ohm terminating resistor associated with the RG8U cable since at the most, the electrical capacity of the barium titanate cable is only twenty times that of the RG8U cable used here.

The high light intensity and short time of the spark together with the convenient size of the cable make it particularly useful for studying high speed phenomena such as turbulence and ultrasonic wave-systems where photographic methods are used. We have observed while employing this device that the light intensity and spark duration are functions of many parameters principal of which are, gap spacing, current density in the gap, which depends on the initial charge on the line (the results shown here have been made, with the cable charged to 10,000 volts), and type of confining gap; a confined spark produces higher intensity but longer duration, an open gap less light intensity but shorter duration.

The authors wish to acknowledge with thanks the advice of Mr. Bert H. Marks, Product Engineer for Centralab Incorporated, which fabricated the cable.

Emissivity Changes of Thoria Cathodes*

O. A. Weinreich
Bartol Research Foundation of The Franklin Institute, Swarthmore, Pennsylvania
(Received June 1, 1950)

Spectral and total emissivity measurements of thoria-coated tungsten filaments show that irreversible and reversible changes of the emissivity occur. ϵ_λ ($\lambda=0.65\mu$) varies from 0.2 to 0.7 and ϵ_t from 0.2 to 0.5.

Certain variations of the thermal radiation can be related to changes of thermionic emission.

Passage of current through the coating affects emissivity and thermionic emission. This is shown by measuring infra-red radiation and electron current simultaneously. The existing relationship between emissivity and thermionic activation is discussed.

1. INTRODUCTION

THE numerous published values[1–7] of spectral emissivities for thoria vary over a wide range. (If thin coatings on metals are investigated, one should keep in mind that part of the radiation comes from the base metal.) The extinction coefficient at $\lambda=0.665\mu$ for thoria sleeves has been found to be 26 cm^{-1}.[8] The results of our investigations show that both reversible and irreversible changes in spectral and total emissivities can be effected by various treatments of the thoria.

Spectral and total emissivity measurements of thoria-coated tungsten cathodes are of interest in two respects:

(1) Total emissivity changes of thoria cathodes which occur during processing and life affect temperature and heater power; emissivity changes in the red affect the pyrometer corrections.

(2) Emissivity changes, insofar as they involve impurity levels, may yield information on the mechanism of thermionic emission.

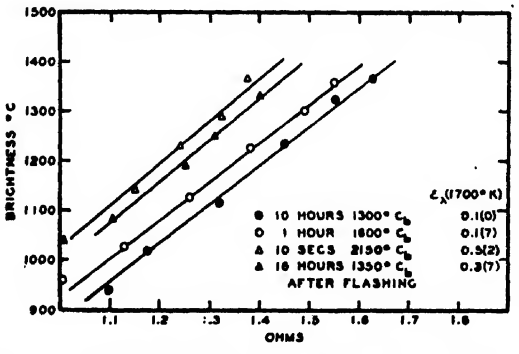

FIG. 1. Spectral emissivity ($\lambda=0.65\mu$) of a thoria-coated tungsten filament (coating thickness 50μ) after various heat treatments. True temperature is measured by filament resistance. Calibration curve not shown.

2. EMISSIVITY CHANGES OF THORIA-COATED W FILAMENTS

In an earlier paper[9] it was shown that a small spot of thoria on a tungsten filament appeared brighter than the tungsten, when previously flashed to ~2800°K. The brightness of the spot relative to the brightness of the tungsten decreased at lower temperatures with time. In the present investigation the emissivity changes of thoria-coated cathodes were investigated further by using thoria-coated tungsten filaments with potential leads. The filament resistance can be taken as a measure of the true temperature for the thoria surface if we assume that:

(1) The temperature drop in coatings $\lesssim 50\mu$ is negligible, which appears to be justified on account of the relatively high thermal conductivity of thoria, 0.01 cal. per cm deg.[10]

(2) The change of the tungsten filament resistance due to chemical reaction between tungsten and thoria is negligible. This has been shown to be true by evaporating completely a 10μ thoria coating from a tungsten filament. Before coating and after evaporation the resistance was the same within the experimental errors.

Tungsten filaments of 10 and 12 mils diameter and about 25 cm length were used. The potential leads of 2 mils diameter were spot-welded about 3 cm above the

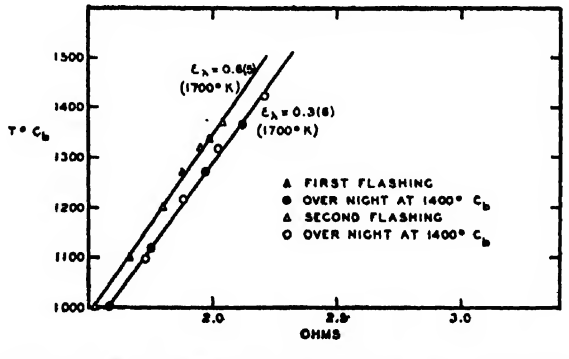

FIG. 2. Reversible spectral emissivity changes ($\lambda=0.65\mu$) of a thoria-coated tungsten cathode. Flashing to about 2300°C$_b$ increases the emissivity to $\epsilon_\lambda=0.7$ and subsequent heating at 1400°C$_b$ causes the emissivity to drop to $\epsilon_\lambda=0.4$.

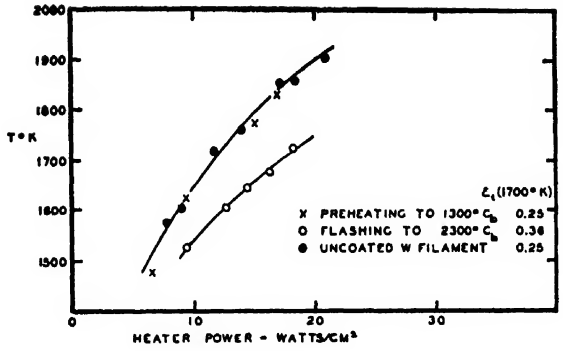

FIG. 3. Total emissivity of a thoria-coated tungsten filament. Coating thickness 10μ. Flashing to 2300°C$_b$ increases the total emissivity from $\epsilon_t=0.25$ to $\epsilon_t=0.36$ (at 1700°K).

filament terminals. The resistance was measured by the current through the filament and the voltage drop across the potential leads. The general procedure was the following: Filaments with potential leads were mounted in a tube which was pumped and baked in the usual manner, and the resistance-temperature characteristic of the uncoated tungsten filament was measured using pyrometer readings and corrections for the spectral emissivity of tungsten. The tube was then taken off the pumping system and opened, and a thoria coating was deposited on the filament. Commercial thoria powder supplied by Lindsay Light and Chemical Company was suspended in butyl alcohol, and the particles charged by addition of a small amount of thorium nitrate, as described by E. T. Hanley.[11] The tube was then sealed and put back on the pumping system. The resistance of the coated W filament was measured with the same instruments as used for the resistance-temperature plot of the pure tungsten filament.

Figure 1 shows the change of the apparent spectral emissivity of a thoria coating of 50μ thickness, when heated in steps to higher temperatures. The brightness temperature is plotted against the filament resistance. We see that heat treatment of the filament at increasing temperatures increases the spectral emissivity; i.e., for a given filament resistance the brightness temperature increases. (It should be noted that the initial emissivity increase may be partly an apparent increase due to a sintering effect, prior to which a temperature difference between filament and coating may exist.) The emissivity increase after flashing to ~2800°K is not stable but decreases with time if the filament is allowed to remain at lower temperatures, e.g., 1350°C$_b$.

The reversible change of the spectral emissivity of another filament is shown in Fig. 2. The emissivity increases, after flashing, to $\epsilon_\lambda=0.7$ and decreases with time, when held at 1400°C, to $\epsilon_\lambda=0.4$. This process can be repeated until finally the coating thickness decreases by evaporation during the flashing.

Changes of the total emissivity which occur with the same heat treatments are shown in Fig. 3. The heater

[11] E. T. Hanley, J. App. Phys. 19, 583 (1948).

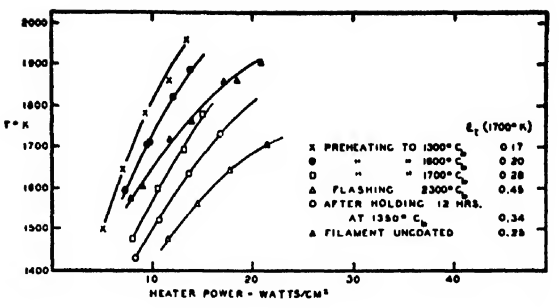

FIG. 4. Total emissivity of a thoria-coated tungsten filament (coating thickness 50μ) after various heat treatments.

power in watts/cm^2 is plotted against the temperature as measured by the filament resistance. The coating thickness is 10μ. The initial total emissivity at 1300°C$_b$ is very near to that of the pure tungsten, $\epsilon_t=0.25$. Again, as seen for the emissivity in the red, the total emissivity also increases, $\epsilon_t=0.36$, as a result of the flashing.

Figure 4 shows the same measurements for a 50μ coating. An initial heat treatment not exceeding 1300°C$_b$ gives $\epsilon_t=0.17$, which value increases after flashing to $\epsilon_t=0.45$. As the temperature is allowed to remain at 1350°C$_b$ the emissivity drops to $\epsilon_t=0.34$.

3. EMISSIVITY CHANGES AND ACTIVATION CHANGES OBSERVED WITH DIODES

As was shown in an earlier paper,[9] flashing to 2800°K increases electron emission and emissivity. Subsequent current drawing accelerates the deactivation, which normally occurs slowly with time after flashing if the cathode is maintained at a lower temperature. Here we

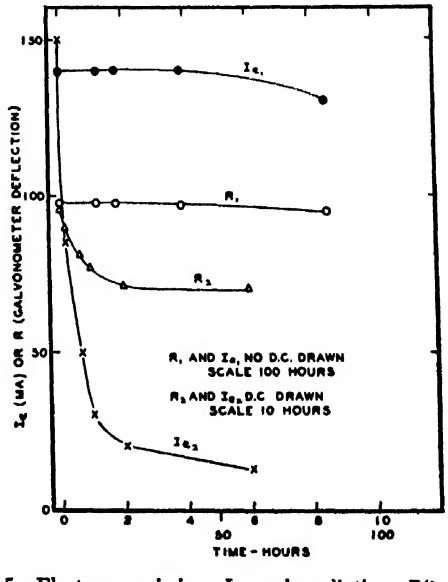

FIG. 5. Electron emission Ie and radiation $R(\lambda=1\mu)$ at $T=1175$°C of a thoria-coated tungsten filament as a function of time after flashing to 2300°C$_b$. Curves Ie_2 and R_2 show that the rates of decrease of Ie and R are highly increased if electron emission is drawn.

observe further the emissivity changes of a thoria cathode by measuring the intensity of radiation at an arbitrary wave-length in the infra-red with a thermopile, if the true temperature is kept constant by keeping the filament resistance at a constant value. Several diodes, the cathodes of which had potential leads, were made. The cylindrical anodes were made of tungsten mesh. In this way the decrease of the spectral emissivity with time, together with the thermionic deactivation after the flashing could be measured. The following

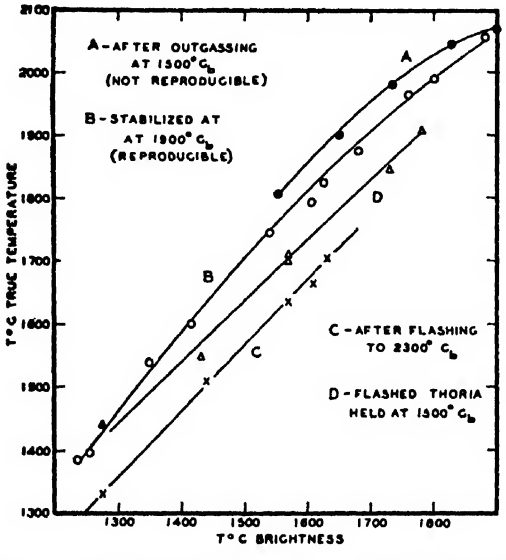

FIG. 6. Irreversible (curves *A* and *B*) and reversible (curves *C* and *D*) changes of the spectral emissivity ($\lambda=0.65\mu$) of a thoria-coated tungsten cathode after various heat treatments. The true temperature is measured by a Mo—W thermocouple.

observations were made at lower temperatures after flashing the cathode to ~2800°K:

(a) If no electron emission is drawn, both intensity of radiation and thermionic activity decrease slowly with time. The rate of this decrease depends on the temperature. For example, at 1400°C radiation and emission decreased about 10 percent after 100 minutes, while at 1150°C, no appreciable decrease was seen after 85 hours.

(b) The drawing of electron currents accelerates drastically the rate of deactivation and of emissivity decrease. For example, at 1400°C the electron emission decreased 50 percent and the radiation by 33 percent after ten minutes.

(c) The accelerated decrease of thermionic emission and emissivity due to the drawing of current could still be seen if, after flashing, the cathode was first held "quiescent" at 1400°C for 16 hours and then the anode voltage applied. The described phenomena were qualitatively reproducible and observed with several diodes and at different wave-lengths. Figure 5 shows the results for 1175°C at $\lambda=1\mu$.

4. EMISSIVITY CHANGES AS OBSERVED WITH A THERMOCOUPLE

Further verification of the emissivity changes of thoria was made using a W—Mo thermocouple,[12] spot-welded to a 20 mil tungsten filament to measure the true temperature. The known spectral emissivity of the uncoated tungsten filament was used to calibrate the e.m.f. of the thermocouple against true temperatures. A plot of the true temperature against the e.m.f. was made over a range from 1200° to 2100°C. The tube was then opened, the tungsten filament coated with thoria by cataphoresis (about 20μ thick), sealed, and put again on the pumping system. In Fig. 6 the brightness temperatures of the thoria coating are plotted against the true temperatures as measured by the thermocouple. After outgassing at 1500°C$_b$ the temperature of the filament was raised in steps to 1900°C$_b$ (curve *A*). Curve *B*, obtained by decreasing the temperature from 1900°C to 1200°C does not coincide with curve *A* and is the reproducible curve. In contrast, curve *A* is not reproducible. This behavior is believed to be the result of a certain sintering action, which occurs along curve *A* and is completed at 1900°C. (The very low initial value of the spectral emissivity of thoria coatings ($\epsilon_\lambda=0.09$) found recently by S. Mesnard[7] may be an apparent one for the same reason.) Following flashing to 2300°C$_b$ temperature measurements gave curve *C*. After several hours at 1500°C$_b$, curve *D* is obtained. The spectral emissivity values ($\lambda=0.65\mu$) for the different states, taken from Fig. 6 for $T=1700$°C are:

Before flashing: $\epsilon_\lambda=0.3$ (curve *B*).
After flashing: $\epsilon_\lambda=0.7$ (curve *C*).
After flashing and 10 hours at 1500°C$_b$: $\epsilon_\lambda=0.4$ (Curve *D*).

The tube was now sealed off, and after a new flashing to 2300°C$_b$ the radiation of the thoria-coated filament at $\lambda=1\mu$, as obtained from the galvanometer deflections of the thermopile of the spectrograph, was plotted against time for a temperature of 1520°C, this temperature being maintained constant by holding the e.m.f. of the thermocouple on the filament at a constant value. Again, the emissivity decreased with time as was expected from the previous measurements when the true temperature was measured by the resistivity.

5. CONCLUSION

It is premature to attempt to draw theoretical conclusions from the results presented here. However, apart from the bearing on practical problems of heater power and pyrometer corrections, it seems that the results show the existence of a relationship between intensity of thermal radiation and thermionic activation.

Undoubtedly chemical reactions occur between tungsten and thoria when flashed to 2800°K. Reaction products may be metallic thorium and/or some thorium

[12] F. H. Morgan and W. E. Danforth, J. App. Phys. 21, 112 (1950).

suboxide. W. L. B. Burgers and T. M. Liempt[13] have made x-ray analyses of thoriated tungsten filaments. They found that when these tungsten filaments are heated to 2500°K, thoria is partly reduced to metallic thorium. Besides this, their results show some evidence for incomplete reduction and formation of an oxide with an oxygen content between Th and ThO_2. The authors found a similar reaction product when heating superficially oxidized thorium rods. The only impurity considered so far for thoria cathodes is free thorium, and many activation phenomena fit into this picture.[14] On account of Burgers and Liempt's work, one should also consider the possibility of suboxide impurities.

Some doubt may be held as to whether or not a density of impurity centers, sufficient to account for conduction and thermionic emission, is also sufficient to provide observable changes of optical emission. It is possible that our reversible emissivity changes might be linked to thermionic activation in an indirect way only, i.e., impurity material produced in such quantity that colloidal agglomeration occurs. Present views concerning thoria[15, 16] indicate a density of impurity centers of the order of 10^{18} cm^{-3}. This figure, although its value is subject to further investigation, is of the same order as the density of color centers of the alkali halides in which measurable optical effects are found. It therefore seems possible that knowledge regarding impurity levels in thoria might be gained from infra-red emission studies, and further work is in progress in this connection.

ACKNOWLEDGMENT

The writer wants to thank Mr. F. H. Morgan for his aid in assembling and calibrating the W—Mo thermocouples and for his assistance in carrying out the experiments described in Sec. 4.

Techniques for Measuring the Dynamic Characteristics of a Low Pressure Discharge

BENTLEY T. BARNES AND STEPHEN EROS
General Electric Company, Lamp Development Laboratory, Nela Park, Cleveland, Ohio

(Received June 13, 1950)

The dynamic characteristics of a discharge can be determined by making square-wave changes of arc current. This is done by putting the discharge tube in the plate circuit of a group of pentodes connected in parallel and supplied with a square-wave signal superimposed on a d.c. bias.

Probes operated at constant current are very useful in recording the characteristics of a modulated discharge. For measuring electron temperature (T_e), two identical probes are centered about points having the same space potential. If the probes are operated at different fixed currents on the straight line part of the probe characteristic, the voltage between them is proportional to T_e. Longitudinal voltage gradient or radial potential differences may be recorded by use of identical probes operated at the same current.

A probe operated at a suitable current will follow roughly the variations in space potential of the adjacent region of the discharge. Another probe made sufficiently negative with respect to such a probe will collect only positive ions. A probe made 0–10 volts positive with respect to the constant-current one gives records from which electron concentrations can be computed. In this case, a bias connection without current flow is obtained by use of a cathode-follower with two stages of direct-coupled amplification.

The oscillograph amplifier used for dynamic probe records must be either a differential one or one with ungrounded power supply. In the latter case, the stray capacitance is many times larger; but fairly reliable records can be obtained if the arc current is 0.1 ampere or more, and if the time constant for the decay of the transient effects being measured is at least 10 microseconds. The oscilloscope amplifier and any preamplifier used for recording spectral intensities should be direct-coupled.

IF a discharge is operated on a.c. at a frequency of 1000 c.p.s., or more, the volt-ampere curve obtained on an oscilloscope screen is quite different from the curve obtained by plotting voltage readings taken on a d.c. discharge operated at various currents. This difference in behavior shows that the dynamic characteristics of a discharge are not the same as those indicated by a series of static tests. Since this is of considerable interest from both practical and theoretical viewpoints, we have developed methods for getting fairly complete data on the dynamics of a discharge. The latter is subjected to square-wave changes of arc current. The time between successive square-wave changes should, of course, be long enough to permit the discharge to approach steady-state conditions. This permits one to observe both the instantaneous effect of a change in current and the rate of adjustment toward the steady state. To make measurements under these conditions, one needs to modify the techniques developed by Langmuir[1,2] for measurements on discharges operated at a constant current. In this article we describe equipment and procedures for obtaining square-wave changes of arc current and for recording the instantaneous values of various properties of the discharge.

SQUARE-WAVE MODULATION

The circuit used for controlling arc current is shown in Fig. 1. We have used twelve 6L6 tubes, connected in

[1] I. Langmuir, G. E. Rev. **26**, 731 (1923).
[2] I. Langmuir and H. Mott-Smith, Jr., G. E. Rev. **27**, 449 (1924).

parallel except for a non-inductive resistor in series with each grid. These resistors prevent parasitic oscillations. They are connected to the cathode-follower output stage of a square-wave generator. To provide the proper bias for the 6L6's, the negative terminal of the voltage supply for the square-wave generator is put at −60 volts with respect to the negative lead of the voltage supply for the circuit shown in Fig. 1. Figure 2 shows how provision is made for controlling both the d.c. bias and the amplitude of the square-wave signal. This permits one to adjust the modulation and the average arc current independently.

With the circuit shown in Fig. 1, inductance in the leads of the voltage supply tends to round the corners of the square wave. Although the plate current of a pentode is insensitive to changes in plate voltage, it is affected to a much greater extent by changes in screen voltage. A better wave-shape would be obtained if a separate low-impedance supply were used for the screens of the 6L6's. This improvement may not be needed in a study of the dynamics of the flow of ions to the tube wall, but it is essential if one wishes to record the increase in ion concentration when the current is suddenly increased. In the latter case, a square wave with a rise time which does not exceed a few microseconds is required for even a rough separation of instantaneous effects from subsequent adjustments toward steady state conditions.

We have not tested the circuit change suggested in the preceding paragraph, partly because it did not occur to us until after a fairly complete set of data had been taken, and partly because our oscilloscope equipment could not resolve the details of changes which take place within a few microseconds. With a common plate-screen supply, 90 percent of a square-wave change in lamp current was made in about 80 microseconds. With the lamp current zero, the corresponding change in the grid voltage of the 6L6 tubes took less than one-third of this time.

PROBE TECHNIQUES

Sudden large changes in arc current are accompanied by proportionately larger instantaneous changes* in the

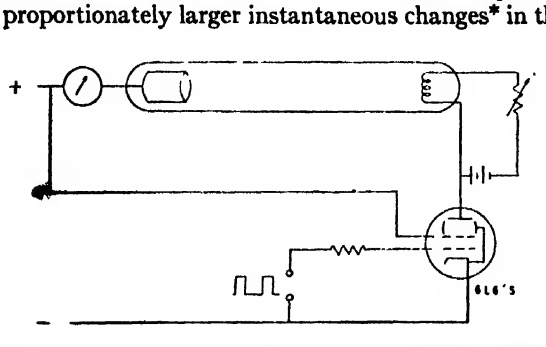

FIG. 1. Circuit diagram for discharge tube with square-wave modulation of arc current.

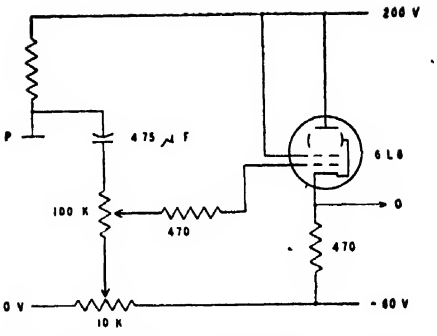

FIG. 2. Output stage of square-wave generator. *P*. Plate of clipper stage. *O*. Output to pentode current-control tubes.

longitudinal voltage gradient. These variations make it inconvenient to use a constant-voltage probe for recording arc characteristics throughout a cycle of modulation. It is much simpler to obtain these records with the aid of a probe operated at constant current, or a pair of these probes. Probe current can be held constant by use of the floating-pentode circuit shown in Fig. 3.

If the electrons in a discharge have a Maxwellian distribution of velocities, the usual plot of the logarithm of the electron current to a probe against the probe voltage has a straight-line portion[1] whose slope is proportional to the reciprocal of the electron temperature T_e. If the probe current i_P is at least 10 percent of the current i_s drawn when the probe is at space potential,† then the electron current to the probe is many times larger than the positive-ion current. In this case, the probe voltage V_P with respect to space potential is approximately equal to $(T_e/5040)\log(i_P/i_s)$. If two probes of the same area are located in regions of the discharge having the same average potential, but are operated at different currents which are on the straight-line portion of the characteristic, then the voltage between the probes is proportional to T_e. Thus two constant-current probes can be used to get a continuous record of T_e during the cycle of modulation described above, or during any transient for which the variations in i_s and T_e are small enough to permit both values of probe current to remain on the straight-line portion of the characteristic. When i_s does not vary by more than a factor of ten, the constant-current technique is more convenient than the floating-double-probe technique described by Johnson and Malter,[2] since the former gives T_e directly on a single oscillogram. (Ordinarily, two oscillograms are taken, with the probes interchanged to eliminate errors due to contact differences of potential.) One could cover a larger range of i_s by using two or more sets of probe currents, provided that one used only the portion of each record corresponding to the straight-line part of the probe characteristic. However, even this part of each oscillogram might not be a true record of T_e if the oscillograph amplifier were overloaded at any

* An article in which the dynamic characteristics of a discharge are demonstrated will be submitted by one of us (B.T.B.) for publication in the Physical Review.

time during the cycle. Recovery from an overload may not be complete until several milliseconds after the input signal returns to the normal range.

If the distribution of electron velocities is non-Maxwellian, the probe characteristics may have no straight-line portion. In this case, the voltage between two constant-current probes measures the slope of a chord drawn between two points on the characteristic. The apparent T_e indicated by this slope would depend on the values chosen for the two probe currents. To find how the velocity distribution varied during a transient one would have to take a series of oscillograms—using several pairs of values for the probe currents, distributed over the probe characteristic.

Constant-current probes also are useful for measuring the difference of potential between two points in a discharge. If T_e is the same at the two points, one operates the probes at currents which are the same fraction of the respective values of i_s. This procedure allows one to obtain a continuous record of longitudinal voltage gradient, or of the radial fall in potential between the axis of the tube and the inner edge of the wall sheath.

A constant-current probe is useful as an auxiliary in two other types of probe measurement. If the current is made a little less than the minimum value of i_s, the probe will follow roughly the variations in space potential in the adjacent region of the discharge. (When i_s is at its maximum value, the probe may be 2–3 volts negative with respect to space potential.) A nearby probe made sufficiently negative with respect to the auxiliary one will collect only positive ions. By inserting a suitable resistance between the bias battery and the second probe, one can obtain a continuous record of positive ion current during a cycle of modulation.

Figure 4 shows an elaboration of this procedure which is useful for obtaining records of probe current near space potential. The cathode follower shown in this circuit allows one to bias the measuring probe with respect to the auxiliary one, and to draw whatever probe current is appropriate with this bias. In case a single 6L6 output tube does not furnish sufficient current, two or three of them are used in parallel. Two stages of direct-coupled amplification make it possible to cover a wide range of probe current with only a small change in the voltage between the input grid and the common cathode lead of the amplifier-cathode-follower circuit. Thus the voltage of the second probe follows quite closely the voltage variations of the auxiliary probe.

Using this cathode-follower, oscillograms of probe current can be taken with various bias voltages. If the latter are so chosen that probe potentials above and below space potential are obtained, then one can find i_s by making the usual semilogarithmic plot.[1] From the measured values of i_s and T_e, one can compute the electron concentration in the adjacent region of the discharge. (See reference 2, Eq. (44).)

AMPLIFIERS FOR PROBE MEASUREMENTS

In the probe measurements described above, both leads to the oscillograph amplifier have varying potentials during a cycle of modulation. One must use either a differential amplifier or an amplifier whose power supply is ungrounded. In the latter case, one must make sure that the capacitance associated with the negative lead of the supply does not cause serious errors. With a rectifier type of supply, the principal source of unwanted capacitance may be that between the primary and the secondary windings of the power transformer. In a small amplifier, this capacitance is likely to be of the order of 1×10^{-9} farads. Its effect would be most marked if the space potential at the probe suddenly shifted in the positive direction, because this would reduce the probe current. The current charging the stray capacitance in the amplifier-probe circuit could not exceed the current for which the floating pentode (Fig. 3) connected to the probe was set. If this were 10 milliamperes and if space potential shifted 10 volts, a capacitance of 1×10^{-9} farads would require only one microsecond to charge completely, if the full current were available for this time. Actually, the required time would be longer because the probe would start drawing current as its voltage approached its equilibrium value; in a typical case the adjustment would be 98 percent complete in 1.25 microseconds. Thus an amplifier with single-ended input may be entirely satisfactory for instantaneous probe measurements such as we have described, provided that the negative return lead of the

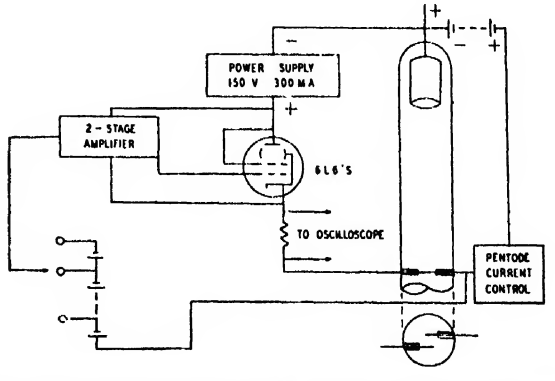

FIG. 4. Circuit for recording probe current at voltages near space potential, in order to determine electron concentration.

power supply is connected to a probe from which a current of several milliamperes is drawn.

It is advantageous to use a direct-coupled amplifier for probe measurements, since the d.c. components of voltage are needed. The frequency response should be essentially constant from 0 to at least 100,000 cycles per second. An input resistance of about 0.2 megohms and a maximum sensitivity such that two volts gives full-scale deflection have been satisfactory for our conditions of measurement (arc current >0.2 amp.). If the arc current were less than 0.1 amp., a more sensitive amplifier might be needed in order to get a reliable record of positive ion current.

RECORDING SPECTRAL INTENSITIES

To record the intensity of a spectral line or band during a cycle of modulation, one may need to use a photo-multiplier tube. An output current of the order of 10 μamp from the multiplier tube would deflect the oscilloscope spot the full height of the screen, if an amplifier similar to the one described in the preceding paragraph were used.

If the line or band to be measured is fairly strong and can be isolated with a filter, an ordinary photo-tube may suffice. In this case, it probably will be necessary to add a direct-coupled preamplifier to the amplifier used for probe measurements. To maintain adequate speed of response, the input resistance of the preamplifier ordinarily should be made no larger than 0.2 megohms. To insure sufficient stability of the zero-input trace, a d.c. heater supply should be provided for the preamplifier.

DISCUSSION

The circuits described in this article were developed for use with a mercury-vapor discharge operated in the presence of rare gas at a pressure of a few millimeters. In this case, the transient effects accompanying a sudden change in current may last several milliseconds. If the rare gas had not been present, the transients obtained with a mercury-vapor pressure of a few microns would have lasted only a few microseconds.[4] Then a 100-fold increase in both the frequency of modulation and in the speed of response of the measuring circuits would have been needed in order to get satisfactory oscillograms. This would not be possible unless the stray capacitance were kept to a minimum by use of a suitable differential amplifier and by other precautions.

Even with a gas pressure of a few millimeters, stray capacitance will be troublesome if the arc current is quite low (50 milliamperes, or less). In this case, probe currents and photo-currents will be so small that the resistors used for measuring them will have relatively high values. Then the spurious effects introduced by stray capacitance will have time constants of the same order of magnitude as those of the transients one wishes to record.

When a differential amplifier is used for probe measurements during a cycle of modulation, care must be taken to keep the amplifier operating within its linear range. Because of variations in space potential, the voltage difference between the constant-current probe and the anode or the cathode may vary over a wide range—perhaps several times as much as the voltage one wishes to measure. To offset this, one must either (1) connect the amplifier ground to a probe near to the one, or pair, with which measurements are being made, or (2) make the linear range of plate voltage for the output tubes several times the maximum voltage to be applied between the deflection plates of the oscilloscope.

SUMMARY

In studying the dynamic characteristics of a low-pressure discharge, we have found the following procedures and equipment particularly useful.

1. Pentodes in series with the discharge tube provide a convenient means of making square-wave changes in arc current.

2. A floating, self-biased pentode in series with a probe permits one to hold probe-current constant in spite of changes in the voltage gradient in the discharge. Pairs of constant-current probes can be used to get instantaneous records of electron temperature or of the voltage difference between two points in the discharge.

3. A constant-current probe is a useful auxiliary in making records of positive-ion current during a transient.

4. For measuring variations in ion concentration when the arc current is modulated, one can use a probe biased positive by various amounts with respect to a constant-current probe. The bias voltage is applied by use of a cathode-follower with two stages of direct-coupled amplification.

5. The oscilloscope amplifier used for recording probe characteristics must have both input terminals floating. An amplifier with single-ended input and ungrounded power supply may be satisfactory, but a differential amplifier is required if the arc current is relatively low or if the transients to be recorded are of very short duration.

6. Amplifiers for recording discharge characteristics should be direct-coupled.

On the Radiation Patterns of Dielectric Rods of Circular Cross Section—the $TM_{0,1}$ Mode*†

C. W. Horton, F. C. Karal, Jr., and C. M. McKinney
Defense Research Laboratory, The University of Texas, Austin, Texas
(Received July 12, 1950)

The radiation patterns have been measured for five dielectric rods of circular cross section which were excited in the $TM_{0,1}$ mode. These rods were each $0.870\lambda_0$ in diameter, and the lengths were $2\lambda_0$, $4\lambda_0$, $6\lambda_0$, $8\lambda_0$, and $10\lambda_0$. The theoretical radiation patterns have been computed by means of equivalent surface electric and magnetic currents. Excellent agreement is obtained when it is assumed that the diameter of the surface on which these currents are distributed is 0.65 of the diameter of the dielectric rod. Representative experimental and theoretical patterns are shown for the full 360°.

INTRODUCTION

ONE of the authors (C.W.H.) has developed a theory[1,2] of the radiation patterns of dielectric rods based on the radiation theorems of Schelkunoff. This theory was expanded and supplemented by experimental measurements in two later papers[3,4] of which this is a continuation. This early work was applied to dielectric rods of rectangular cross section and, consequently, suffered from a lack of knowledge of the electromagnetic field components in and on the surface of the rod. In order to minimize this difficulty, the theory has been applied to rods of circular cross section which are excited in the transverse magnetic mode with radial symmetry.

The theory developed in Part I can be applied directly to this problem. It is assumed that the contributions to the surface integral over Σ arise only from the cylindrical surface $S(r=a, 0\leqslant z\leqslant l)$ shown in Fig. 1 and, to a negligible amount, from the end cap $C(0\leqslant r\leqslant a, z=l)$. One would expect that the radius a of the surface S should be equal to the radius b of the dielectric rod. it is found, on the contrary, that the agreement with experimental data is significantly improved if the radius of S is smaller than that of the rod.

In lieu of a rigorous solution to the radiation problem, it is assumed that the fields interior to and on the surface of the dielectric rod are the same as those on an infinitely long dielectric rod of the same material and diameter. In order to test the validity of this assumption, the electric field components over the surface of the radiating rod were measured with a probe.

Since the field in a radiating rod of finite length cannot be the same as that in an infinitely long rod, two factors are introduced whose variation can be used to achieve agreement between theory and experiment. One of these factors is the radius of the surface S over which the equivalent electric and magnetic currents are distributed. The other factor arises from the assumption that the amplitude of the field components is a function of the distance along the rod.

THEORETICAL DEVELOPMENT

The nature of the waves propagated along a dielectric rod of circular cross section is discussed by Stratton.[5] He shows that a dielectric rod will propagate a transverse magnetic wave of radial symmetry, provided the frequency is greater than some minimum value. It can be shown from Stratton's discussion that in the case of a nonmagnetic and lossless dielectric rod surrounded by free space, the field components inside and on the surface of the dielectric rod are given by

$$\left.\begin{aligned} E_r &= -iE_0[n_a/(n^2-n_a^2)^{\frac{1}{2}}]J_1(\lambda_1 r)\exp(ikn_a z-i\omega t)\\ E_t &= 0\\ E_z &= E_0 J_0(\lambda r)\exp(ikn_a z-i\omega t)\end{aligned}\right\}, \quad (1)$$

$$\left.\begin{aligned} H_r &= 0\\ H_t &= -i(E_0/Z_0)[n^2/(n^2-n_a^2)^{\frac{1}{2}}]J_1(\lambda_1 r)\\ &\qquad \times\exp(ikn_a z-i\omega t)\\ H_z &= 0\end{aligned}\right\}. \quad (2)$$

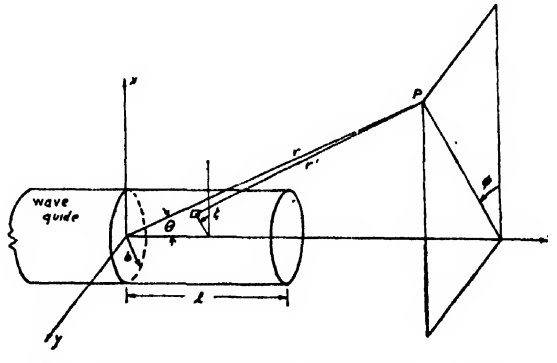

FIG. 1. The orientation of the coordinate systems with respect to the dielectric rod.

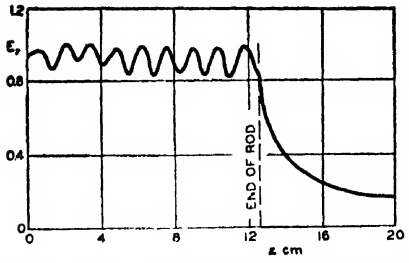

FIG. 2. The variation of the electric field component E_r with the distance along a radiating dielectric rod $4\lambda_0$ long. The mouth of the wave guide is at $l=0$.

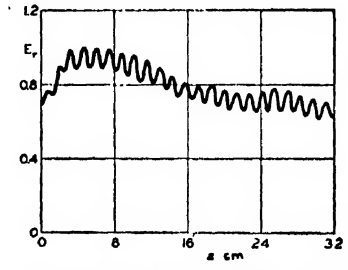

FIG. 3. The variation of the electric field component E_r with the distance along a radiating dielectric rod $10\lambda_0$ long. The mouth of the wave guide is at $l=0$.

Here, n=index of refraction of the rod material, n_a=apparent index of refraction, $k=2\pi/\lambda_0=2\pi/$free space wave-length, Z_0=impedance of free space, E_0=amplitude factor, ω=angular frequency, b=radius of the rod, and $\lambda_1=k(n^2-n_a^2)^{\frac{1}{2}}$. The apparent index of refraction, which is the ratio of the free space wave-length and the guided wave-length, is a function of the index of refraction n, the radius of the rod b, and the order of the radial mode. The value of n_a for any rod may be measured experimentally, or it may be computed from the characteristic equation.[6]

The radiation through the end C has been computed by the same method used earlier in a study of horn patterns.[7] If the dielectric rod is longer than one guided wave-length, the error introduced by neglecting the end C is not greater than 1 db at $\theta=10°$ and 1.5 db at $\theta=90°$. As the length of the rod is increased, the error caused by neglecting the end fluctuates but does not decrease because of the periodicity of the field along the rod.

When the radiation through the end C of the dielectric rod is neglected, the radiation pattern can be computed by a straightforward evaluation of a surface integral over S. The analysis is so similar to that given in Papers A and B that only the final radiation formulas are given. The integral over S reduces to the product of an integral I_1 around the circumference of S and an integral I_2 along the length of S.

In Papers A and B the possibility of radiation from standing waves as well as traveling waves was considered. The measurements of the surface fields shown in Figs. 2 and 3 show that most of the energy is found in the traveling wave. Thus the analysis of Paper B is relevant and one has for I_2

$$I_2=\frac{1}{2}\int_0^l \omega(z)\exp(iqkz)dz, \qquad (3)$$

where $\omega(z)$=a shading function arbitrarily introduced to allow for the termination of the rod, $q=n_a-\cos\theta$, and θ=angle between the axis of the rod and a line to the field point (see Fig. 1).

For the transverse magnetic wave whose components are given by (1) and (2), the components of the radiation field at a point P in the far zone are given by

$$E_r=0,$$

$$E_\theta=-(ika/2\pi r)(\exp ikr)I_2 \times\int_0^{2\pi}[Z_0\bar{H}_\zeta\sin\theta-\bar{E}_z\cos(\phi-\zeta)] \times\exp[-ika\sin\theta\cos(\phi-\zeta)]d\zeta, \qquad (4)$$

$$E_\phi=0.$$

Here the barred quantities $\bar{H}_\zeta$ and $\bar{E}_z$ are the same as the corresponding unbarred quantities except that the factor $\exp(ikn_az)$ has been split off. The components of H are easily found, since this is a transverse wave.

Since it has been found necessary to introduce a distinction between the physical radius of the rod and the radius of the equivalent surface S, one would expect

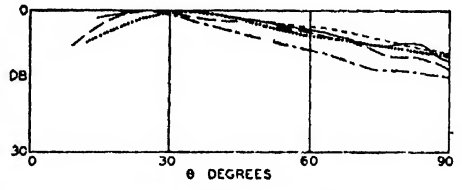

FIG. 4. The envelopes of the experimental patterns *versus* angle. — — — — $l=10\lambda_0$. ——— $l=8\lambda_0$. — — — — — — $l=6\lambda_0$. — — — — — — — — $l=4\lambda_0$. . . . . $l=2\lambda_0$.

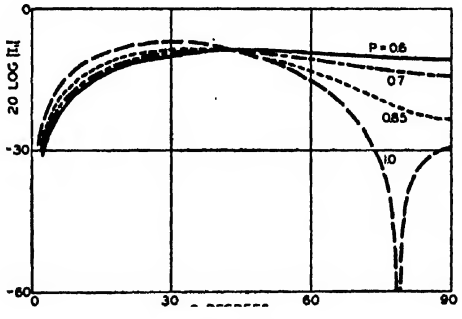

FIG. 5. The angular variation of $20\log|I_1|$ for various values of the ratio P of the radius of the surface S to the radius of the dielectric rod. The field components E_z and H_ζ are evaluated on the surface S.

[6] See reference 5, Eq. (9), p. 526.
[7] C. W. Horton, Proc. I.R.E. 37, 744 (1949).

that field components H_ξ and E_z should be evaluated on the surface S. This has been done and good agreement was obtained. However, it was necessary in this case to make the radius of the surface S smaller as the length of the rod was increased. On the other hand, if the field components were evaluated on the surface of the physical rod, a constant diameter for S is obtained for rod lengths from $2\lambda_0$ to $10\lambda_0$. Furthermore, the agreement between experimental and theoretical patterns is even better than in the first case.

When one examines (4), it is clear that the choice of the surface S on which H_ξ and E_z are evaluated is significant only in that it determines the ratio E_z/H_ξ, or, in other words, it changes the relative contribution of the magnetic currents and the electric currents to the radiation field.

When the integration is performed, one finds

$$E_\theta \propto \psi I_1 I_2, \tag{5}$$

where the constant of proportionality is immaterial for relative patterns. In Eq. (5)

$$\psi=(1/r)\exp(ikr-i\omega t),$$
$$I_1=J_0(ka\sin\theta)\sin\theta-CJ_1(ka\sin\theta), \tag{6}$$

$$C=\frac{E_z}{H_\xi}\bigg|_r=\frac{(n^2-n_a^2)^{\frac{1}{2}}}{n^2}\frac{J_0(\lambda_1 r)}{J_1(\lambda_1 r)}, \tag{7}$$

r = surface at which E_z and H_ξ are evaluated.

The integral I_2, which is defined in (3), will be discussed later. The envelope of the radiation pattern is determined primarily by I_1, while the lobe structure arises from I_2.

EXPERIMENTAL OBSERVATIONS

In order to test the equations derived in the preceding section, a series of rods of constant radius were constructed of Lucite. The diameter of each of these rods was $0.870\lambda_0$, but the lengths of the rods were $2\lambda_0$, $4\lambda_0$, $6\lambda_0$, $8\lambda_0$, and $10\lambda_0$. The rods fitted snugly in the wave guide, and the ends of the rods were terminated by a tapered section to avoid a sudden discontinuity. The index of refraction of the Lucite was measured[8] by a transmission method and a reflection method and found to be 1.60 ± 0.01.

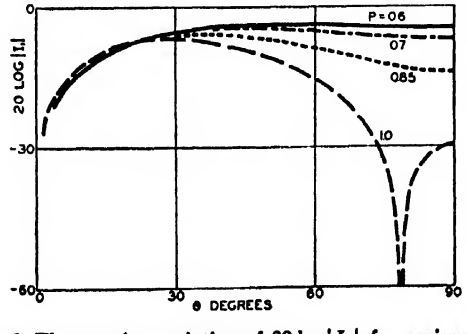

FIG. 6. The angular variation of $20\log|I_1|$ for various values of the ratio P of the radius of the surface S to the radius of the dielectric rod. The field components E_z and H_ξ are evaluated on the surface of the dielectric rod.

TABLE I. The value of the parameters d and D that yield best agreement with the experimental patterns. $b=0.435\lambda_0$; $P=0.65$.

Length l/λ_0	d	D
2	2.0	−0.5
4	1.11	−0.1
6	1.0	0
8	0.5	1.0
10	0.3	2.33

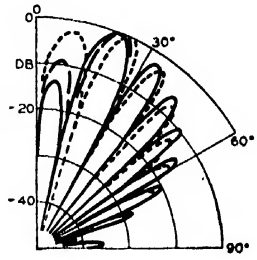

FIG. 7. An illustration of the effect of the shading factor d on the theoretical pattern. —— $d=1.0$; — — — $d=0.5$; - - - - $d=0.2$. Length of rod $=6\lambda_0$. $P=1.0$.

In the experimental pattern measurements, the dielectric rods were used as transmitters. The power source consisted of a type 723 a/b velocity modulated tube operated at a frequency of 9375 m c.p.s. or a wavelength of 3.20 cm. The $TM_{0,1}$ mode was obtained with a mode transducer. A motor-driven turntable was used to rotate the transmitting antenna through 360° in azimuth. The receiving antenna was 40 feet from the transmitting antenna, and both antennas were mounted approximately 12 feet above the roof of a three-story building. The output of the receiver was recorded on an Esterline-Angus recording milliammeter.

Figures 2 and 3 show the dependence of E_r at the surface of the rod on the distance along the rod for the rods of length $4\lambda_0$ and $10\lambda_0$, respectively. These measurements were made with a small probe while the antenna was radiating. These measurements and similar ones on the other rods of the series show low standing wave ratios. They also show that the apparent index of refraction for the series of rods is 1.163 ± 0.008. The value obtained from long rods used as wave guides is 1.175 ± 0.008. It is interesting to note that the transition from the field in the metallic guide to the field in the dielectric guide appears to be complete in a distance of approximately one or two guide wave-lengths.

THE CONTRIBUTION OF THE INTEGRAL I_1

The envelopes of the experimental patterns throughout the first 90° of the five rods are shown in Fig. 4. It appears that the envelope oscillates about a mean value that is independent of the length. Figure 5 shows a series

[8] C. G. Montgomery, *Technique of Microwave Measurements* (McGraw-Hill Book Company, Inc., New York, 1947), Chapter 10.

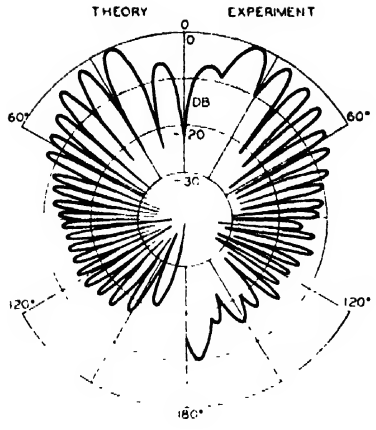

FIG. 8. The experimental and theoretical patterns of a Lucite rod $10\lambda_0$ long and $0.87\lambda_0$ in diameter.

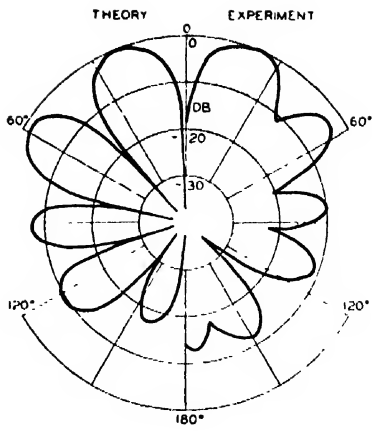

FIG. 10. The experimental and theoretical patterns of a Lucite rod $2\lambda_0$ long and $0.87\lambda_0$ in diameter.

of curves of $20\log|I_1|$ for various values of P, the ratio of the radius of the surface S to the radius of the dielectric rod; i.e., $P=a/b$. In calculating these curves, the field components E_z and H_t are evaluated on the surface S. The curves are plotted to 90° only, because the theoretical curve for I_1 is symmetric about 90°. Also, beyond 90° the influence of I_2 is so great that the behavior of I_1 alone is not significant.

Figure 5 shows that the pattern depends on the radius of the surface S qualitatively in the same way that any radiation pattern depends on a physical dimension of the source. Further, it is evident that agreement with the experimental curves shown in Fig. 4 will not be obtained unless P is less than one. In particular, it was found that if the field components were evaluated on S, the optimum values of P depended on the length as follows: $P=0.85$, 0.70, 0.65, 0.625, 0.60 for $l/\lambda_0=2$, 4, 6, 8, 10, respectively.

Figure 6 shows a plot of $20\log|I_1|$ for various values of P when the field components E_z and H_t are evaluated on the surface of the physical rod. A comparison of Figs. 5 and 6 shows that the variation of $|I_1|$ with the angle θ is less when the ratio E_z/H_t is evaluated on the surface of the physical rod than when it is evaluated on the surface S.

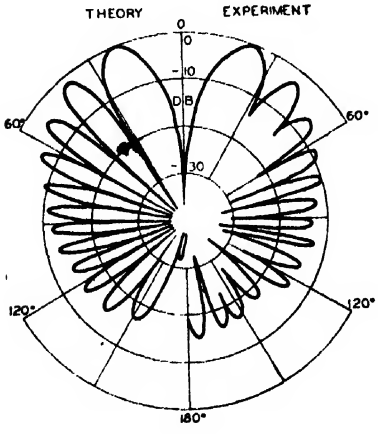

FIG. 9. The experimental and theoretical patterns of a Lucite rod $6\lambda_0$ long and $0.87\lambda_0$ in diameter.

THE VARIATION OF AMPLITUDE ALONG THE LENGTH OF THE ROD

Before one can compute theoretical patterns for comparison with theory, it is necessary to evaluate the integral I_2 defined in (3). Undoubtedly, the best method of procedure would be to determine the shading function $\omega(z)$ for each individual rod from surface measurements such as those shown in Figs. 2 and 3. However, since a very large number of patterns have been measured and computed, it is more convenient to choose a standard form for the function $\omega(z)$ and to obtain agreement with the theoretical patterns by a variation of the parameters in this function.

Mueller and Tyrell[9] have found that a function $\omega(z)$ of the form

$$\omega(z)=d+(1-d)\sin(\pi z/l), \tag{8}$$

is useful in discussions of dielectric rods. This function includes as a special case, $d=1$, the case treated in Paper B. When (8) is substituted into (3), one obtains

$$I_2=\frac{ld}{2}\left|\frac{(\pi/2)D\cos\phi}{(\pi/2)^2-\phi^2}+\frac{\sin\phi}{\phi}\right|\exp(i\phi), \tag{9}$$

where

$$\phi=(kl/2)(n_a-\cos\theta),$$
$$D=(1-d)/d.$$

The constant factor $(ld/2)$ may be ignored in a study of relative patterns.

In order to illustrate the effect of d (or D) on the pattern, three theoretical patterns are shown in Fig. 7 in which only d is changed. These patterns are computed for the rod F-4 when the radius of the surface S is equal to the radius of the dielectric rod. It is seen that the first lobe is very sensitive to the choice of d, while the third and higher lobes are not very sensitive. This conclusion is borne out by a study of the extrema of (9).

The first major lobes of the patterns result from the interaction of I_1 and I_2 and not from a maximum in either one separately. The remaining lobes are caused

[9] G. E. Mueller and W. A. Tyrell, *Bell Syst. Tech. J.* **26**, 837 (1947).

by extrema in I_2, although their exact positions are influenced by the behavior of I_1. This interaction is significant in the rods $2\lambda_0$ and $4\lambda_0$ long, but when the rod is $6\lambda_0$ or more in length, the angular positions of the lobes agree with the extrema of $(\sin\phi)/\phi$ within the limits of experimental error.

THE THEORETICAL PATTERNS

When the values of d (or D) are adjusted to give best agreement with the experimental data, one finds the values listed in Table I. The values are based on the assumption that the electromagnetic field components are evaluated on the surface of the rod but that the radius of the surface S is only 0.65 of the radius of the rod.

Theoretical patterns for all the rods were computed by means of (5) on the basis of the assumptions just mentioned and for the values of d shown in Table I. The excellence of the agreement is illustrated in Fig. 8 which shows on the right the experimental pattern of a rod $10\lambda_0$ long and on the left the theoretical pattern computed by means of (5). Figures 9 and 10 show similar patterns for rods $6\lambda_0$ and $2\lambda_0$ long, respectively.

SUMMARY

In view of the accurate knowledge that one has of the distribution of the field components in a dielectric rod of circular cross section, the formulas developed in this paper apply to any length of rod unless the rod is so short that the effect of the end cannot be neglected. This is in pleasing contrast to the work in Paper A in which the theory failed for rods longer than $6\lambda_0$. The difficulty with the height of the minor lobe encountered in Fig. 6 of Paper A has vanished also.

Precision Determination of the Lattice Constants of Zinc Oxide

R. B. Heller, J. McGannon,† and A. H. Weber
Physics Department, Saint Louis University, St. Louis, Missouri
(Received June 12, 1950)

A total of 350 back-reflection ZnO powder x-ray diffraction lines on 25 photographic films have been measured and analysed by the Cohen analytical least squares extrapolation method to yield $a=(3.2495\pm0.0000_3)$A, $c=(5.2069\pm0.0001_1)$A; where the stated errors are the probable errors. The statistical reliability of the results is emphasized.

In the measurement of the Debye-Scherrer ring radii the accuracy obtained with a metric scale and indicator (employing no optical lens system) and with a dividing engine equipped with a microscope are compared and the former simpler method is found more reliable. It is concluded that the use of precision measuring instruments for observing diffraction ring radii are unnecessary and even undesirable apparently because the magnifying power of the optical system of precision micrometers leads to uncertainties in settings on photographic lines.

THE Cohen analytical extrapolation method[1] has been applied to twenty-five powder photographs of ZnO in the back-reflection region using Cu $K\alpha$ x-radiation employing the Straumanis technique.

The specimen was granulated ZnO powder* of purity better than 99.85 percent. The powder was ground and sifted through a 200-mesh screen to insure some uniformity of fragment size. It was packed into an enamel tube (0.025-in. diameter, 0.5-in. length). This cylindrical specimen holder is the coating of magnet wire,** sleeved off by stretching the wire. The specimen was then carefully centered in a Debye camera (57.296-mm radius) and exposed to x-rays. The Debye-Scherrer rings were measured to 0.005 in. with a metric scale.

From each of the twenty-five photographs data were recorded for a total of fourteen lines, using reflections of the $K\alpha_2$ and $K\alpha_1$ radiations. The procedure was to convert all $K\alpha_2$ reflections to the equivalent $K\alpha_1$ reflection by multiplying $\sin^2\theta$ by $(\lambda K\alpha_1/\lambda K\alpha_2)^2$. The values[2] of Cu wave-lengths ($\lambda K\alpha_1=1.54050$A, $\lambda K\alpha_2=1.54434$A) recommended by the American Society for X-ray and Electron Diffraction were used.

Data taken from one of the films are shown in Table I. $\Phi'=(\pi-2\theta/2)$ is one-half the back-reflection angle and θ is the Bragg angle. The results for the twenty-five films are shown in Table II. The stated error is the probable error of all the determinations.

To determine the effect of measuring a greater number of significant figures in the Debye-Scherrer radii, a dividing engine reading to 0.00025 cm was employed for remeasuring of the same twenty-five films. Because of the limited length of the dividing engine scale, the Straumanis method could not be employed. Instead, a constant R, obtained by calibrating the camera with NaCl, was used. The application of the Cohen method yields: $a=(3.24892\pm0.00008)$A and $c=(5.20489\pm0.00037)$A. The spread for a is 0.00244A and that for c is 0.01245A. Note that the spread here is greater than that of the results shown in Table II.

3.2494	5.2063
(mean) 3.2495A	(mean) 5.2069A

$a=(3.2495\pm0.00002)$A,
$c=(5.2069\pm0.00011)$A.

To determine whether this larger spread is due to employing a constant R (not using the individual calibration of the Straumanis method) or to greater uncertainties in the dividing engine readings, five of the twenty-five films were analyzed in the following manner. The Debye-Scherrer radii measurements of the second method (employing dividing engine) were combined with the Straumanis calibration for camera radius data available from the first method. The results of this procedure are $a=3.24877$A with a spread of 0.00127A and $c=5.20549$A with a spread of 0.00414A. The values of a and c determined from the same five films using the second method (dividing engine and constant R) show a spread in a of 0.00125A and a spread in c of 0.00415A. These almost identical results show definitely that the uncertainties in setting the dividing engine, not the small variation in R, are responsible for the original larger spread of the second method. Therefore, a practical conclusion is that the use of a precision measuring instrument, such as the dividing engine, for measuring Debye-Scherrer ring radii is not necessary and is even undesirable apparently because the magnifying power of the optical system of precision micrometers leads to uncertainties in settings on the photographic lines.

Bunn's values[3] for a and c (obtained by the Bradley-Jay graphical extrapolation method, not the Cohen analytical method) corrected for the wave-lengths here employed are: $a=(3.2492\pm0.0001)$A and $c=(5.2054\pm0.0003)$A. It is seen that the present Table II results are somewhat larger than those of Bunn. As originally observed and explained by Bunn,[3] in the present work the error in c is larger than the error in a. It is pointed out that in the present work a total of 350 back-reflection lines were measured and therefore the statistical reliability should be good.

The Virtual Mass of a Sphere Entering Water Vertically*

ALBERT MAY AND JEAN C. WOODHULL
Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland
(Received June 23, 1950)

The manner in which a sphere behaves when it enters the water from air depends on the rate at which energy is taken from it, and most of this energy is utilized in setting water into motion. The virtual mass is a partial measure of this motion. An investigation of virtual mass for spheres shortly after vertical water entry is described. The spheres used had specific gravities between 1.06 and 16.77 and impact velocities ranged from 21 to 103 ft./sec. The value of the virtual-mass coefficient was found to be much smaller than had previously been estimated, an average value of 0.08 being obtained. The method used recognizes the dependence of C_D on sphere speed and depth, and makes comparisons only where these parameters have the same value.

INTRODUCTION

THE concept of virtual mass is well known[1] in its application to the motion of a body completely immersed in a fluid. It arises from the fact that when a body moves through a fluid a quantity of fluid shares in the motion of the body. When the body is accelerated, this virtual mass (or "apparent additional," "induced," or "dragged" mass) must be accelerated also, and the body accordingly behaves approximately as though its mass were increased by an amount equal to the virtual mass.

The virtual-mass concept is useful, but not necessary, in the mathematical treatment of such problems as the accelerated motion of a completely immersed body. When this concept is used the assumption is made that the drag force, dependent on the speed but not on the acceleration, acts on both the moving body and on the entrained mass of water. In other words, the entrained water is treated as if it were a part of the moving body and the effective forces are those which act on their combined masses. This viewpoint has been used in the present report. Alternatively, attention could be focused on the actual forces (e.g., drag) acting on the sphere alone. For accelerated motion the magnitude of such forces would depend on the amount of water entrained by the body. Hence from this second viewpoint the drag coefficient is a function of the acceleration of the body, but the drag forces act totally on the sphere itself.

If potential flow is assumed, computation for a completely immersed sphere moving through a fluid shows the increase of mass to be one-half the mass of the displaced fluid.[2] This result is reasonably verified by experiment.[3]

The drag which a body experiences when it moves in a fluid is not measured directly but is deduced from the acceleration. Generally it is expressed in terms of the drag coefficient C_D which is defined by the relation,

$$\text{drag}=\tfrac{1}{2}\rho v^2 A C_D, \tag{1}$$

where ρ is the density of the fluid, and v and A are the speed and cross-sectional area of the missile.

The equation of motion of a body moving through a fluid may be written

$$-(1/v^2)dv/dt=d(1/v)/dt=\alpha, \tag{2}$$

where the retardation coefficient α is constant or variable, depending upon the conditions under which the body is moving. Obviously from Eq. (2), if $1/v$ is plotted against t, the slope of the graph will be α. To study the drag at water entry[4] high-speed motion pictures are taken of the entry, time and position data are read from the film, and instantaneous values of speed are obtained from increments of distance and time. Next a graph is drawn of reciprocal speed against time and from its slope α is obtained.

So far the analysis has been entirely kinematic. Since α is a measure of the acceleration, its value, of course, depends on the mass of the sphere, but it is uniquely determined by position-time data and does not depend on the viewpoint that is chosen in regard to the mass of the moving body, that is, whether it is taken as the mass of the body alone or this increased by the virtual mass.

The mass of a homogeneous body may be written as $V\sigma\rho$, where V is the volume of the body, σ its specific gravity relative to water, and ρ the absolute density of water. When the body is moving in water the mass of entrained water may be written $kV\rho$, where k is a proportionality constant which will be called the virtual-mass coefficient. This coefficient has also been known as the "induced mass factor" and the "relative apparent mass." The total mass accelerated is therefore $(\sigma+k)V\rho$.

From Eq. (2) the acceleration is αv^2. Hence,

$$\text{drag}=(\sigma+k)V\rho\alpha v^2. \tag{3}$$

Suppose that two spheres differing only in specific gravity are moving vertically downward at the same speed. If it is assumed that the drag force is the same

TABLE I. Measured specific gravities of ½-inch spheres used.

Material	Specific gravity
Polystyrene	1.06
Magnesium	1.79
Steel	7.76
Tungsten	16 77

for the two spheres, and that it acts both on the sphere itself and on the added mass of the entrained water, then

$$\text{drag}=(\sigma_1+k)V\rho\alpha_1 v^2=(\sigma_2+k)V\rho\alpha_2 v^2, \qquad (4)$$

where the subscripts 1 and 2 refer to the lighter and heavier spheres, respectively. From Eq. (4) we may write

$$k=\frac{\sigma_2\alpha_2-\sigma_1\alpha_1}{\alpha_1-\alpha_2}. \qquad (5)$$

The experiment just outlined furnishes one of the principal means of investigating virtual mass.

DETAILS OF THE METHOD

In the present paper, calculations of virtual mass will be given only for the vertical water entry of spheres and in particular for that phase which immediately follows the actual entry, during which an air-filled cavity is still attached to the sphere. Previous determinations of virtual mass for this case have been made in an attempt to systematize the empirical data of water entry but have apparently been described only in literature which was restricted in distribution for reasons of national security. A value of 0.40 or 0.45 was generally reported for k. The values of α (or C_D) from which these determinations were made were not comparable in precision with values obtainable today.

Numerous improvements in method were found desirable or necessary in the course of the present work. In the determinations of α that we reported previously,[4] values of $1/v$ were plotted against t and the slope of a least-square straight line through these points was taken as the value desired. The accuracy has now been improved sufficiently to justify replacing this straight line by a curve which yields instantaneous values of α.

When Eq. (5) is used for determining the virtual-mass coefficient it is assumed that the same drag acts on the two spheres used. Forces which are not hydrodynamic in nature should preferably be eliminated but it is sufficient that they be the same for the two spheres. In obtaining values of k from Eq. (5), we have always compared two spheres when the speed and depth of the spheres were the same and their cavities had the same pressure. Further, as will be discussed later, the contribution of weight to the total force on the sphere was removed mathematically.

Each determination of k was made from the water entry of a pair of half-inch spheres: one of steel or tungsten and the other of polystyrene or magnesium. The measured specific gravities of these spheres are given in Table I. The choice of such a pair depends on the fact that if two shots are so chosen that the entry speed of the lighter is slightly greater than that of the heavier, corresponding points can always be found in the two trajectories where the depths and speeds are the same. The choice of such conditions prevents the drags differing because of different speeds and should result in reasonably equal hydrostatic buoyant forces on the two spheres.

The effect of cavity pressure was removed by reducing the air pressure above the water, thus preventing surface closure of the cavity.[5] The cavities obtained and the considerable difference in cavity formation for light and heavy spheres can be seen in the photographs of Fig. 1. These were taken 26 milliseconds after the ½-inch tungsten and polystyrene spheres had entered the water at 63 ft./sec. The tungsten sphere had reached about three times the depth of the polystyrene sphere and was traveling about three times as fast. At shallower and equal depths the cavities are much more alike than those of Fig. 1. This is important since different

cavity shape means a different flow pattern and probably different drag.

In writing Eq. (2) the effect of gravity was omitted. Instead, it may be written

$$d(1/v)/dt = -g/v^2 + \alpha. \tag{6}$$

It is seen from Eq. (6) that the slope of the $1/v$ against t graph is $-g/v^2+\alpha$. The effect of gravity can be eliminated and α determined, by adding g/v^2 to the slope of the graph at any desired point. This correction of α effectively eliminates the weight which otherwise would make large and considerably different contributions to the drag of the light and heavy spheres.

RESULTS

High-speed motion pictures were taken of numerous shots of each of the spheres listed in Table I at various entry speeds from 21 to 103 ft./sec. Position-time data were read from each film, values of $1/v$ were plotted against t, and a smooth curve was drawn. By comparing each shot of a dense sphere with each suitable shot of a light one, the corresponding positions were found where the speed and depth of the spheres were the same. The slopes of the $1/v$ against t graphs were read at these points and values of α were obtained by adding g/v^2 to the slopes. Finally k was found by means of Eq. (5).

The values found for k and related information are given in Table II. These values for k range from −0.04 to 0.16. Negative values are surely meaningless but may give some indication of the accuracy attainable. It should be noted especially that the values here reported for k are considerably smaller than the values of about 0.45 previously obtained by others. A small part of this difference may be due to the low ambient pressure used in the present work. This changes the cavity shape and hence the flow pattern, and may change the virtual mass slightly.

An attempt was made to determine whether the variations of k shown in Table II were due to variations of depth or of instantaneous velocity, by plotting the k values against these quantities as coordinates in Fig. 2. Nothing significant appears in this presentation.

In studying the self-consistency of the data, the scatter of the data will appear worst if all variation of k is regarded as due to experimental error, rather than to dependence of k on experimental parameters. On this basis the data yield a mean value of 0.08 for k and a standard deviation of 0.06.

It should be noted that the average value of k obtained by use of polystyrene spheres was twice that for the magnesium spheres: 0.109 for polystyrene, 0.054 for magnesium. The reason for this is not known.

An interesting view of the virtual-mass coefficient may be obtained by a method which requires that random errors in determining the values of α be more important than actual variations in the value of α. Suppose that $1/v^2$ times the drag, in Eq. (4), is negligibly dependent on sphere density, depth and speed. Then, since the expression in Eq. (4) has the same value for either subscript 1 or 2, this subscript can be written as i,

and Eq. (4) becomes:

$$\alpha_i\sigma_i + k\alpha_i = \text{constant}. \tag{7}$$

If $\alpha_i\sigma_i$ is plotted against α_i, Eq. (7) shows that a straight line should be obtained, of slope $-k$. The data of Table II are plotted in Fig. 3, but no attempt has been made to draw in this line for the determination of k, because of the large spread in the data. Instead groups of straight lines are seen drawn transverse to the principal extension of the data. Each of these lines represents the spread of data obtained from one water entry and the individual values of α from Table II are shown as dots on these lines. To determine k it would be possible to draw straight lines which lie within the range of values plotted for all materials. They would give k values between 0.07 and 0.13.

DISCUSSION

The reasons why the value of virtual mass obtained for the cavity phase of vertical water entry is so small can best be understood by considering the significance of virtual mass as it occurs in various idealized hydrodynamic problems.

For potential flow about a completely immersed body, with no attached cavity, energy is conserved and the drag is zero. The fluid surrounding the body has at each point a speed which is proportional to that of the body, and the body is in "immediate" communication with all of the water affected by the body's motion. When the speed of the body changes, the speed of each particle of the water changes proportionately. The virtual mass is that mass of the fluid which would have a kinetic energy equal to the actual kinetic energy of the fluid if this mass had the same speed as the body, or $(\int v^2 dm)/v_s^2$, where v is the speed of the fluid at any point and v_s is the speed of the body at the same instant. For this situation all the water which is in motion contributes in some degree to the virtual mass.

Let us now determine the virtual mass by subjecting the completely immersed body to an imaginary acceleration. The speeds of all water particles will be changed proportionately and the total work done by the accelerating force will be that done in changing the speed of the combined mass; mass of the sphere plus virtual mass.

Next let the proposed experiment be repeated with two bodies that differ only in specific gravity, and arrange that the total forces are the same on the two bodies (disregarding gravity, whose influence can be removed mathematically). The accelerations will be different for the two bodies. From the accelerations the virtual mass can be calculated. The experimental tests described in this report were of this type except that cavities were attached to the bodies.

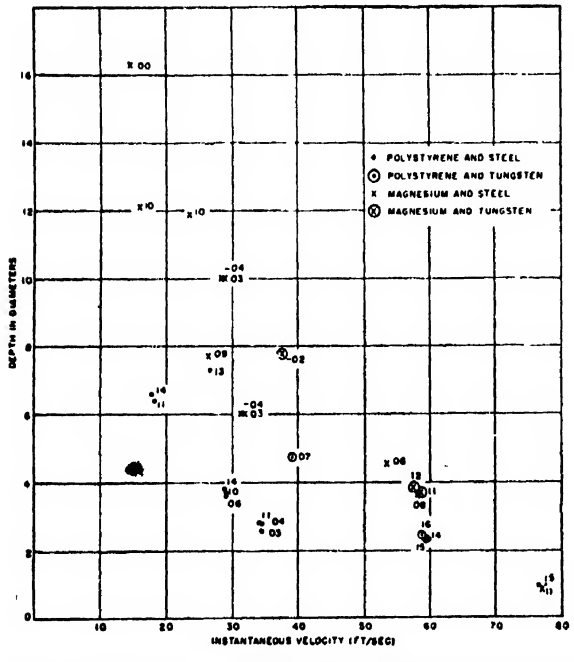

FIG. 2. Virtual-mass coefficient for vertical water-entry of spheres. Values (in percent) are plotted against the depth of the sphere and its velocity, at the instants for which the values were determined.

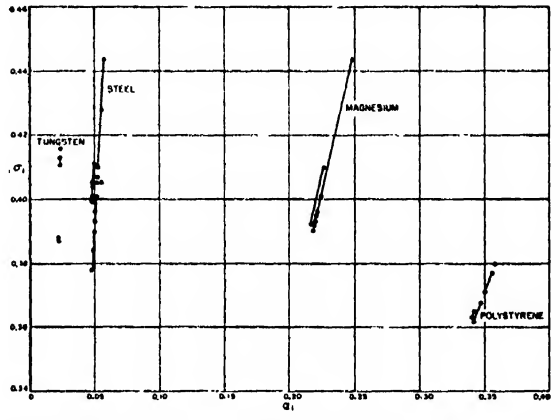

FIG. 3. Plot for the determination of virtual-mass coefficient on assumption that it has a single fixed value. The value required would be the negative of the slope of a straight line (not shown) passing through the center of several groups of points.

Before discussing the case of the water-entry cavity it is instructive to consider the steady-state cavity behind an obstacle in a water tunnel. One important difference between this case and the case of potential flow without a cavity is the absence of liquid immediately behind the body. There are still forces on the rear of the body due to water vapor and perhaps air in the cavity, but the "immediate" connection between the body and much of the water which it affects has disappeared. If the water throughout the tunnel were given a sudden increment of speed, water surrounding after-portions of the cavity would not be informed of the change of relative velocity between the water and the body for an appreciable time. The transverse diameter of any section of the cavity, therefore, depends not

so much on the present relative speed between body and water, as on the relative speed when that cross section of water was traversing the body's nose. (This effect is evident in the water-entry case shown in Fig. 1 where the diameters of the two cavities are nearly the same at the water surface because the speeds of entry were the same, and in spite of the greatly different speeds that existed later.) Because of this effect the virtual mass associated with steady-state cavity flow will be small.

Water which is set into motion by the body and is then without hydrodynamic contact with it, contributes to the drag but not to the virtual mass. It is evident from the geometry of the cavity that only a small amount of the water pushed out of the way by a body followed by a cavity, remains in hydrodynamic communication with the body, and this means simply that the virtual mass is small. While the cavity phase of water-entry is more difficult of treatment it is reasonable that it should have a virtual mass similar to that of the water-tunnel cavity.

CONCLUSION

The values reported here for virtual mass in the cavity phase of water-entry are small and show large percentage fluctuations. No systematic trends in the data and no reasons for the fluctuations have been found. However, it is not surprising that the small value of virtual mass should vary considerably because of the transient and variable character of the motion.

Because its magnitude is small and variable it appears improbable that virtual mass can help greatly in systematizing the data from water-entry experiments.

ACKNOWLEDGMENTS

The authors wish to express their indebtedness to members of the Hydroballistics Division, especially to Dr. J. Howard McMillen for stimulating discussions during the progress of this work, and to Mr. D. J. Milano who carried out the experimentation; also to Mr. Noel R. Corngold for his assistance in analyzing the data and to Professor Garrett Birkhoff for his many helpful discussions.

Plastic Flow of Platinum Wires

R. P. Carreker, Jr.

Research Laboratory, General Electric Company, Schenectady, New York

(Received June 16, 1950)

The strain-time behavior of annealed platinum wires at constant stress and temperature is reported for a wide range of experimental conditions, namely: 1550 to 78°K, 900 to 40,000 p.s.i., 0.001 to 0.1 strain, 10^{-1} to 10^{-6} min.$^{-1}$ strain rate.

The following relations were found to describe the results satisfactorily:

$$\sigma = A\dot{\epsilon}^n|_{\epsilon,T}; \quad \sigma = Be^{pT}|_{\epsilon,\dot{\epsilon}},$$
$$\epsilon = Ct^a|_{\sigma,T}; \quad \frac{\partial n}{\partial T} = \frac{\partial p}{\partial \log\dot{\epsilon}}\Big|_{\epsilon},$$
$$Q \sim \log\sigma|_{\epsilon};$$

where σ = stress, ϵ = strain, $\dot{\epsilon}$ = strain rate, T = absolute temperature, Q = activation energy for rate of deformation, t = time, and A, B, C, a, n, and p are constants.

INTRODUCTION

THERE is a paucity of good experimental data on the resistance to plastic deformation as a function of the amount, temperature, and rate of the deformation. Many experiments pertaining to deformation are reported in the literature, but surprisingly few data exist for which tests were performed on a single material with a definite prior history, under definitely stated and controlled conditions, over a sufficiently wide range of rate and temperature to be useful in formulating and testing theories of deformation.

This paper reports the results of a study of the strain-time behavior of a pure metal as a function of stress and temperature. The tests were of the short-time variety, lasting from a few seconds to several days.

MATERIAL

In view of the large number of identical specimens required, small wire specimens seemed appropriate. All specimens were taken from the same length of 99.98+ percent platinum[1] wire, which was cold-drawn through diamond dies from 0.020 to 0.015 in. diameter. After mounting in the testing equipment each specimen was annealed *in situ* for 10 min. at 1670°K by passing a predetermined electric current through the wire. This treatment produced a grain size of two to four grains per cross section.

TESTING EQUIPMENT

The testing apparatus was obtained from S. Dushman, of this Laboratory. A description of its original form has been published.[2] Extension of the wire specimen permits the movement of a grating parallel to a similar stationary grating, modulating a light beam

[1] Spectrographic analysis indicated traces (<0.01 percent) of Fe and Pd.

[2] Dushman, Dunbar, and Huthsteiner, J. App. Phys. 15, 108 (1944).

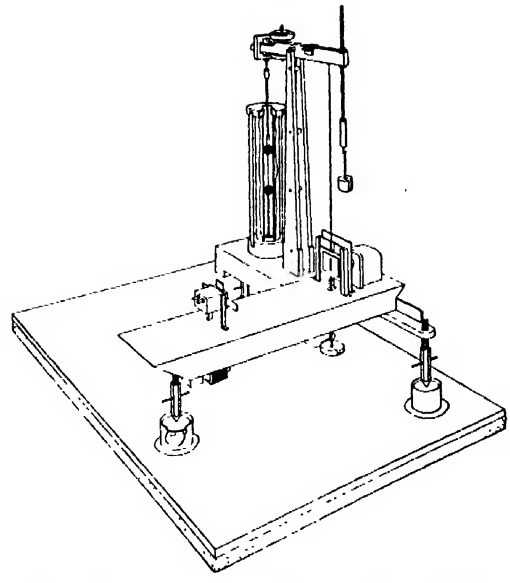

FIG. 2. Creep test equipment used between 300 and 1200°K.

striking a photo-cell. A change in light intensity from a minimum to a maximum corresponds to a grating displacement of 0.004 in. This system necessarily records only time-dependent strain.

Figure 1 shows the apparatus, as modified for use at temperatures above approximately 1200°K. In this arrangement the specimen is in the shape of a "V," supported at each end and loaded at the vertex. The specimen is heated internally by an electric current. Temperature of the specimen was indicated by a galvanometer which was activated by a photo-cell. The galvanometer was calibrated using an optical pyrometer as a secondary standard, correcting for emissivity and transmission effects. A black screen, not shown in Fig. 1, surrounded the glass test chamber, eliminating light from sources other than the specimen. Temperature control was achieved by bringing the specimen to the desired temperature, noting the reading of the indicating galvanometer, and manually adjusting the input voltage to correct any temperature change. Control within ± 10°K was attained.

Figure 2 shows the equipment as modified for use in the range 300 to 1200°K. A straight wire specimen was used, heated by a surrounding electric furnace that was controlled within ± 5°K by a Bristol potentiometer controller.

A liquid nitrogen bath was used to obtain the testing temperature of 78°K. In this case an insulated tank replaced the furnace of Fig. 2. Care was taken to maintain a constant bath level during each test. Temperatures were maintained within five degrees of the boiling point of liquid nitrogen, 78°K.

The choice of platinum as the specimen material eliminated the problem of oxidation at high temperatures. Pure dry nitrogen was passed through the furnace to increase the useful life of the stainless steel grips used with the straight wire specimens. The "V"-type specimens were tested in air.

CONSTANT STRESS

Two devices were used to maintain constant stress. The initial vertex angle of the "V" specimen was chosen to be 93°, so that constant stress was automatically maintained within 0.5 percent as the specimen elongated and the vertex angle became more acute.[3] The straight wire specimens were loaded through the bent lever shown in Fig. 2, whose dimensions were chosen to maintain constant stress within 0.2 percent as the specimen elongated.[4] Neither of these methods maintains constant stress after necking begins.

TESTING PROCEDURE

A. High Temperature "V"-Type Specimen

The specimen was mounted in the grips so that the distance between leg extremities was 20 cm. After annealing, the temperature was adjusted to the proper testing temperature by regulating the current flowing in the specimen. The load was placed on a weight pan hanging beneath the movable grating; a long, hooked wire (stainless steel 0.100 in. diameter) was then attached to the top of the movable grating and the hook lowered into the vertex of the "V." The displacement of the vertex was recorded as a function of time.

B. Straight Wire Specimens

The specimen was mounted between appropriate grips to give a gauge length of 3.0 in. The specimen and

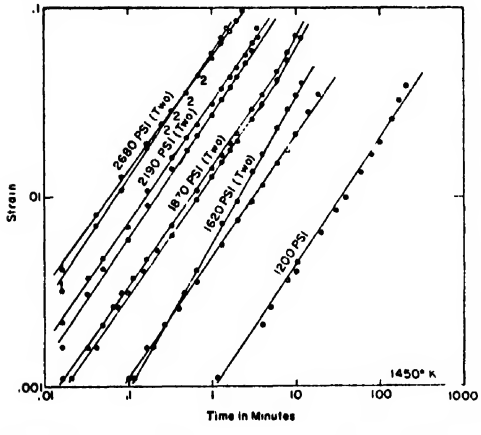

FIG. 4. Plastic strain of platinum as a function of time.

grips were lowered into the uniform temperature zone of the furnace, the lower grip securely fastened, and the upper grip attached to the constant stress lever. The position of the lever was such that no force was exerted on the specimen at this time. Electrical leads were fastened temporarily to the upper and lower grips for the annealing treatment. After removing the electrical leads from the specimen grips, the furnace (or tank) was brought from room temperature to the testing temperature. The selected load was then applied to the lever arm. Elongation of the specimen was recorded automatically as a function of time.

EXPERIMENTAL RESULTS

Several tests at different stresses were made at each of the following temperatures: 1550, 1450, 1350, 1250, 1100, 950, 850, 750, 650, 550, 450, 300, and 78°K. The experimental data are presented as plots of log time-dependent strain *vs.* log time in Figs. 3 to 15, each figure presenting the data obtained at a particular temperature.

Short-time points are absent in the data taken at 1550°K. In this series the specimens were first loaded at room temperature and the heating current then applied. The recorded movement was corrected for total thermal expansion. A short time elapsed before temperature equilibration was attained. Thus, this technique did not give satisfactory results during the first few seconds of the test. The 1550°K data have been included for their value at large strains. At all other temperatures the specimens were at temperature prior to loading.

In general, the log strain *vs.* log time plots are straight lines or approach straight lines at times in excess of one minute. The departures from linearity at short times are probably due to the difficulty in establishing the zero of time-dependent strain. This error is particularly noticeable at small strains and at times comparable with that required to apply the load to the specimen, approximately 1 to 2 sec. The error is negligible at strains greater than 0.01 and times greater than 1 min.

ANALYSIS OF EXPERIMENTAL RESULTS

The slopes of the log strain *vs.* log time plots, at strains not appreciably influenced by the zero error, depend strongly on temperature but are insensitive to

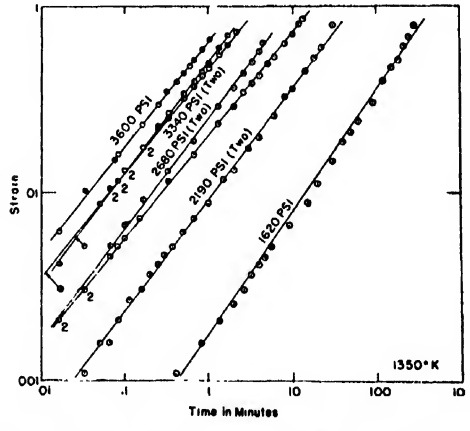

FIG. 5. Plastic strain of platinum as a function of time.

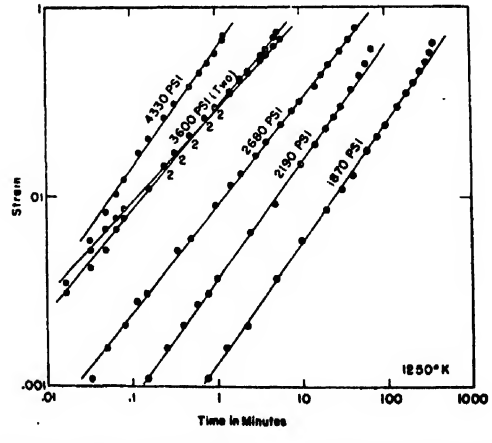

FIG. 6. Plastic strain of platinum as a function of time.

stress. These slopes have been plotted *vs.* temperature in Fig. 16. Figures 3 to 16 suggest the equation[5]

$$\epsilon = Ct^a,$$

where a is a number which apparently approaches 1.0 at the melting point and is small but positive at 0°K.

Consider the strain rates $\dot{\epsilon}$ of the various strain-time curves, at a particular value of the strain ϵ, as a function of the stress σ. At a strain of 0.01, the data from Figs. 3 to 15, when plotted as log stress *vs.* log strain rate, give the family of straight lines shown in Fig. 17, each line representing the results obtained at a particular temperature. Straight-line plots obtained in this manner imply that the relationship between stress and strain rate is of the form $\sigma = A\dot{\epsilon}^n|_{\epsilon, T}$. There is some scatter, but the trends are well established. Similar families were obtained by considering the results for strains equal to 0.005, 0.01, 0.02, and 0.03.

Consider the relationship between temperature and the stress necessary to produce a given strain rate at a given strain. The necessary data were obtained from Fig. 17 and plotted in Fig. 18. Log stress is linear in temperature, with some uncertainty below 450°K. Similar plots were obtained at strains of 0.005, 0.01, 0.02, and 0.03.

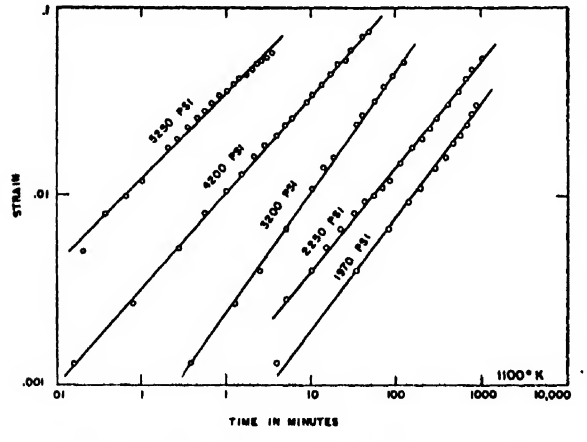

FIG. 7. Plastic strain of platinum as a function of time.

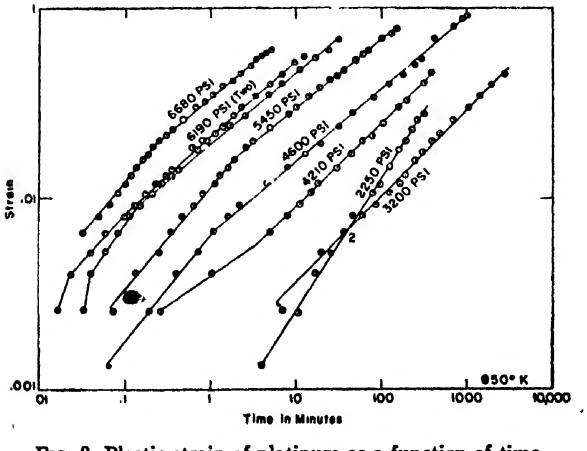

FIG. 8. Plastic strain of platinum as a function of time.

[5] The following notations are used throughout this analysis: t = time. σ = stress = applied force ÷ instantaneous area. ϵ = natural strain = $\ln(l/l_0)$. $\dot{\epsilon}$ = strain rate. T = absolute temperature. $e = 2.718 \cdots$. A, B, C, a, n, and p = constants.

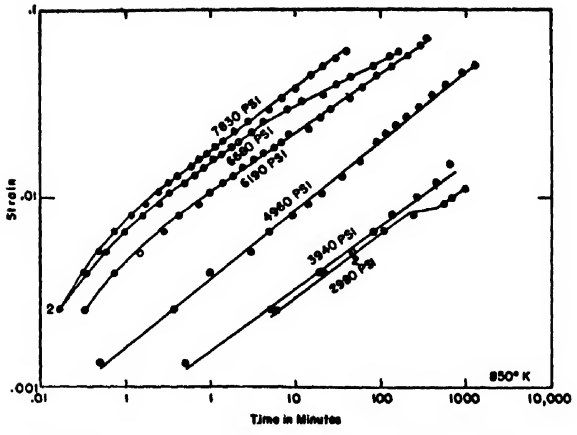

FIG. 9. Plastic strain of platinum as a function of time.

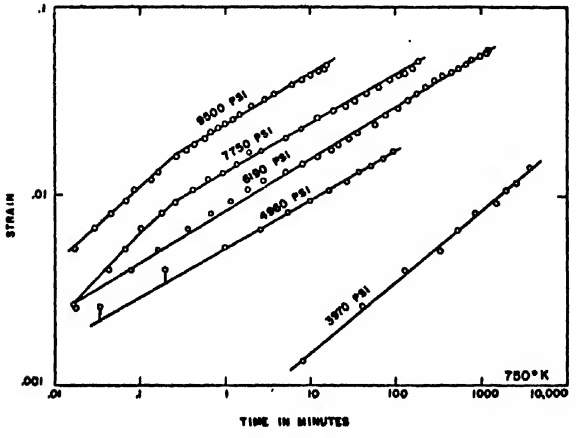

FIG. 10. Plastic strain of platinum as a function of time.

From consideration of Figs. 17 and 18, the following equations may be written:

$$\log\sigma = \log A + n\log\dot{\epsilon}|_{\epsilon, T} \tag{1}$$

and

$$\log\sigma = \log B + pT|_{\epsilon, \dot{\epsilon}}. \tag{2}$$

Previous research[6] has established the relation

$$\log\sigma = \log K + m\log\epsilon|_{\dot{\epsilon}, T}. \tag{3}$$

If it is assumed that stress is a point function of strain, strain rate, and temperature, one may write

$$d\log\sigma = \frac{\partial\log\sigma}{\partial\log\epsilon} d\log\epsilon + \frac{\partial\log\sigma}{\partial\log\dot{\epsilon}} d\log\dot{\epsilon} + \frac{\partial\log\sigma}{\partial T} dT, \tag{4}$$

or

$$d\log\sigma = m\,d\log\epsilon + n\,d\log\dot{\epsilon} + p\,dT. \tag{5}$$

[6] J. H. Hollomon, Metals Tech. 162, 268 (1945).

It is then possible to obtain analytically the general solution of Eq. (4).[7] Lubahn[8] has geometrically derived a general equation $\sigma=f(\dot{\epsilon}, \epsilon, T)$ using the relationships expressed in (1) and (3) and an expression for the activation energy for the deformation process. His equation may be written in the form

$$\sigma=CG^{T}(\dot{\epsilon}/\dot{\epsilon}_0)^{DT}e^{(E+E'T-FT\ \ln\dot{\epsilon}/\dot{\epsilon}_0)}, \qquad (6)$$

where C, G, $\dot{\epsilon}_0$, D, E, E', and F are constants. It should be noted that Eq. (6) includes the term $E'T$ which was omitted through a typographical error in the last equation of reference 8.[9] This equation is identical with that Leschen obtained analytically by the method of the exact differential and Eqs. (1) to (3).

The following relationships are obtained by differentiating the general equation (6). These relations offer alternative methods of determining the material constants from experimental data.

$$\frac{\partial^2 \log\sigma}{(\partial \log\dot{\epsilon})(\partial \log\epsilon)}=\frac{\partial m}{\partial \log\dot{\epsilon}}=\frac{\partial n}{\partial \log\epsilon}=-FT, \qquad (7)$$

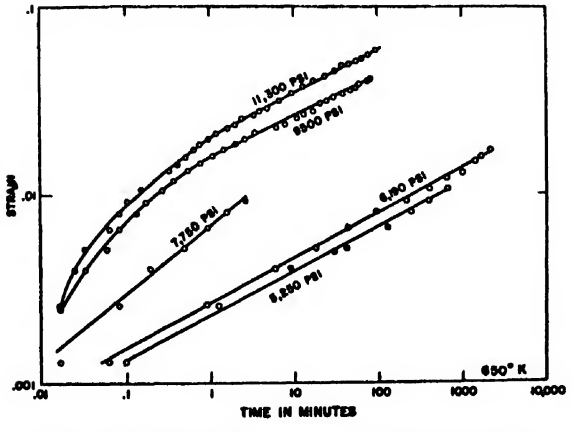

FIG. 11. Plastic strain of platinum as a function of time.

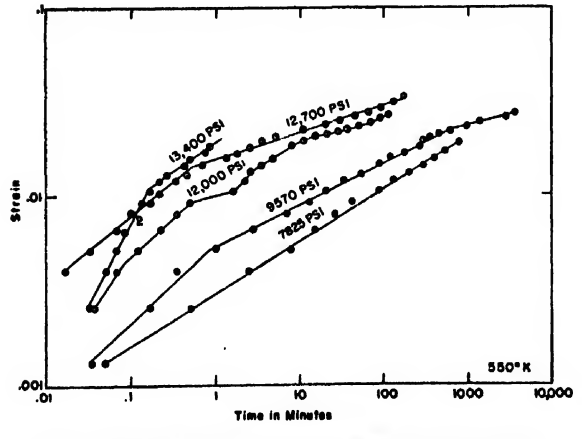

FIG. 12. Plastic strain of platinum as a function of time.

[9] C. Zener (private communication).

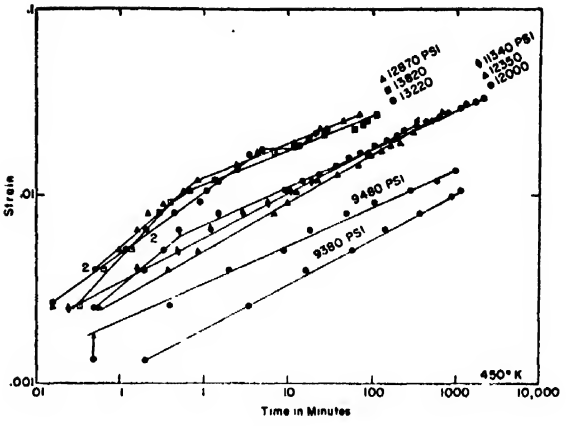

FIG. 13. Plastic strain of platinum as a function of time.

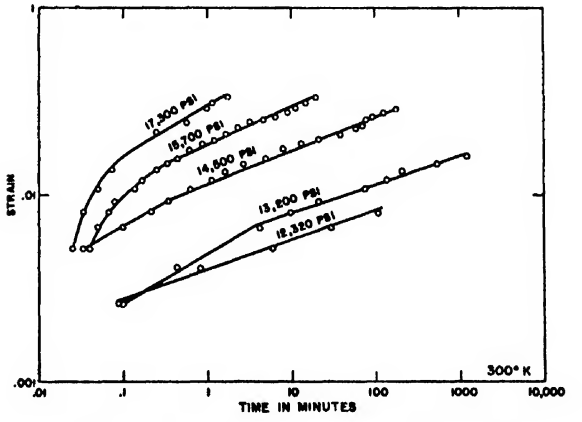

FIG. 14. Plastic strain of platinum as a function of time.

$$\frac{\partial^2 \log\sigma}{(\partial T)(\partial \log\dot{\epsilon})}=\frac{\partial n}{\partial T}=\frac{\partial p}{\partial \log\dot{\epsilon}}=D-F\log\epsilon, \qquad (8)$$

$$\frac{\partial^2 \log\sigma}{(\partial T)(\partial \log\epsilon)}=\frac{\partial m}{\partial T}=\frac{\partial p}{\partial \log\epsilon}$$

$$=E'-F\log\left(\frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right), \qquad (9)$$

$$\frac{\partial^3 \log\sigma}{(\partial \log\epsilon)(\partial \log\dot{\epsilon})(\partial T)}=-F. \qquad (10)$$

Values of $\partial n/\partial T$ and $\partial p/\partial \log\epsilon$ may be obtained at constant values of strain. Values of n may be obtained from the slopes of the lines relating log stress to log strain rate at constant strain and temperature in Fig. 17. A plot of n *vs.* temperature is presented in Fig. 19. The points at 78°K are poorly defined due to the limited number of tests and small slopes at this temperature. Limits of 0.005 to 0.025 may be set with reasonable assurance. Values of p may be obtained from the slopes of the lines relating log stress to temperature at constant strain and strain rate in Fig. 18.

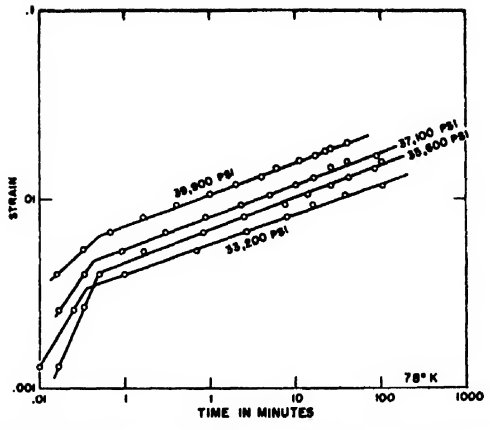

FIG. 15. Plastic strain of platinum as a function of time.

A plot of p *vs.* log strain rate is presented in Fig. 20. Equation (8) predicts that $\partial n/\partial T=\partial p/\partial \log\dot{\epsilon}|_{\epsilon}$. The following values for these quantities were obtained from Figs. 19 and 20:

$$\partial n/\partial T=1.04\times10^{-4}\ \text{deg.}^{-1}$$

and

$$\partial p/\partial \log\dot{\epsilon}=1.06\times10^{-4}\ \text{deg.}^{-1}.$$

Equations (7) to (9), together with Figs. 19 and 20, permit the quantity F to be taken as zero. Equation (6) then simplifies to the form

$$\sigma/\sigma_0=(\dot{\epsilon}/\dot{\epsilon}_0)^{DT}\epsilon^{(E+E'T)}. \qquad (11)$$

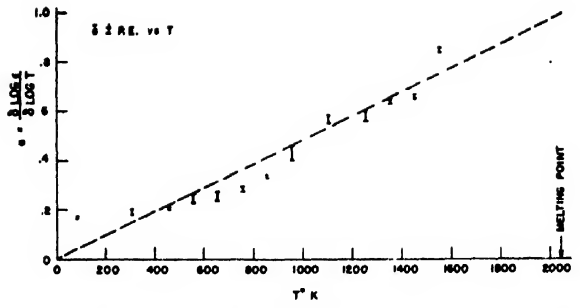

FIG. 16. Slopes of log strain-log time curves as a function of temperature (mean slope plus and minus probable error of mean).

In a creep test σ and T are constant and (11) can be reduced to $\epsilon=Ct^{\alpha}$, the form observed in the present experiments.

Many rate processes are dependent on temperature through a relationship of the form

$$\text{rate}\sim e^{-Q/RT},$$

where Q is the "activation energy" of the process per gram atom, $R=1.968$ cal. deg.$^{-1}$ mole^{-1} is the gas constant, and T is the absolute temperature. It may be instructive to consider deformation to be such a rate process. Then

$$d\epsilon/dt=\dot{\epsilon}=Ke^{-Q/RT}|_{\sigma,\epsilon}. \qquad (12)$$

Thus, a value of Q may be obtained from the slope of a

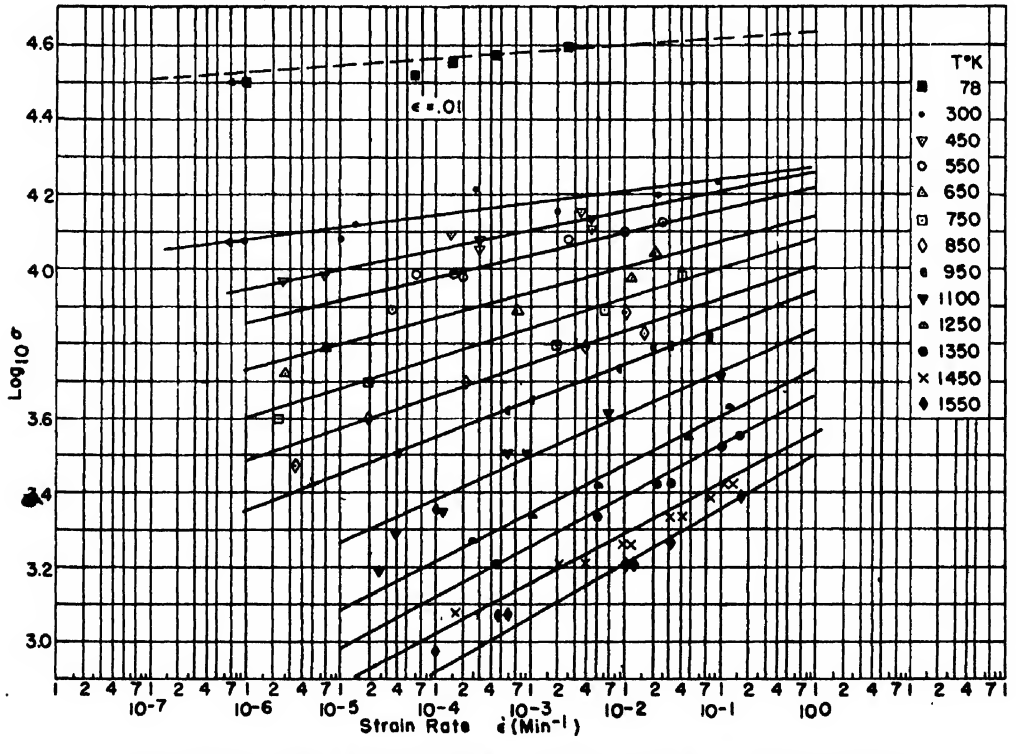

FIG. 17. Strain rate at a strain of 0.01 as a function of stress at several temperatures.

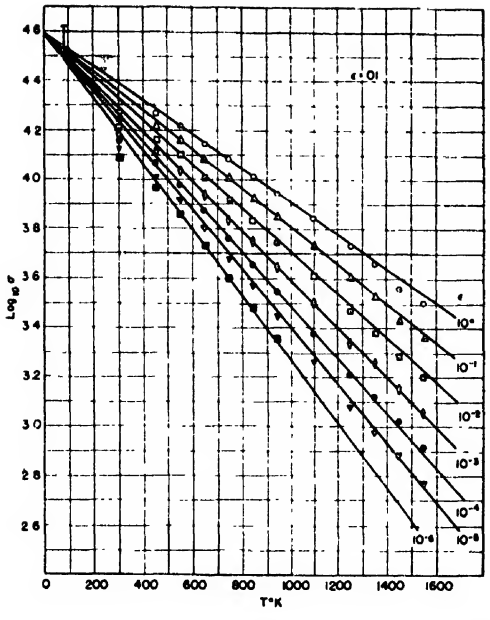

FIG. 18. Stress to produce several strain rates at a strain of 0.01 as a function of temperature.

plot of log$\dot{\epsilon}$ *vs.* $1/T$ at a particular value of stress and strain. The procedure may be repeated at other values of stress and strain to give the dependence of the activation energy on those variables. The data of Fig. 17 were cross plotted according to this procedure, resulting in Figs. 21 and 22. A similar procedure was followed considering strains of 0.005, 0.01, 0.02, and 0.03.

The form of the $Q=f(\sigma)$ relationship is of particular theoretical interest. Figure 22 shows that the decrease in Q with stress is not linear. The Becker[10]-Orowan[11] theory, in which attention is focused on the shear stress required to plastically deform an elementary region, predicts a linear relationship between $Q^{\frac{1}{2}}$ and σ. The data do not conform to this relationship. Nucleation theory, as applied to the formation of slip bands by Leschen, Carreker, and Hollomon,[12] predicts linearity between $Q^{\frac{1}{2}}$ and σ. The data do not confirm this prediction. The (empirical) equation (6) predicts Q to be linear in logσ, at constant strain.[13] Figure 23 shows the data plotted in this manner. The relationship is more nearly linear than the other functions of stress considered.

A CRITICAL APPRAISAL

There are definite undesirable features in the experimental techniques employed in this investigation. The most important of these is the narrow range of strain available for analysis. The upper limit of strain, 0.03, was dictated by the practical consideration of time per test at low strain rates and a desire to avoid strains near fracture, which occurred at 0.05 to 0.10. The lower value, a strain of 0.005, was limited by the accuracy with which the zero of time-dependent strain could be established. The zero of strain was established within 0.001.

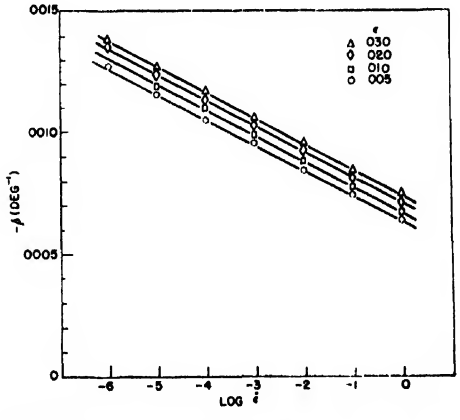

FIG. 20. Slopes of log stress-temperature curves as a function of strain rate.

The effective initial gauge lengths of the specimens were taken as 3.0 in. for the straight specimens and 5.57 in. for the "V" specimens, but these values are subject to some error. The wires were inserted in the grips and the lengths measured within 0.1 in. The grips would not be expected to influence the stress pattern in more than ten diameters (0.15 in.) of the specimen length. The "V" wires were heated by electric current and had cold ends where they contacted more massive pieces of metal. The distance affected by such end losses was estimated at less than 0.5 in. from each point of contact. Thus, the gauge lengths of the high tem-

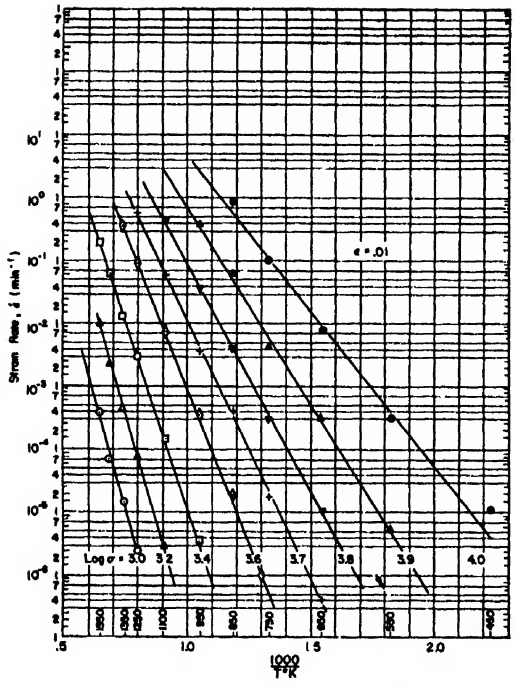

FIG. 21. Log strain rate at a strain of 0.01 *vs.* $1/T$ for several stresses.

perature "V"-type specimens were subject to a maximum error of 18 percent while the gauge lengths of the straight wire specimens were subject to a maximum error of eight percent. These errors might possibly lead to a maximum error of a factor of 1.2 in the strain rates. This error is negligible, considering the wide range of rates covered, and is certainly much less than the experimental scatter.

Although it is possible to measure and control temperature more accurately than was done in these experiments, it is felt that any errors in temperature are negligible with respect to the range of temperature explored.

It is believed that the experimental errors are insignificant with respect to the magnitude of the measured effects and that they do not obscure the basic description of the creep of platinum. The consistency and regularity of the data substantiate this belief.

The relations obtained from the present experiments were determined under a particular stress history, namely, constant stress. Tensile tests on the same material would be desirable as they would incorporate a different stress history and establish its effect, if any, upon these relations.

The assumption that σ is a point function of ϵ, $\dot{\epsilon}$, and T, which forms the basis of the foregoing empirical analysis, is not strictly correct. Dorn[14] has shown that the $\sigma-\epsilon$ relationship is influenced by temperature history when $\dot{\epsilon}$ is constant. In the present experiments σ and T were constant, during any one test, while ϵ and $\dot{\epsilon}$ were changing. The assumption appears to be valid under these conditions.

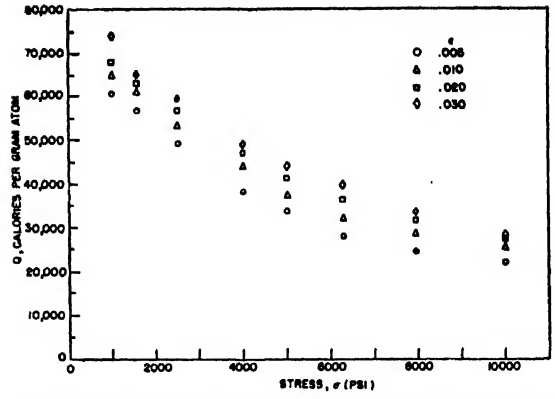

FIG. 22. Activation energy for plastic flow as a function of stress at several strains.

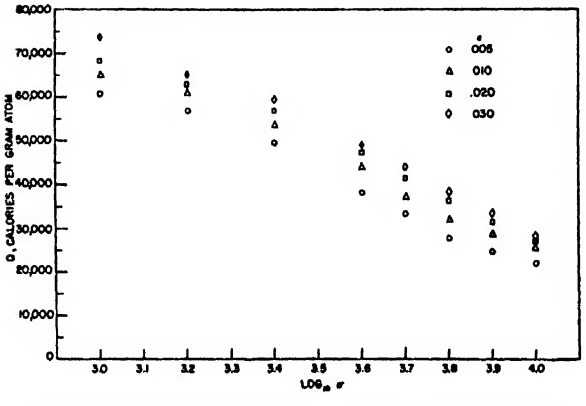

FIG. 23. Activation energy for plastic flow *vs.* logarithm of the stress at several strains.

It is interesting and important that the strain-time behavior of a metal subjected to such a wide range of experimental conditions can be described by simple relationships, even though these relationships are empirical. The present results indicate that useful information might be obtained by conducting similar experiments on other materials. Such experiments are in progress in this laboratory.

ACKNOWLEDGMENT

The writer wishes to acknowledge the assistance of Mrs. M. Wells in the experimental portion of this work; J. G. Leschen's contribution in developing the general equation relating stress, strain, strain rate, and temperature; and S. Dushman's contribution of equipment. The continued interest and helpful criticism of members of the Metallurgy Division of this Laboratory is sincerely appreciated.

The Effect of Magnetic Field on the Breakdown of Gases at Microwave Frequencies*

BENJAMIN LAX,† W. P. ALLIS, AND SANBORN C. BROWN
Research Laboratory of Electronics, Massachusetts Institute of Technology
(Received July 3, 1950)

The effect of magnetic field on the high frequency breakdown of gases has been studied. The presence of energy resonance and the modification of diffusion are shown experimentally and explained theoretically. An application is made of both the average electron theory and the Boltzmann theory, and the correspondence between these two theories is discussed.

THE breakdown of gases by high frequency electric fields in the presence of a constant magnetic field has been studied by Townsend and Gill[1] and by A. E. Brown.[2] It is the purpose of this paper to carry the analysis further, including the effect of the magnetic field on both the random diffusion of the electrons and their directed mobility.

Two approaches are available to such kinetic problems, and as there are advantages to each, both will be used. In Part I, the average electron theory will be given. In this method the orbit of a free electron in the assumed fields is computed first, and from this one computes the displacement and the energy gain in the time $\tau=t-t_0$ elapsed since a collision. These quantities are then averaged over the phase of the a.c. field at the time t_0 of the last collision, over the direction in space of the velocity after the collision, and over the free time up to the next collision. The result is the mean square displacement and energy gain of the average electron between collisions. One can then discuss an average electron from its initial low energy until it ionizes a gas atom or diffuses out of the tube. The condition for breakdown is that these two final achievements be equally probable. This method has the advantage that each step in the analysis has a direct physical meaning.

In Part II the Boltzmann transport equation is expanded in spherical harmonics in space, and in Fourier series in time. There results a differential equation for the distribution function which is integrated. Most of the properties of a discharge follow directly from a knowledge of the distribution function.

I. AVERAGE ELECTRON THEORY

Velocity between Collisions

Consider the motion of an electron between collisions under the influence of an electric field along the x-axis, $E=E_p\exp(j\omega t)$, and a constant magnetic field B along the z-axis. The equation of motion is then

$$\mathbf{F}=-e\mathbf{E}-ev\times\mathbf{B}=m\dot{\mathbf{v}}. \tag{1}$$

The solution of this equation is the sum of a general and a particular integral, which correspond to the superposition of a circular helical motion and a plane elliptical motion. For the helical motion whose axis is along the magnetic field, the velocity is

$$\left.\begin{aligned} v_{1x}&=(a+jb)\exp(j\omega_b\tau)\\ v_{1y}&=(b-ja)\exp(j\omega_b\tau)\\ v_{1z}&=c \end{aligned}\right\} \tag{2}$$

and oscillates at the cyclotron frequency $\omega_b=eB/m$. Because the helical motion contains the three arbitrary constants, the energy of this motion is constant and is given in electron-volts by:

$$u_1=\frac{mv_1^2}{2e}=\frac{m}{e}\frac{a^2+b^2+c^2}{2}. \tag{3}$$

For the elliptical motion, the velocity is

$$\left.\begin{aligned} v_{2x}&=\frac{eE_p}{m}\frac{j\omega}{\omega^2-\omega_b^2}\exp(j\omega t)\\ v_{2y}&=\frac{eE_p}{m}\frac{\omega_b}{\omega^2-\omega_b^2}\exp(j\omega t) \end{aligned}\right\} \tag{4}$$

and oscillates at the frequency of the applied field. The kinetic energy of this motion is uniquely determined by the magnitude and frequency of the applied field and is given by:

$$u_2=\frac{eE_p^2}{8m}\left[\frac{1}{(\omega-\omega_b)^2}+\frac{1}{(\omega+\omega_b)^2}+\frac{2\cos 2\omega t}{\omega_b^2-\omega^2}\right]. \tag{5}$$

The total energy $u=(m/2e)|(\mathbf{v}_1+\mathbf{v}_2)|^2$ will contain cross product terms u_{12} which are important but rather lengthy to write down. Their average value will be given later. The three constants, a, b, c, of the helical motion are determined by the velocity $\mathbf{v}_0=\mathbf{v}_1(\tau=0)+\mathbf{v}_2(t=t_0)$ immediately after a collision. As the time τ has been used in Eqs. (2) one has simply

$$\left.\begin{aligned} a&=v_{0x}-\frac{eE_p}{m}\frac{j\omega}{\omega^2-\omega_b^2}\exp(j\omega t_0)\\ b&=v_{0y}-\frac{eE_p}{m}\frac{\omega_b}{\omega^2-\omega_b^2}\exp(j\omega t_0)\\ c&=v_{0z}. \end{aligned}\right\} \tag{6}$$

* This work has been supported in part by the Signal Corps, the Air Materiel Command, and ONR.

[2] A. E. Brown, Phil. Mag. 29, 302 (1940).

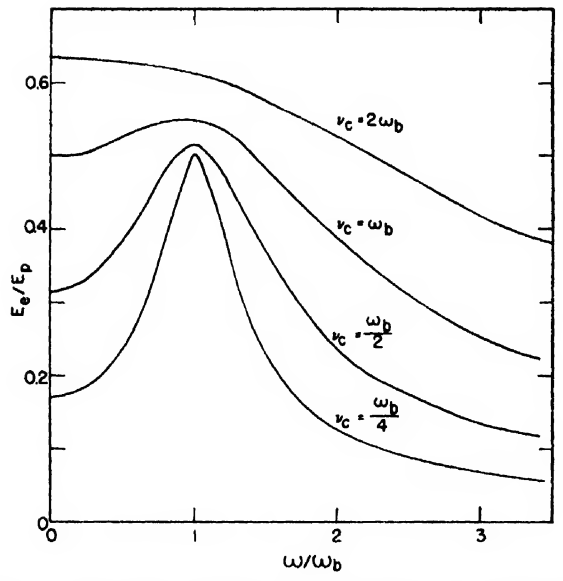

FIG. 1. The effective field E_e as a function of the frequency showing the resonance in the presence of a magnetic field.

It is noted that the elliptical motion exhibits a resonance at frequencies near the cyclotron frequency. Exactly at this frequency Eqs. (4) no longer hold and the solution corresponds to a spiral, but as collisions interrupt the motion it will not be necessary to use this singular solution.

Diffusion

From the velocities one obtains the displacements x_1, y_1, z_1, x_2, y_2 by integration. From these one can calculate the mean displacements $\langle x_1\rangle$, etc. but these all vanish on averaging over orientations of v_0, which is assumed isotropic, and over collision times t_0. In the average, an electron stays where it is in a high frequency discharge.

We are interested, however, in the mean square displacements $\langle x_1^2\rangle$, $\langle y_1^2\rangle$, $\langle z_1^2\rangle$ because these lead[3] to the diffusion coefficient. One finds the cross product terms such as $\langle x_1 y_1\rangle$ all vanish when averaged.

$$x_1^2+y_1^2=2\frac{a^2+b^2}{\omega_b^2}(1-\cos\omega_b\tau)$$
$$z_1^2=c^2\tau^2. \tag{7}$$

Averaging over orientations and times t_0, one finds that

$$\langle a^2\rangle=\langle b^2\rangle=\langle c^2\rangle=\frac{v_1^2}{3};\quad \langle ab\rangle=0. \tag{8}$$

The cross terms between the helical and elliptical motions also vanish but terms $\langle x_2^2\rangle$ and $\langle y_2^2\rangle$ do not vanish. However, these latter terms represent the mean square displacements due to mobility in the applied a.c. field and are not wanted in calculating the diffusion.

The average of a quantity X over the free times $\tau_c=1/\nu_c$ between collisions is, by definition,

$$\bar{X}=\int_0^\infty X\exp(-\nu_c\tau)\nu_c d\tau. \tag{9}$$

Applying this to the quantities in Eqs. (7) and defining the diffusion coefficients in terms of the mean square displacements, we obtain

$$D_{vv}=D_{xx}=\frac{\langle x_1^2\rangle}{2\tau_c}=\frac{v_1^2\nu_c}{3(\omega_b^2+\nu_c^2)}$$
$$D_{zz}=v_1^2/3\nu_c. \tag{10}$$

This definition of the diffusion tensor is of necessity symmetric. We shall see later that there are skew-symmetric terms which the random-walk definition cannot give. Diffusion along the z-axis is not altered by the magnetic field, but in the plane at right angles to the field it is reduced in the ratio $\nu_c^2/(\omega_b^2+\nu_c^2)$. For a given collision frequency, the diffusion coefficient is proportional to the energy of the electrons in their helical motion.

Energy Gain

The mean energy gain between collisions is best obtained by considering the power input to an electron $P=-e\mathbf{E}\cdot\mathbf{v}$. As the velocity v_{2x} is out of phase with the field, the corresponding power P_2 into this motion is zero in the average and only the power P_1 need be considered where

$$P_1=-eE_p\cos\omega t(a\cos\omega_b\tau-b\sin\omega_b\tau) \tag{11}$$

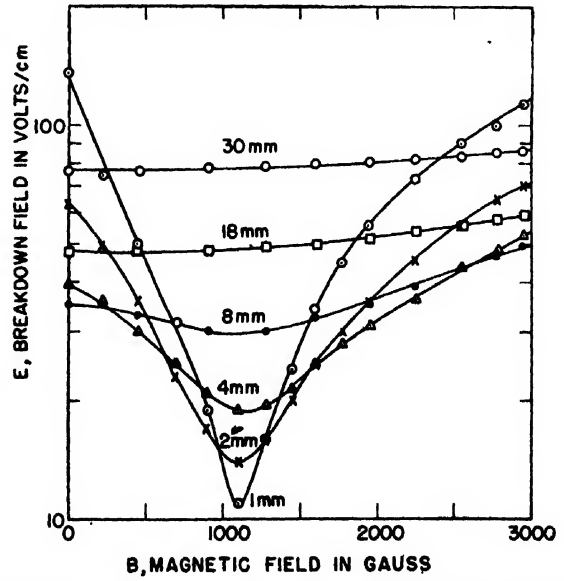

FIG. 2. Breakdown of helium in transverse electric and magnetic fields. (Diameter=7.32 cm and height=4.60 cm.)

[3] E. H. Kennard, *Kinetic Theory of Gases* (McGraw-Hill Book Company, New York, 1942), p. 286.

and the constants a and b are given by Eqs. (6). Averaging over orientations of the initial velocity the terms in v_0 drop out. Averaging over t_0 also we obtain

$$\bar{P}=\frac{e^2E_p^2}{4m}\left[\frac{\sin(\omega+\omega_b)\tau}{\omega+\omega_b}+\frac{\sin(\omega-\omega_b)\tau}{\omega-\omega_b}\right] \quad (12)$$

from which the average energy is obtained by integrating with respect to τ from 0 to τ.

$$\langle u_{12}\rangle=\frac{eE_p^2}{4m}\left[\frac{1-\cos(\omega+\omega_b)\tau}{(\omega+\omega_b)^2}+\frac{1-\cos(\omega-\omega_b)\tau}{(\omega-\omega_b)^2}\right]. \quad (13)$$

Averaging this quantity over collision times gives the mean energy gain between collisions

$$u_c=\frac{eE_p^2}{4m}\left[\frac{1}{(\omega+\omega_b)^2+\nu_c^2}+\frac{1}{(\omega-\omega_b)^2+\nu_c^2}\right]\equiv\frac{eE_e^2}{m\nu_c^2}. \quad (14)$$

This is a fundamental quantity in this theory. At low pressures ($\nu_c\to 0$) we see that it approaches twice the mean energy $\bar{u}_2$ of the elliptical motion of an electron, and in no case does it exceed this. At higher pressures, such that there are many collisions per oscillation, the energy $\bar{u}_2$ loses its meaning and the collision energy becomes $eE_p^2/2m\nu_c^2$. One can use Eq. (14) to define an effective field E_e which is the root-mean-square-field at high pressure. This concept is useful when the collision frequency ν_c is independent of velocity as this single function takes into account the effects of frequency and magnetic field on the energy.

At low pressures the effective field has a maximum at resonance with the cyclotron frequency as shown in Fig. 1.

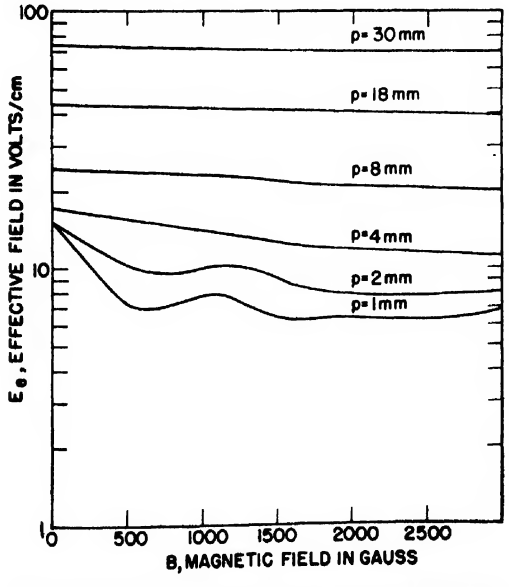

FIG. 3. Representation of experimental data of Fig. 2 in terms of the effective field.

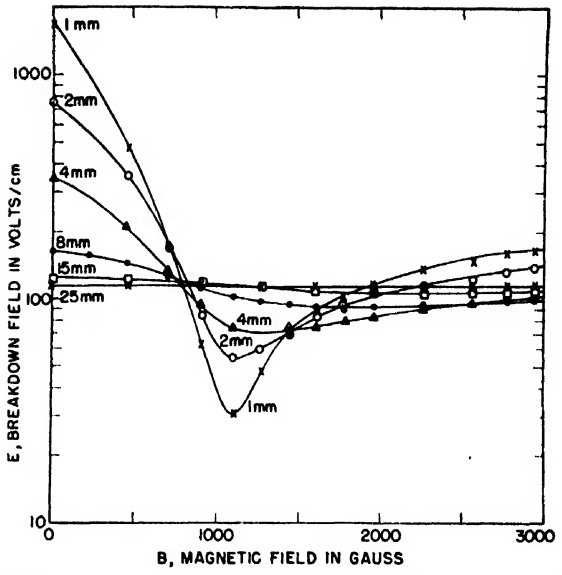

FIG. 4. Breakdown of helium in transverse electric and magnetic fields. (Diameter=7.32 cm and height=0.318 cm.)

Breakdown

The electrons produced by ionization have initially very little energy, but this increases by steps of u_c until the energy reaches a value u_i, at which ionization occurs. This is above the ionization potential V_i by an amount which we shall neglect. Excitations are disregarded in the following simple theory. The number N of free times to ionize is $N=u_i/u_c$ when ν_c is constant.

The electrons thus double their number by ionization every N collisions and unless some equally effective process exists which removes electrons their number will increase exponentially. In most cases diffusion to the walls of the discharge tube is the balancing process. In absence of the magnetic field, the random walk theory[4] gives the mean square distance $\Lambda^2=Nl^2/3$ reached in N free paths of mean square length l^2, so that if the average electron reaches the wall in a distance Λ the diffusion process will just balance ionization. This is the condition for breakdown and we can write it

$$\frac{u_c}{u_i}=\frac{\langle l^2\rangle}{3\Lambda^2}=\frac{\langle v^2\rangle}{3\Lambda^2\nu_c^2} \quad (15)$$

where Λ is now a length characteristic of the discharge tube and known as the diffusion length.[5]

If there is a magnetic field u_c will be altered according to Eq. (14). At the same time the random walk theory must be altered to take into account the curved paths between collisions. This may be done by appropriately decreasing l or increasing Λ. We shall adopt the latter and denote the new length by Λ_e. Its value will be given later.

[4] See reference 3, p. 271.
[5] M. A. Herlin and S. C. Brown, Phys. Rev. 74, 291 (1948).

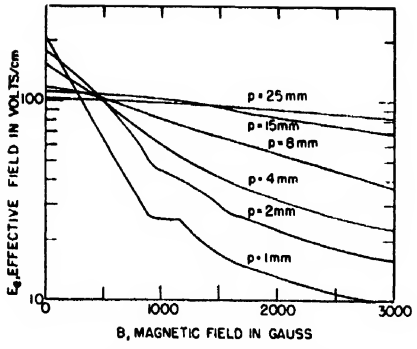

FIG. 5. Representation of experimental data of Fig. 4 in terms of the effective field.

When the mean free path is much smaller than Λ_e, the intercollision energy gain u_c is correspondingly smaller than the ionization potential. From Eq. (15) we see that breakdown should occur at the same effective field if the ratio of the mean free path to the effective diffusion length is the same, that is, the effective field for breakdown is a function of $p\Lambda_e$ only.

Combining Eqs. (14) and (15) we get

$$E_e^2=\frac{2\bar{u}u_i}{3\Lambda_e^2}. \tag{16}$$

Experimental data for breakdown in helium containing small admixtures of mercury vapor are shown in Fig. 2. The result of using the effective field with $\nu_e=2.37\times10^9 p$ as given by Brode's[6] collision probability measurements in place of the actual field but without taking the variation of Λ_e into account is shown in Fig. 3 for the same data. This shows that the resonance effect of the magnetic field and the high frequency are removed by using the effective field.

In order to test formula (10) for the diffusion coefficient, breakdown was studied in a flat cylindrical cavity whose length was very short compared to the radius. With the magnetic field placed transverse to the axis most of the diffusion has to take place perpendicular to the magnetic field and hence will show the full reduction. By Eq. (10) the mean square of the distance travelled by an electron is proportional to the diffusion coefficient D, and therefore the effective diffusion length Λ_e appropriate to infinite parallel plates is

$$\Lambda_e^2=\frac{\omega_b^2+\nu_e^2}{\nu_e^2}\Lambda^2. \tag{17}$$

The effect of a magnetic field is to make the dimensions of the cavity at right angles to the field appear larger to an electron. By Eq. (16) this should reduce the effective field for breakdown in the same proportion. Figure 4 shows a set of breakdown curves for helium in a cavity $2\frac{7}{8}$ in. in diameter and $\frac{1}{8}$ in. high. In Fig. 5 the effective field for the same data is plotted. In this figure the resonance peak has been removed as in Fig. 3, but now the curves are not horizontal because the magnetic field is increasing the effective cavity size.

However, Eq. (16) does not correspond with experiment except when used for comparative purposes. Equation (14) and the random walk theory give the number of free times for the average electron to ionize and reach the wall, respectively. But in a discharge it is the "faster-than-average" electron which ionizes and the "more-mobile-than-average" electron which leaves the tube and these are not the same electron. The mean free path method must therefore fail in predicting quantitative breakdown, and the failure should be worst when there are many collisions and therefore the greatest deviations from the mean.

II. BOLTZMANN THEORY

Spherical and Fourier Expansions

The Boltzmann transport equation is given by

$$C=\frac{\partial F}{\partial t}+\nabla\cdot(\mathbf{v}F)-\nabla_v\cdot\frac{e\mathbf{E}F}{m}-\nabla_v\cdot\frac{e}{m}\mathbf{v}\times\mathbf{B}F \tag{18}$$

where C is the production rate due to collisions per unit volume in phase space, ∇ and ∇_v are gradients in configuration and velocity space, respectively, and F is the distribution function. If F and C are expanded in spherical harmonics and substituted into the transport equation, we obtain two equations by equating the zero and first order terms

$$\begin{aligned}C_0&=\frac{\partial F_0}{\partial t}+\frac{v}{3}\nabla\cdot\mathbf{F}_1-\frac{e\mathbf{E}}{3mv^2}\cdot\frac{\partial(v^2\mathbf{F}_1)}{\partial v}\\ \mathbf{C}_1&=\frac{\partial\mathbf{F}_1}{\partial t}+v\nabla F_0-\frac{e}{m}\mathbf{E}\frac{\partial F_0}{\partial v}-\frac{e}{m}\mathbf{B}\times\mathbf{F}_1.\end{aligned} \tag{19}$$

We consider separately the elastic and inelastic collisions. Let C_{el} represent the elastic collision term. Morse, Allis and Lamar[7] have computed the zero- and first-order components of this term:

$$\begin{aligned}C_{0,el}&=\frac{m}{M}\frac{1}{v^2}\frac{\partial}{\partial v}\left(\frac{v^4F_0}{l}\right)\\ \mathbf{C}_{1,el}&=-\frac{v}{l}\mathbf{F}_1,\end{aligned} \tag{20}$$

where M is the mass of the gas molecule and l the mean free path of the electron.

The inelastic term C_{in} shows no angular dependence and hence, $C_{1,in}=0$ and only $C_{0,in}$ is retained. Equation

[6] R. B. Brode, Rev. Mod. Phys. 5, 243 (1933).

[7] Morse, Allis, and Lamar, Phys. Rev. 48, 412 (1935).

(19) then becomes

$$[0]\quad C_{0,in}+\frac{m}{M}\frac{1}{v^2}\frac{\partial}{\partial v}(\nu_c v^3 F_0)=\frac{\partial F_0}{\partial t}$$

$$+\frac{v}{3}\nabla\cdot\mathbf{F}_1-\frac{e}{3mv^2}\frac{\partial(v^2\mathbf{E}\cdot\mathbf{F}_1)}{\partial v} \quad (21)$$

$$[1]\quad 0=\nu_c\mathbf{F}_1+\frac{\partial\mathbf{F}_1}{\partial t}+v\nabla F_0-\frac{e}{m}\mathbf{E}\frac{\partial F_0}{\partial v}-\frac{e}{m}\mathbf{B}\times\mathbf{F}_1.$$

If the electric field is given by $\mathbf{E}=\mathbf{E}_p\exp(j\omega t)$, the Fourier expansions become

$$\mathbf{F}_1=\mathbf{F}_1^0+\mathbf{F}_1^1\exp(j\omega t)$$

and, with due caution in multiplying complex quantities,

$$\mathbf{E}\cdot\mathbf{F}_1=\tfrac{1}{2}\mathbf{E}_p\cdot(\mathbf{F}_1^1)_r+\mathbf{E}_p\cdot\mathbf{F}_1^0\exp(j\omega t),$$

where $(\mathbf{F}_1^1)_r$ is the real part of $\mathbf{F}_1^1$. These are now substituted into (21) and the Fourier components equated term by term. Only the constant term of the first equation is needed but the d.c. and a.c. terms of the second must be kept. In the steady state $\partial F_0/\partial t=0$.

$$[0,0]\quad C_{0,in}+\frac{m}{M}\frac{1}{v^2}\frac{\partial}{\partial v}(\nu_c v^3 F_0)-\frac{v}{3}\nabla\cdot\mathbf{F}_1^0$$

$$+\frac{e}{m}\frac{1}{3v^2}\frac{\partial}{\partial v}\left[\frac{v^2}{2}\mathbf{E}_p\cdot(\mathbf{F}_1^1)_r\right]=0 \quad (22)$$

$$[1,0]\quad \nu_c\mathbf{F}_1^0+v\nabla F_0-\frac{e}{m}\mathbf{B}\times\mathbf{F}_1^0=0$$

$$[1,1]\quad (\nu_c+j\omega)\mathbf{F}_1^1-\frac{e}{m}\mathbf{E}_p\frac{\partial F_0}{\partial v}-\frac{e}{m}\mathbf{B}\times\mathbf{F}_1^1=0.$$

These are the necessary equations for handling breakdown problems, which represent steady state conditions for the electrons. The above equations are applicable for any orientation of **E** and **B**. We shall only consider the cases when they are perpendicular or parallel to each other.

Diffusion Tensor

Integrating the [0,0] equations over velocity space in spherical coordinates, the second and fourth terms vanish at the limits. The first term gives the total production rate of electrons, $\nu_i n$, due to ionization. This is because excitations merely withdraw fast electrons to replace them by slow ones, whereas ionizations add an extra electron. The third term gives the divergence of a flow vector Γ

$$\Gamma=\int_0^\infty\frac{4\pi}{3}\mathbf{F}_1^0 v^3 dv \quad (23)$$

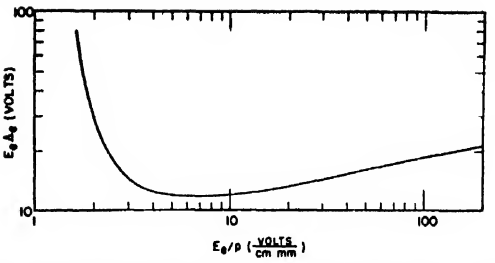

FIG. 6. Theoretical curve for the effective breakdown in helium.

so that

$$n\nu_i=\nabla\cdot\Gamma. \quad (24)$$

Solving Eq. [1,0] for $\mathbf{F}_1^0$ we find

$$\mathbf{F}_1^0=-\frac{v}{\nu_c}\frac{\nu_c^2+\omega_b\omega_b\cdot+\nu_c\omega_b\times}{\nu_c^2+\omega_b^2}\nabla F_0 \quad (25)$$

and this must be substituted in (23) and, assuming that F_0 can be written as a product $n(x,y,z)f_0(v)$ we find that Γ is proportional to ∇n but not necessarily in the same direction. Accordingly it is possible to define a diffusion coefficient but it must be a tensor

$$(D_{ij})=\int_0^\infty\frac{lv}{3(1+b^2)}$$

$$\times\begin{pmatrix}(1+b_x^2) & (b_xb_y-b_z) & (b_xb_z+b_y)\\ (b_xb_y+b_z) & (1+b_y^2) & (b_yb_z-b_x)\\ (b_xb_z-b_y) & (b_yb_z+b_x) & (1+b_z^2)\end{pmatrix}4\pi v^2 f_0 dv \quad (26)$$

$$\Gamma_i=-\textstyle\sum_j D_{ij}\dfrac{\partial n}{\partial j};\quad i,j=x,y,z$$

where $b_x=(\omega_b)_x/\nu_c$ and $b^2=b_x^2+b_y^2+b_z^2$. This expression reduces to the ordinary coefficient $D=\langle v^2\rangle/3\nu_c$ with no magnetic field when $b=0$. If the magnetic field is taken along the z-axis, it reduces to

$$D_{ij}=\int_0^\infty\frac{lv}{3(1+b^2)}\begin{pmatrix}1 & -b & 0\\ b & 1 & 0\\ 0 & 0 & 1+b^2\end{pmatrix}4\pi v^2 f_0 dv, \quad (27)$$

which is equivalent to Eq. (10) except that the present tensor has skew-symmetric terms which were not obtained by the random walk definition.

Substituting in (24) we obtain the diffusion equation

$$D_{xx}\frac{\partial^2 n}{\partial x^2}+D_{yy}\frac{\partial^2 n}{\partial y^2}+D_{zz}\frac{\partial^2 n}{\partial z^2}+\nu_i n=0 \quad (28)$$

which determines the spatial distribution of the electrons. One can use the normal diffusion coefficient D provided lengths are expanded at right angles to the magnetic field in the ratio $(1+b^2)^{\frac{1}{2}}$.

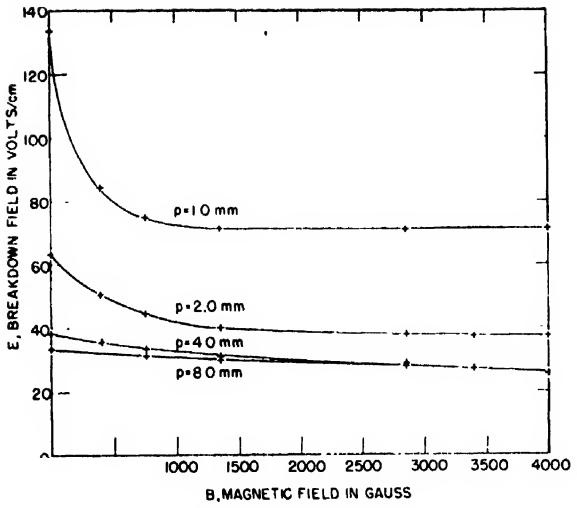

FIG. 7. Breakdown of helium in parallel electric and magnetic fields in a cylindrical cavity (diameter = 7.32 cm, height = 4.60 cm). The solid curves are theoretical and the points are experimental.

The solution of this equation depends on the boundary conditions. One must define an effective diffusion length Λ_e for the whole cavity which takes into account these expansions

$$\frac{1}{\Lambda_e^2}=\left(\frac{1}{\Lambda_x^2}+\frac{1}{\Lambda_y^2}\right)\frac{\nu_c^2}{\nu_c^2+\omega_b^2}+\frac{1}{\Lambda_z^2}. \tag{29}$$

The condition for the existence of a solution of (28) satisfying the boundary conditions is

$$D=\Lambda_e^2\nu_i \tag{30}$$

where D is the ordinary diffusion coefficient. The effect of the magnetic field is equivalent to expanding the cavity in the ratio $(\nu_c^2+\omega_b^2)^{\frac{1}{2}}\nu_c$ in all directions perpendicular to the magnetic field.

Differential Equation for F_0

The distribution function F_0 is obtained by eliminating $\mathbf{F}_1^0$ and $\mathbf{F}_1^1$ from Eqs. (22). One obtains in this way

$$C_{0,in}=\frac{v^2F_0}{3\nu_c\Lambda_e^2}-\frac{1}{v^2}\frac{\partial}{\partial v}\left[\frac{m}{M}\nu_c v^3F_0+\frac{e^2E_e^2}{3m^2\nu_c}v^2\frac{\partial F_0}{\partial v}\right] \tag{31}$$

where the effective field E_e is defined by (14) when E is at right angles to B. Should E make any other angle with B, the component at right angles is reduced by Eq. (14), and the square of this added to the mean square along B. Introducing the energy variable $u=mv^2/2e$ and the inelastic ratio $h=-C_{0,in}/\nu_eF_0$, Eq. (31) becomes

$$\frac{1}{(u)^{\frac{1}{2}}\nu_e}\frac{\partial}{\partial u}\left[\frac{2m}{M}\nu_c u^{\frac{1}{2}}F_0+\frac{2eE_e^2}{3m\nu_c}u^{\frac{1}{2}}\frac{\partial F_0}{\partial u}\right]=\left(h+\frac{2eu}{3m\nu_e^2\Lambda_e^2}\right)F_0. \tag{32}$$

The four terms of this equation are readily interpreted: the first, with $2m/M$, represents energy lost to recoil of the atoms, the second, with E_e^2, is the energy gain due to the field, h gives the loss of electrons through inelastic collisions, and the last term, in $1/\Lambda_e^2$, the loss through diffusion to the walls. It is noted that the magnetic field and the frequency are entirely contained in the effective quantities E_e and Λ_e. The pressure enters only in ν_c and indirectly through ν_c into E_e and Λ_e. The pressure cancels out of the first and third terms, and the only experimental parameters are thus E_e/p in the second term and $p\Lambda_e$ in the fourth. The other quantities are universal constants such as e/m and m/M and atomic constants such as the excitation and ionization cross sections included in h. It follows that all the breakdown data should plot on a single curve when $E_e\Lambda_e$ is plotted against E_e/p. This exact law is, however, of very limited applicability. The effective quantities E_e and Λ_e depend on ν_c, which is a function of the electron's energy. It is therefore in general impossible to make the effective values the same at all energies as the law requires. For helium and hydrogen the collision frequency ν_c is very nearly constant so the effective values are significant as shown in Fig. 6.

Because inelastic impacts set in discontinuously at the excitation potential u_x, it is necessary to solve Eq. (32) in two parts: Below u_x, $h=0$ and above u_x recoil and diffusion may generally be neglected. The solution of this equation in the completely analogous non-magnetic case has been carried out by MacDonald and Brown.[8]

The Boltzmann theory can be compared with the simple average electron theory in the case of helium

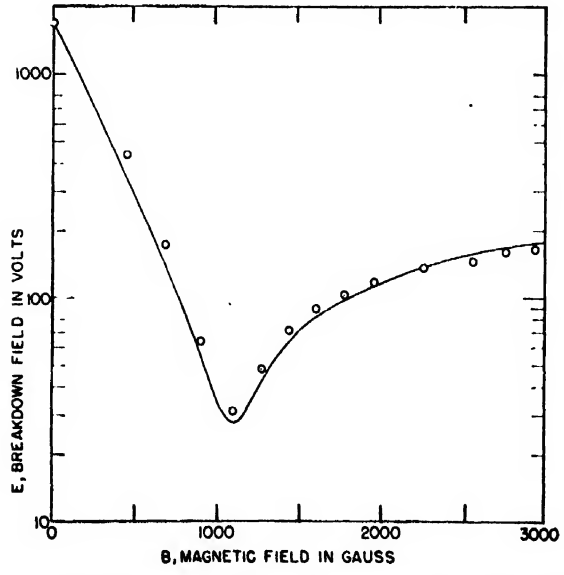

FIG. 8. Breakdown of helium at 1 mm pressure in a cylindrical cavity (diameter = 7.60 cm, height = 0.318 cm). Solid line is obtained from the Boltzmann theory and points are experimental.

[8] A. D. MacDonald and S. C. Brown, Phys. Rev. 75, 411 (1949).

containing traces of mercury so that all excitations result in ionizations. We must then neglect the recoil and excitation terms. The solution of the Eq. (32) is then expressible in terms of Bessel functions of order $\pm 1/4$. Setting the coefficients so that the function vanishes at u_i

$$F_0 = w^{-1/4}[J_{1/4}(w_i)J_{-1/4}(w) - J_{-1/4}(w_i)J_{1/4}(w)]$$

where

$$w = ju/\Lambda_e E_e.$$

The breakdown condition then reduces to

$$(1/4)!J_{1/4}(w_i) = 2w_i^{1/4}$$

or

$$u_i = 2.273\Lambda_e E_e.$$

This corresponds to using for the mean energy in (16)

$$\bar{u} = u_i/3.44.$$

III. NON-UNIFORM FIELDS

To study the effect of the magnetic field on diffusion alone the electric and magnetic fields are oriented in the same direction, and in order to reduce diffusion along the magnetic field it is necessary to perform the experiment in a cavity whose height is greater than the radius. In such a cavity the electric field may no longer be considered uniform and a correction to the computations must be made in a manner which has been shown by Herlin and Brown.[9] In the presence of the longitudinal magnetic field the equivalent diffusion length of the cylinder, from Eq. (29), is

$$\frac{1}{\Lambda_e^2} = \frac{\nu_c^2}{\nu_c^2 + \omega_b^2}\left(\frac{2.405}{R}\right)^2 + \left(\frac{\pi}{L}\right)^2.$$

Using this and the non-uniform field correction to the Boltzmann theory one obtains the agreement with experiment shown in Fig. 7. This result confirms the predicted effect of the magnetic field upon diffusion.

The breakdown measurements shown in Fig. 4 were made in a flat cavity with the magnetic field transverse to the axis. The effect of the latter is to require the solution of the diffusion equation in an elliptical cylinder whose diffusion length is then given by

$$\frac{1}{\Lambda_e^2} = \frac{\nu_c^2}{\nu_c^2 + \omega_b^2}\left[\left(\frac{\pi}{L}\right)^2 + \frac{1}{2}\left(\frac{2.405}{R}\right)^2\right] + \frac{1}{2}\left(\frac{2.405}{R}\right)^2.$$

Using this and the non-uniform field correction gives the theoretical curves shown in Fig. 8.

IV. EXPERIMENTAL APPARATUS AND PROCEDURE

The block diagram of the experimental equipment is shown in Fig. 9. The source of microwave energy is a

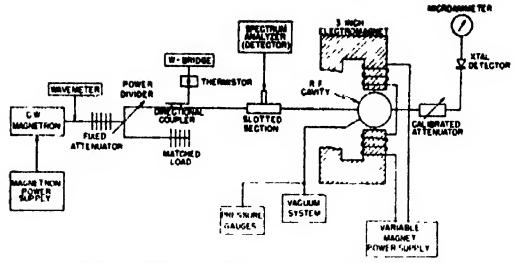

FIG. 9. Block diagram of the apparatus.

10-cm tunable c-w magnetron whose frequency is monitored by a calibrated wavemeter. The power fed into the cavity is varied by a balanced power divider and measured through a directional coupler by a bolometer, consisting of a thermistor and a balanced power bridge. The slotted section and detector are used to determine the electrical constants of the cavity.[10] The cavity, which is vacuum-tight, is loop coupled to the transmission line on either side. The output loop feeds into a variable calibrated attenuator, a crystal detector and a sensitive microammeter, which are adjusted to measure the power fed into the cavity at resonance. The magnetic field across the cavity is applied by an adjustable electromagnet. The magnetic field for a given gap size is calibrated as a function of the current through the coils by the use of a snatch coil and a ballistic galvanometer or by a compensated torque type fluxmeter. The pressure in the cavity during the experiment is measured by a McLeod gauge.

The breakdown experiment was performed at fixed values of pressure while the current through the coils and hence the magnetic field was set at different values. The power fed into the cavity was increased from nearly zero until the needle on the microammeter rose to a maximum and then suddenly dropped. This occurred at breakdown since the sudden increase in electron density detuned the cavity and produced a mismatch in the line. The setting of the calibrated attenuator and the maximum reading of the microammeter measured the power fed into the cavity. The breakdown field was then calculated from the measured constants and geometrical dimensions of the cavity.

V. CONCLUSIONS

The two principal effects of a magnetic field on high frequency breakdown of gases, the energy resonance with transverse fields and the reduction of diffusion, have been demonstrated experimentally and explained theoretically. The diffusion effect was shown to exist by itself when the electric and magnetic fields were parallel. The resonance phenomenon could not be separated because of the presence of diffusion at all times. Nevertheless this effect was brought into major

[9] M. A. Herlin and S. C. Brown, Phys. Rev. 74, 1650 (1948).

[10] S. C. Brown *et al.*, "Methods of measuring the properties of ionized gases at microwave frequencies," Technical Report No. 66, Research Laboratory of Electronics, M.I.T., Cambridge, Massachusetts.

prominence in breakdown by reducing the diffusion loss in a large cavity.

The development of the diffusion tensor in the presence of a magnetic field resulted in a more general diffusion equation. This led to the concept of the effective diffusion length, which together with the effective field, extended here to include the magnetic field, served to generalize the theory. The correspondence of the Boltzmann theory and the average electron theory was shown.

Quantum Limits of the Electrostatic Image Force Theory

R. G. Sachs and D. L. Dexter*
Department of Physics, University of Wisconsin, Madison, Wisconsin
(Received July 17, 1950)

The quantum mechanical problem of the interaction of a charged macroscopic body with a metal surface is treated by means of the variation method. The resulting expression for the interaction energy is the same as that obtained by the classical image force method except for three correction terms. These corrections are caused by the change in kinetic energy associated with the concentration of the electrons on the surface of the metal, the reduction in the electron-electron interaction energy in the metal resulting from the antisymmetrization of the wave function and the effect of the finite thickness of the surface charge. It is found that these terms are negligible except for distances between the charged body and metal surface such that surface structure effects are important.

I. INTRODUCTION

THE calculation of the interaction between a charged body and a much larger metal body is usually carried out by means of the classical image force theory. This treatment is certainly justified when the ratio of the distance between the bodies to atomic dimensions is sufficiently great. However, the method may be questioned when this ratio is of the same order of magnitude as the square root of the ratio of the total charge on the body to the electronic charge.[1] Such a condition may occur in experiments on the Schottky effect[2] and in the Van der Waals adsorption of molecules on a metal surface. The latter effect has been discussed by Lennard-Jones[3] from the point of view of the image force theory. A discussion of the limitations of this treatment due to the fact that the molecule must be treated quantum mechanically has been given by Bardeen.[4]

Bardeen has in addition treated the image force problem for an electron from the quantum mechanical point of view and has demonstrated that the classical formula for the force on an electron can be expected to hold asymptotically when the electron is at great distances from the metal. It is the purpose of this paper to determine the order of magnitude of the distance at which the classical formulas break down. In determining this distance, account will not be taken of the detailed surface structure of the metal, but the order of magnitude of the deviation from the classical formula due to purely quantum effects in the metal will be obtained.

This deviation is due to three effects. The first is the change in kinetic energy of the electrons that is associated with the increased charge density on the surface of the metal. The second effect is that due to the antisymmetrization of the wave function. This increases the average distance between electrons and therefore causes the electron-electron interaction to be smaller than that expected from classical considerations. Finally, in the determination of the self-interaction of the induced charge density account must be taken of the fact that one cannot assume an infinitely thin surface layer of charge in the quantum treatment since such an assumption would lead to an infinite kinetic energy of the electrons on the surface.

II. CLASSICAL TREATMENT

The classical theory of image forces will be briefly reviewed in this section from a point of view that may be easily compared with the quantum treatment. It will be assumed throughout the paper that a charged body (taken positive for the sake of definiteness), which gives rise to a potential $v(\mathbf{r})$ in the absence of other matter, interacts with the plane surface of a half-infinite metal body at distance R away. The origin of the coordinate system used is at the foot of the normal from the charged body to the metal surface. The positive z axis is taken as the normal into the metal and $\mathbf{s}$ is the two dimensional position vector on the surface of the metal.

In electrostatic theory it is shown that the potential $v(\mathbf{r})$ gives rise to a charge density, $\sigma_0(\mathbf{s})$, on the surface of the metal. The interaction energy, $W(R)$, is the sum of two terms. The first is the direct interaction between

* Research supported in part by ONR.
[1] Classical image force theory would not be expected to hold when the induced charge density, ρ', becomes equal to ρ_0, the charge density of free electrons in the metal. Since $\rho' \approx \sigma/a \approx Q/R^2 a$, where Q is the magnitude of the external charge, R its distance from the metal, and a is an atomic dimension, and since $\rho_0 \approx e/a^3$, ρ' becomes equal to ρ_0 when $Q/e \approx (R/a)^2$.
[2] E. Guth and C. J. Mullin, Phys. Rev. 59, 575 (1941).
[3] Lennard-Jones, Trans. Faraday Soc. 28, 334 (1932).
[4] J. Bardeen, Phys. Rev. 58, 727 (1940).

the charge density $\sigma_0(\mathbf{s})$ and the potential $v(\mathbf{r})$, and is given by

$$W_1(R)=\int \sigma_0(\mathbf{s})v(\mathbf{s})dS, \tag{1}$$

where the integration is carried out over the surface of the metal. The second term is due to the interaction of the charge density on the surface with itself:

$$W_2(R)=\frac{1}{2}\int\int \frac{\sigma_0(\mathbf{s})\sigma_0(\mathbf{s}')dSdS'}{|\mathbf{s}-\mathbf{s}'|}. \tag{2}$$

We can now make use of the fact that the total potential due to the charged body and the surface charge must vanish everywhere within the metal:

$$v(\mathbf{r})+\int \frac{\sigma_0(\mathbf{s}')dS'}{|\mathbf{r}-\mathbf{s}'|}=0, \tag{3}$$

for $Z>0$, from which it follows that

$$2\pi\sigma_0(\mathbf{s})=\frac{\partial v(\mathbf{r})}{\partial z}\bigg|_{z=0}.$$

Since the integral in Eq. (3) is a continuous function of s (although its derivative is not), we can set

$$v(\mathbf{s})=-\int \frac{\sigma_0(\mathbf{s}')dS'}{|\mathbf{s}-\mathbf{s}'|}.$$

Therefore

$$\int\int \frac{\sigma_0(\mathbf{s})\sigma_0(\mathbf{s}')dSdS'}{|\mathbf{s}-\mathbf{s}'|}=-\int v(\mathbf{s})\sigma_0(\mathbf{s})dS, \tag{3'}$$

and the total interaction energy is given by

$$W(R)=W_1(R)+W_2(R)=\frac{1}{2}\int \sigma_0(\mathbf{s})v(\mathbf{s})dS. \tag{4}$$

For future reference we wish to show that the energy $W(R)$ is a minimum with respect to variations in the charge density $\sigma(\mathbf{s})$. The variation of

$$W(R)=\int v(\mathbf{s})\sigma(\mathbf{s})dS+\frac{1}{2}\int\int \frac{\sigma(\mathbf{s})\sigma(\mathbf{s}')dSdS'}{|\mathbf{s}-\mathbf{s}'|}, \tag{5}$$

associated with the variation $\delta\sigma$ of σ is

$$\delta W(R)=\int v(\mathbf{s})\delta\sigma(\mathbf{s})dS+\frac{1}{2}\int\int \frac{\delta\sigma(\mathbf{s})\sigma(\mathbf{s}')dSdS'}{|\mathbf{s}-\mathbf{s}'|}+\frac{1}{2}\int\int \frac{\sigma(\mathbf{s})\delta\sigma(\mathbf{s}')dSdS'}{|\mathbf{s}-\mathbf{s}'|}.$$

Since the latter two integrals are equal, the condition that $\delta W(R)=0$ becomes

$$\int\left[v(\mathbf{s})+\int \frac{\sigma(\mathbf{s}')dS'}{|\mathbf{s}-\mathbf{s}'|}\right]\delta\sigma(\mathbf{s})dS=0,$$

and, taking into account the fact that the variations $\delta\sigma$ are arbitrary, this is equivalent to

$$v(\mathbf{s})+\int \frac{\sigma(\mathbf{s}')dS'}{|\mathbf{s}-\mathbf{s}'|}=0.$$

According to Eq. (3), this condition is satisfied by our choice of $\sigma_0(\mathbf{s})$. It follows that the energy given by Eq. (4) is a stationary value of Eq. (5); it also seems reasonable on physical grounds to assert that this stationary value is a minimum.

III. THE VARIATION METHOD

The wave equation for the metal electrons can be set up formally but, of course, it cannot be solved directly. The problem can, however, be treated by the variation method. In choosing a trial function, it will be assumed that the function leads to the classical surface charge density in very good approximation. All other details of the function will remain arbitrary. When this function is inserted into the variation integral, terms of the type (1) and (2) will occur. In addition there will be terms due to the change in kinetic energy, to the reduced interaction between electrons associated with the antisymmetric wave function, and to the non-zero thickness of the surface charge density. These latter terms turn out to be small compared to those given by Eqs. (1) and (2) as long as the distance between the charged body and metal surface is sufficiently great. Therefore, for such distances, the variation energy is essentially equal to (5). Since it has been shown in Section II that (4) is the minimum of Eq. (5) for variations in σ, it follows that, except for the small terms, this will also be the minimum of the energy with respect to variations in the wave function. It is, therefore, the proper energy associated with the wave equation as long as the correction terms may be neglected. Thus the quantum treatment leads directly to the same interaction as the classical image force theory.

In order to estimate the order of magnitude of the distance at which the image force theory may be expected to break down, it is necessary to seek that region in which the terms that have been neglected become of the same order of magnitude as the image force energy.

We consider as a variation function the normalized function $\Psi(\mathbf{r}_1, \mathbf{r}_2, \cdots \mathbf{r}_N)$ of the positions of the N electrons in the metal. The electronic charge density associated with this function is

$$\rho(\mathbf{r})=-e\sum_{j=1}^{N}\int\int\cdots\times\int|\Psi(\mathbf{r}_1, \mathbf{r}_2, \cdots \mathbf{r}_{j-1}, \mathbf{r}, \mathbf{r}_{j+1}, \cdots \mathbf{r}_N)|^2 d\tau^{N-1}, \tag{6}$$

where the $d\tau^{N-1}$ indicates that the integration is to be carried out over all the electrons except the j'th. e is the absolute value of the electronic charge. It is assumed that Ψ is chosen in such a way that $\rho=\rho_0+\rho'(\mathbf{r})$, where ρ_0, a constant, is the electronic charge density in the metal when the charged body is absent and $\rho'(\mathbf{r})$ is a small added volume density that arises in the presence of the charged body. It is also assumed that the charge distribution of the positive ions may be represented by a charge density $-\rho_0$, which is unchanged in the presence of the charged body. This assumption is certainly valid if $\rho'(\mathbf{r})$ varies slowly over the lattice spacing.

The general form of ΔE, the change in the energy of the system external charge plus metal, can be easily determined. There must be a term [see Eq. (1)]

$$\Delta E_V=\int \rho'(\mathbf{r})v(\mathbf{r})d\tau, \tag{1'}$$

corresponding to the interaction between the additional charge density $\rho'(\mathbf{r})$ and the potential $v(\mathbf{r})$. Also there is a term [see Eq. (2)]

$$\Delta E_R=\frac{1}{2}\int\int \frac{\rho'(\mathbf{r})\rho'(\mathbf{r}')d\tau d\tau'}{|\mathbf{r}-\mathbf{r}'|}, \tag{2'}$$

for the self-interaction of the additional charge density. The change ΔT in the kinetic energy of the electrons associated with a change in the wave function will have the form of a volume integral of some function of ρ over the metal, minus a volume integral of the same function of ρ_0 over the metal as long as changes in ρ are small within an electron wave-length. Expanding these functions in power series in ρ' and integrating, it is clear that the leading term will be of the form $\int\rho'^2d\tau$ since the terms involving only ρ_0 will cancel and the volume integral of ρ' is zero. Finally there must be a correction term ΔE_A to Eq. (2'), taking account of the reduced interaction between the metal electrons due to correlations of pairs of electrons. By the same argument used in connection with ΔT, ΔE_A will have a leading term $\int\rho'^2d\tau$. Thus

$$\Delta E=\int \rho'(\mathbf{r})v(\mathbf{r})d\tau + \frac{1}{2}\int\int \frac{\rho'(\mathbf{r})\rho'(\mathbf{r}')d\tau d\tau'}{|\mathbf{r}-\mathbf{r}'|}+\kappa\int\rho'(\mathbf{r})^2d\tau, \tag{7}$$

where κ is a constant depending on the detailed quantum properties of the metal electrons.

To estimate the order of magnitude of κ, we apply the Fermi-Thomas-Dirac statistical model to the metal electrons. According to this model, if the electron density is $n=-\rho/e$, the total kinetic energy of the electrons in the metal is

$$T=\left(\frac{3}{8\pi}\right)^{\frac{1}{3}}\left(\frac{3h^2}{10m}\right)\int n^{5/3}d\tau,$$

where the integration is carried out over the volume of the metal. Therefore, for a small change, $n'=-\rho'/e$, in n the change in T is

$$\Delta T=\frac{h^2}{2m}\left(\frac{3n_0}{8\pi}\right)^{\frac{1}{3}}\int n'd\tau+\frac{h^2}{6mn_0}\left(\frac{3n_0}{8\pi}\right)^{\frac{1}{3}}\int n'^2d\tau.$$

The first term vanishes because of the condition for the conservation of charge and we are left with

$$\Delta T=\frac{(2\pi)^2}{6}\left(\frac{3}{8\pi}\right)^{\frac{1}{3}}\frac{h^2}{me^2}n_0^{-\frac{1}{3}}\int\rho'(\mathbf{r})^2d\tau. \tag{8}$$

ΔE_A can be estimated in a similar way. The change in the electron-electron interaction due to the antisymmetrization of plane electron waves is

$$-\frac{3}{2}\left(\frac{3}{8\pi}\right)^{\frac{1}{3}}e^2\int n^{4/3}d\tau,$$

and the change in this quantity associated with a change, n', in n can be obtained just as before. The result is

$$\Delta E_A=-\frac{1}{3}\left(\frac{3}{8\pi}\right)^{\frac{1}{3}}n_0^{-\frac{1}{3}}\int\rho'(\mathbf{r})^2d\tau; \tag{9}$$

so

$$\kappa\approx-\frac{1}{3}\left(\frac{3}{8\pi}\right)^{\frac{1}{3}}n_0^{-\frac{1}{3}}+\frac{(2\pi)^2}{6}\left(\frac{3}{8\pi}\right)^{\frac{1}{3}}\frac{h^2}{me^2}n_0^{-\frac{1}{3}}. \tag{10}$$

κ is of the order of the square of the inter-electronic distance for the free electrons and is a positive quantity; letting β denote the distance into the metal within which ρ' differs appreciably from zero, it is clear that in order to use the Fermi-Thomas approximation β must be larger than the free electron wave-length, or $\beta\gtrsim\kappa^{\frac{1}{2}}$. If β is the distance over which ρ' is not ≈ 0, ρ' in this region is of the order $\sigma(\mathbf{s})/\beta$; then the third term in Eq. (7) is of the order βR^{-1} times the first or second term, and for R large enough it is a small correction. Thus for large R, ρ' will be closely equal to the classical value $\sigma_0(\mathbf{s})\delta(z)$ where $\delta(z)$ is the Dirac delta function. But because of the third term in Eq. (7) we expect ρ' to have a small but non-zero extension in the z direction. The thickness of this region will be estimated below.

In order to evaluate ΔE, let us approximate $\rho'(\mathbf{r})$ by

$$\begin{aligned}\rho'(\mathbf{r})&=\beta^{-1}\sigma(\mathbf{s}) \quad \text{for} \quad z<\beta,\\ &\approx 0 \quad \text{for} \quad z>\beta,\end{aligned}$$

where $\sigma(\mathbf{s})$ is a surface charge density. Then the variation $\delta\Delta E$ in the energy ΔE associated with the variation

$\delta\beta$ in β and $\delta\sigma(\mathbf{s})$ in $\sigma(\mathbf{s})$ is

$$\delta\Delta E=\Big\{-\frac{1}{\beta^2}\int\int_0^\beta v(\mathbf{r})\sigma(\mathbf{s})d\tau+\frac{1}{\beta}\int v(\mathbf{s},\beta)\sigma(\mathbf{s})dS$$
$$-\frac{1}{\beta^3}\int_0^\beta\int_0^\beta\int\int\frac{\sigma(\mathbf{s})\sigma(\mathbf{s}')dSdS'dzdz'}{|\mathbf{r}-\mathbf{r}'|}$$
$$+\frac{1}{\beta^2}\int_0^\beta\int\int\frac{\sigma(\mathbf{s})\sigma(\mathbf{s}')dz'dSdS'}{((\mathbf{s}-\mathbf{s}')^2+(\beta-z')^2)^{\frac{1}{2}}}$$
$$-\frac{\kappa}{\beta^2}\int\sigma^2(\mathbf{s})dS\Big\}\delta\beta+\int\Big\{\frac{1}{\beta}\int_0^\beta v(\mathbf{r})dz$$
$$+\frac{1}{\beta^2}\int_0^\beta\int_0^\beta\int\frac{\sigma(\mathbf{s})dzdz'dS'}{|\mathbf{r}-\mathbf{r}'|}+\frac{2\kappa}{\beta}\sigma(\mathbf{s})\Big\}\delta\sigma(\mathbf{s})dS.$$

This leads to the following two conditions to be satisfied for minimum energy:

$$\int\int_0^\beta v(\mathbf{r})\sigma(\mathbf{s})d\tau-\beta\int v(\mathbf{s},\beta)\sigma(\mathbf{s})dS$$
$$+\frac{1}{\beta}\int_0^\beta\int_0^\beta\int\int\frac{\sigma(\mathbf{s})\sigma(\mathbf{s}')d\tau d\tau'}{|\mathbf{r}-\mathbf{r}'|}$$
$$-\int\int\int_0^\beta\frac{\sigma(\mathbf{s})\sigma(\mathbf{s}')dSdS'dz'}{((\mathbf{s}-\mathbf{s}')^2+(\beta-z')^2)^{\frac{1}{2}}}$$
$$+\kappa\int\sigma^2(\mathbf{s})dS=0, \quad (11A)$$

$$\int_0^\beta v(\mathbf{r})dz+\frac{1}{\beta}\int_0^\beta\int_0^\beta\int\frac{\sigma(\mathbf{s}')dzdz'dS'}{|\mathbf{r}-\mathbf{r}'|}$$
$$+2\kappa\sigma(\mathbf{s})=0. \quad (11B)$$

To zero order in β Eq. (11B) reads

$$v(\mathbf{s})+\int\frac{\sigma(\mathbf{s}')dS'}{|\mathbf{s}-\mathbf{s}'|}=0,$$

and since this is the condition satisfied by the classical surface charge density, $\sigma(\mathbf{s})$ may be written as $\sigma(\mathbf{s})=\sigma_0(\mathbf{s})+\sigma_1(\mathbf{s})$ where $\sigma_0(\mathbf{s})$ is the classical density and $\sigma_1(\mathbf{s})$ is a first order correction term.

For convenience let us define the quantity

$$\theta(\mathbf{r})\equiv v(\mathbf{r})+\frac{1}{\beta}\int_0^\beta dz'\int\frac{\sigma(\mathbf{s}')dS'}{|\mathbf{r}-\mathbf{r}'|}, \quad z\gtrless 0.$$

This is the total potential within the metal, and to a zero order approximation $\theta(\mathbf{r})$ is clearly zero. Using this definition (11A) and (11B) become

$$\int\sigma(\mathbf{s})\theta(\mathbf{s},\beta)dS=-\kappa/\beta\int\sigma^2(\mathbf{s})dS, \quad (12A)$$

$$\int_0^\beta\theta(\mathbf{r})dz=-2\kappa\sigma(\mathbf{s}). \quad (12B)$$

Now according to Eq. (3) θ may be written

$$\theta(\mathbf{r})=v(\mathbf{r})-\frac{1}{\beta}\int_0^z dz'v(\mathbf{s},z-z')$$
$$-\frac{1}{\beta}\int_z^\beta dz'v(\mathbf{s},z'-z)+\frac{1}{\beta}\int_0^\beta\int\frac{dz'\sigma_1(\mathbf{s}')dS'}{|\mathbf{r}-\mathbf{r}'|}.$$

Since $v(\mathbf{r})$ is a well-behaved function of z, we may expand in a Taylor's series about $z=z'$ and obtain

$$\theta(\mathbf{r})=-2\pi\sigma_0(\mathbf{s})\Big[z^2-2z\beta+\frac{\beta^2}{2}\Big]$$
$$+\frac{1}{\beta}\int_0^\beta dz'\int\frac{\sigma_1(\mathbf{s}')dS'}{|\mathbf{r}-\mathbf{r}'|}. \quad (13)$$

Introducing this expression into (12B) results in

$$\int\frac{\sigma_1(\mathbf{s}')dS'}{|\mathbf{s}-\mathbf{s}'|}=-\frac{2\kappa}{\beta}\sigma_0(\mathbf{s})-\frac{\pi\beta}{3}\sigma_0(\mathbf{s}). \quad (14)$$

Putting (13) and (14) in (12A) and integrating, we obtain the thickness of the surface layer

$$\beta=(3/2\pi)^{\frac{1}{2}}\kappa^{\frac{1}{2}}.$$

Now the expression for ΔE (Eq. 7) can be readily evaluated. Substituting (11) in (7) we obtain

$$\Delta E=\frac{1}{2\beta}\int_0^\beta dz\int\sigma(\mathbf{s})v(\mathbf{r})dS$$
$$+\frac{1}{2\beta}\int_0^\beta dz\int\sigma(\mathbf{s})\theta(\mathbf{r})dS+\frac{\kappa}{\beta}\int\sigma^2(\mathbf{s})dS$$
$$=W(R)+\frac{1}{2}\int\sigma_1(\mathbf{s})v(\mathbf{s})dS+\frac{\pi\beta}{2}\int\sigma^2(\mathbf{s})dS,$$

and using (14), there results

$$\Delta_1E\equiv\Delta E-W(R)=(8\pi/3)^{\frac{1}{2}}\kappa^{\frac{1}{2}}\int\sigma^2(\mathbf{s})dS. \quad (15)$$

Since $\int\sigma^2(\mathbf{s})dS$ is of the order $R^{-1}|W(R)|$, this equation shows that for R large compared with the spacing between the free metal electrons the quantum mechanical correction Δ_1E to the classical image energy $W(R)$ is small.

In the case of copper, n_0 is about one free electron per 100 $(\hbar^2/me^2)^3$, and the plane wave estimate of κ is 3.7 $(\hbar^2/me^2)^2$. Thus β becomes 1.3 $\hbar^2/me^2$ or $\beta \approx a$ where a is the lattice spacing. It is apparent that this is not consistent with the assumption we made when we replaced the positive ion charge density by $-\rho_0$, i.e., $\beta \gg a$. But since the region of high electron density coincides with a surface layer in which the positive ion density is larger than $-\rho_0/e$, it appears that we have underestimated the absolute magnitude of the (negative) interaction energy between the electrons and the positive ions. That is, the energy $\Delta_1 E$ which we have calculated appears to be too large. Thus it would seem that by taking into account the discrete character of the positive ions, energy could be gained by further compressing the charge density near the surface. However, it must be recognized that the electrons with which we form the surface density are taken from the top of the Fermi lake, or, since we are dealing with a metal, from the middle of an energy band. The electrons in the lower part of the band concentrate around the positive ions and provide enough shielding so that the discrete character of the ions is pretty well washed out in its influence on the wave function of a mid-band electron. Thus our estimate of β and $\Delta_1 E$ should be reasonable as long as just a few electrons near the top of the Fermi lake are influenced by the presence of the external field.

Since our calculated $\Delta_1 E$ becomes negligible for $R \gg a$, it is assured that the purely quantal properties of the metal are unimportant unless the charge is so close to the metal that surface structure effects are already important.

In the case of a potential due to a point charge $\Delta_1 E$ becomes

$$\Delta_1 E = 0.46 \kappa^{\frac{1}{2}} R^{-1} |W(R)|,$$

and for copper this is

$$\Delta_1 E = 0.89 (\hbar^2/me^2) R^{-1} |W(R)|.$$

It would perhaps be expected that better approximations to $\rho'(\mathbf{r})$, and hence lower values for $\Delta_1 E$, could be made by using smoother functions of z than the step function. A similar calculation using a triangular function in z

$$\rho'(\mathbf{r}) = \frac{2}{\beta^2}(\beta - z)\sigma(s) \quad \text{for} \quad z \leqslant \beta$$

$$\approx 0 \quad \text{for} \quad z \geqslant \beta,$$

results in

$$\beta = (10/3\pi)^{\frac{1}{2}} \kappa^{\frac{1}{2}},$$

$$\Delta_1 E = 2.55 \kappa^{\frac{1}{2}} \int \sigma_0^2(s) dS.$$

Since $(8\pi/3)^{\frac{1}{2}}$ [see Eq. (15)] is 2.89, the energy $\Delta_1 E$ is in fact lowered by this choice of $\rho'(\mathbf{r})$.

For the exponential in z

$$\rho'(\mathbf{r}) = \beta^{-1} e^{z/\beta} \sigma(s),$$

we obtain

$$\beta = (\kappa/2\pi)^{\frac{1}{2}},$$

$$\Delta_1 E = 2.51 \kappa^{\frac{1}{2}} \int \sigma_0^2(s) dS.$$

It should perhaps be mentioned that for some metals (e.g., Bi) the free electronic density n_0 is so small that the plane wave estimate of κ becomes negative. In this case the Fermi-Thomas-Dirac method as used here is inadequate and better wave functions are required to estimate κ.

It has been assumed throughout this discussion that $\rho' \ll \rho_0$. This condition is satisfied for an external charge of the order of e unless it is so close to the metal that surface structure effects have already become important.[1] If a macroscopic point charge, say 10^{10} e, could be brought up to the metal surface, a deviation from classical results would be expected at a distance $R \approx 10^{-8}$ cm. In general the distance R at which deviations are expected is $R \approx Q^{\frac{1}{2}} a$, where Qe is the charge on the macroscopic body assumed to be a sphere of radius r. Then r must necessarily be less than R and the potential V required to charge up the sphere is $Qe/r > Qe/R = (R/a)(e/a) = 27(R/a)$ volts. To observe a macroscopic effect, R/a must be $\gtrsim 10^6$, which requires a potential $V > 10^6$ volts. Thus it seems safe to assume that this effect has no practical importance.

Production of 2537 Radiation and the Role of Metastable Atoms in an Argon-Mercury Discharge

CARL KENTY
Lamp Development Laboratory, General Electric Company, Nela Park, Cleveland, Ohio
(Received July 17, 1950)

The average population of 6^3P_1 mercury atoms is calculated from the measured 2537 output and resonance radiation diffusion theory. Average populations of $6^3P_{2,0}$ are then found by comparing the absorptions of 5461, 4358, and 4047. Populations for a 0.42-amp. discharge in 3.5-mm argon of high purity plus Hg vapor at 42°C in a tube 1½ inches in diameter are for $6^3P_{2,1,0}$ respectively, 7.6×10^{11}, 1.9×10^{11}, and 3.5×10^{11} cm^{-3}; these are ½, 1/20, and ½ of the corresponding Boltzmann populations, for the electron temperature of 11,100°K.

Rates of collisions of the first and second kinds involving electrons (average concentration 2.1×10^{11} cm^{-3}), and the 6^1S_0 and $6^3P_{2,1,0}$ states are calculated using known excitation functions and detailed balancing. The results predict populations for $6^3P_{2,1,0}$ within 10 percent of those observed; they further predict that ⅔ of the observed 2537, ⅔ of the visible triplet, and ¾ of the 3650 group are produced stepwise via 6^3P. Quenching collisions involving argon are assumed negligible.

The results account fairly well for the maximum in the 2537 *versus* Hg pressure curve, for the decrease in the 2537 output efficiency with increasing current, and for the decrease in electron temperature which is associated with both these effects.

INTRODUCTION

THE phosphor in a fluorescent lamp is activated primarily by the resonance radiation of Hg at 2537A. It is a known fact that this radiation does not increase linearly with current as might be expected if excitation and ionization were produced only by single-stage impacts. The present study[1] indicates that two-stage processes involving the resonance and metastable levels of Hg play a far more important role than direct excitation and ionization from the normal state.

In arriving at this conclusion it has been necessary to consider quantitatively the diffusion of resonance radiation, the populations of the $6^3P_{2,1,0}$ states of Hg and the various elementary processes of excitation and de-excitation involving these states.

The discharge studied is a positive column of 420 ma in a 1½-inch tube containing 3½-mm argon plus Hg vapor at $\sim7\mu$ pressure. This is approximately the discharge met with in the standard 40 w fluorescent lamp.

On account of the retarding effect of the argon, few metastable Hg atoms will be able to diffuse to the wall before they are destroyed by collisions with electrons. These collisions will be of a number of types; (1) collisions of the second kind which return the metastable state to the normal state, or in the case of 6^3P_2 to a lower 6^3P state, (2) collisions of the first kind raising a metastable state to a higher excited state, and (3) collisions resulting in ionization of the metastable state. The resonance state 6^3P_1 will suffer similar collisions, but to a smaller extent, owing to its smaller population (as limited by its radiation of 2537). In the attempt to estimate the rates of all these processes it was first necessary to determine the populations of the $6^3P_{2,1,0}$ states with the help of measurements of the relative absorption of the visible triplet lines. These lines, 5461, 4358, and 4047, have 7^3S_1 as a common initial level and end on $6^3P_{2,1,0}$ respectively.

[1] The principal results as stated here were reported at the Columbus Meeting of the Ohio Section of the American Physical Society, March 13, 1948 [Phys. Rev. 74, 114 (1948)] and at the April 1948 M.I.T. Electronics Conference.

ABSORPTION MEASUREMENTS

Absorption measurements were carried out by placing an emission lamp (1) behind an absorption lamp (2) and arranging a slit system requiring that a beam of light originating in (1) pass through (2) before reaching a photo-cell. The slits were 3½-mm wide and 2-cm long, cut in sheets of aluminum foil wrapped around the lamps. Corning monochromatic filters, placed before the cells, were used to isolate the lines. The lamps were placed 1 cm apart. The photo-cell had an opening 1-cm wide and was placed 10 cm in front of lamp (2).

The fractional absorption A of the beam will be given by

$$A=(I_1+I_2-I_{1+2})/I_1, \qquad (1)$$

where I_1 is the intensity of 2537 received when only lamp (1) is on, I_2 the intensity when only lamp (2) is on and I_{1+2} the intensity when both lamps are on. Measurements were made over a current range of 0.1 to 420 ma in the absorption lamp and of 50 to 500 ma in the emission lamp. Results for equal currents in emission and absorption lamps are shown in Fig. 1. Absorptions were read when the wall temperature of the absorption tube was 42°C, as measured by a fine thermocouple on the tube wall. With a current of 420 ma in the emission lamp, its temperature was also 42°C. The lamps were heated solely by their own currents, and in the case of the absorption lamp, the current was dropped from 420 ma only long enough to obtain an absorption reading. In this time the lamp temperature dropped by only a small amount and the absorption, a slowly varying quantity, did not change appreciably.

In Fig. 1, 5461 is seen to be more strongly absorbed than 4047, indicating a higher population for 6^3P_2 than for 6^3P_0. Substantial saturation is seen to set in at

$\sim$100 ma. Since saturation means constancy of population, it is concluded that at $\sim$100 ma the loss of metastables by diffusion to the walls is no longer important as compared with losses by quenching collisions with electrons. Thus beyond $\sim$100 ma the processes of excitation and destruction of metastables, both being proportional to the electron concentration, will increase with current at about the same rate so no great change in population will result.

The absorption of 4358 in Fig. 1 is seen to be the smallest and to show distinctly less saturation than the others. This is due to the fact the loss of 6^3P_1 by radiation is still high compared with loss by collisions of the second kind with electrons.

Regarding the saturation of the metastable populations at low current, it is instructive to consider the time taken for a metastable to reach the walls. Thus with a mean free path of $\sim$0.006 cm, and a speed of $\sim 1.8\times10^4$ cm sec.$^{-1}$, a metastable will require a time of the order of

$$(1.8/0.006)^2\times0.006/(1.8\times10^4)\cong0.03 \text{ sec.},$$

to reach the wall of a tube 1.8 cm in radius. Calculations show that this is ample time for dissipative collisions with electrons to occur, even with small currents. This means that the distribution of metastables over the cross section of the lamp will be much flatter than that of the resonance atoms as Fabrikant[2] has shown.

The gas in the lamps contained <2 parts per million of impurities and quenching of the 6^3P Hg states by them was negligible. Complete evidence for this, and further evidence concerning the saturation of the metastable populations, resulting from an extended study of these discharges at low currents will be given in a later paper. Quenching of metastables by argon is negligible in comparison to quenching by electrons (cf. the work of Panevkin, to be discussed further below).

While the absorption data were obtained with a d.c. discharge, and the 2537 and visible triplet data were obtained with the usual a.c. discharge, this is probably not of great importance here since within the present accuracy the a.c. and d.c. spectral characteristics are similar.[3]

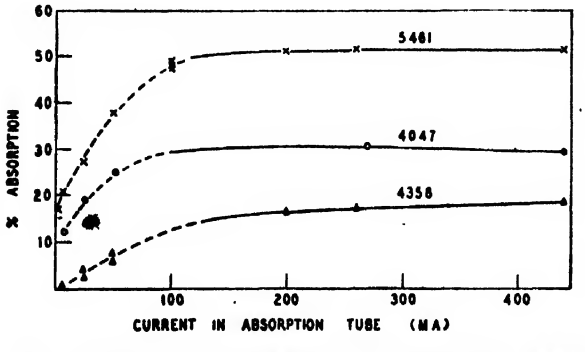

FIG. 1. Absorption of the visible triplet lines of Hg in passing through a d.c. discharge in a mixture of 3.5-mm $A+8\mu$ Hg vapor in a 3.6-cm diameter tube. Emission lamp is a similar tube. Above 100 ma similar currents are used in both tubes for each experimental point. At the higher currents the Hg pressure in the emission tube is also about 8μ.

CALCULATION OF THE RELATIVE POPULATIONS OF THE $6^3P_{2,1,0}$ STATES FROM THE ABSORPTIONS

If in the above absorption study the line radiation passed through the absorbing gas unchanged in nature, the number of absorbing atoms would be proportional to A, for small absorptions, and in general to $\log(1/1-A)$. The values of $\log(1/1-A)$ for 0.42 amp have been evaluated, and their ratios are given in Table I. But the core of the line is relatively the most absorbed and so the line is broadened as it passes through the discharge. Also the breadths of the lines from the emission tube will in general be different. There is one case however solved by Ladenburg and Reiche,[4] where k_0, the absorption coefficient of the core of the line can be deduced from the measured A; this is the case where conditions in the emission and absorption tubes are the same. It was for this reason that care was taken to have currents and temperatures the same at 420 ma in Fig. 1. The value of k_0 for the different lines has been evaluated, using the relation of Ladenburg and Reiche, from the A values of Fig. 1 and are given in Table I. The procedure has followed that of Fabrikant, Butaeva, and Zirg.[5] It has been stated by these authors that the atomic absorption coefficients for the lines of the visible triplet are all equal; this can be proved by application of the sum rules and the Einstein theory of radiation. Consequently the average concentrations of the absorbing atoms will be proportional to the k_0's in Table I, where the ratios are given in the last column.

It will be seen that the k_0's give somewhat smaller relative populations to 6^3P_1 and 6^3P_0 than do the values of $\log(1/1-A)$. This is to be expected since 4358, for example, is relatively sharper coming from the emission lamp than 5461 and, therefore, is more highly absorbed, per absorbing atom.

CALCULATION OF THE POPULATION OF 6^3P_1 ATOMS FROM THE 2537 OUTPUT

Thayer and Barnes[6] determined that in the present lamp operating on a.c. at 420 ma in 3.5-mm A plus Hg at 7.6μ (43°C), about 60 percent of the 40w input, or 24 watts, is converted into radiation able to excite the phosphor. According to further unreported work by the same authors in this laboratory, probably 2 watts of this is 1849 radiation; 22 watts is therefore taken as the 2537 output. Division of this by the length of the dis-

[6] R. N. Thayer, Trans. Electrochem. Soc. 87, 413 (1945).

charge, about 110 cm, between electrodes, and by the energy equivalent of the 2537 quantum (7.78×10^{-19} joule) gives the rate of escape R of 2537 quanta to be 2.5×10^{17} per cm length per second. Assuming that net quenching losses of the 6^3P_1 state are small, and for simplicity that the radial distribution of 6^3P_1 atom concentration n_1 will be roughly the parabolic one

$$n_1=(n_1)_0[1-(r^2/a^2)], \tag{2}$$

where $(n_1)_0$ is the concentration at the center and a is the tube radius, the concentration gradient at the wall will be $-2(n_1)_0/a$ and this multiplied by the diffusion coefficient of the radiation D and the circumference of the tube $2\pi a$ should give the rate of escape. Thus

$$R=4\pi(n_1)_0D. \tag{3}$$

The diffusion coefficient used is the approximate one arrived at by the author[7] and put into more convenient form by Zemansky.[8] Namely,

$$D=1/(4\bar{k}^2\tau). \tag{4}$$

Here τ is the mean life of the 6^3P_1 state (1.08×10^{-7} sec.) and $\bar{k}^2$ is the effective average square absorption coefficient. Tables for $\bar{k}$ the r.m.s. or "equivalent" absorption coefficient are given by Zemansky[9] in the form of $\bar{k}l$ as a function of k_0 where l is the thickness of the absorption cell and k_0 is the absorption coefficient of the core of the line. For the present case $k_0=n_ak_0'$ where k_0' is the atomic absorption coefficient for the core of the line and n_a is the concentration of Hg atoms. Substitution[10] of $k_0'=1.21\times10^{13}$, $n_a=2.13\times10^{14}$ cm^{-3} and $l\cong4/3a$ or 2.4 cm, gives $k_0=27$, $\bar{k}=6.7$ and $D=5.2\times10^4$.

Substitution for D and R in Eq. (3) then yields for $(n_1)_0$ the value 3.8×10^{11} cm^{-3}, an average value of n_1 over the cross section of 1.9×10^{11} cm^{-3}, and a total number N in a 1-cm length of tube (cross section ~10 cm^2) of 1.9×10^{12}. To account for the observed output, $R=2.5\times10^{17}$ per sec. per cm, the effective life T of the 2537 quantum within the tube would need to be $N/R=0.76\times10^{-5}$ sec.

The reciprocal of $\bar{k}$ is the effective mean free path or 0.15 cm. According to the principle of the random walk, the number of absorptions and re-emissions suffered by a quantum generated at the center before escape will be of the order of $(a/\lambda)^2$, i.e., $(1.8/0.15)^2\cong140$. The average for all quanta will be less than this; half the above number or 70 would be closely in accord with value of effective life of 0.76×10^{-5} sec. arrived at above.[11]

[8] M. W. Zemansky, Phys. Rev. 42, 843 (1932).
[9] See also reference 4, Table XII, p. 331.
[10] k_0' has been calculated from Garrett's value of τ of 1.08×10^{-7} sec., following Zemansky, Phys. Rev. 36, 229 (1930). n_a has been calculated for 7.6μ Hg pressure on an average gas temperature in the lamp of 73°C (346°K) as found in work in this laboratory to be reported elsewhere.
[11] V. A. Fabrikant, Comptes Rendus U.S.S.R. 19, 389 (1938) gives the approximate expression $3k_0a\tau$ for this effective life. With $k_0=26$, $a=1.8$ cm and $\tau=1.08$ sec. This expression gives $T=1.5\times10^{-5}$ sec. which is twice the value obtained here.

TABLE I. Absorption of the visible triplet. A, absorption taken from Fig. 1; k_0, absorption coefficient for core of line as obtained from Ladenburg and Reiche's relation between k_0l and A (reference 3 l has been taken as 3.6 cm).

Line	A	Relative $\log(1/1-A)$	k_0	Relative k_0
5461	0.51	100	0.32	100
4358	0.18	28	0.083	25
4047	0.30	49	0.15	46

The problem may be attacked alternatively using the more recent and exact radiation diffusion theory of Holstein.[12] According to this theory, the distribution of 6^3P_1 atoms across a tube quickly assumes a characteristic form after the excitation, in whatever manner, is cut off, and the 2537 emitted thereafter decays with a characteristic time T given by[13]

$$T=\tfrac{5}{8}k_0a\tau(\pi\log k_0a)^{\frac{1}{2}}, \tag{5}$$

where a is the tube radius. Substitution of the values of the constants already used yields $T=0.72\times10^{-5}$ sec. This value of the decay time, or average life, is seen to be only slightly smaller than the average life obtained by the first method (0.76×10^{-5} sec.); which attests to the essential equivalence of the two methods for a case like the present. The first method suffers from the arbitrariness of the choices of the parabolic distribution and of the value of $l=(4/3)a$ as the thickness of the equivalent absorption cell. In the second method, the formula used applies to the characteristic distribution of 6^3P_1 atoms and not necessarily to the distribution existing in the actual discharge. In any case, since the practical difference in the two methods appears to be so small, the results will be left in their original form as based on $T=0.76\times10^{-5}$ sec.

THE POPULATIONS OF THE $6^3P_{2,1,0}$ STATES

If there were thermal equilibrium between the 6^3P states and the electrons at their temperature T_e, their populations would be given by

$$n=n_a(g/g_a)e^{-(eV_e)/(kT_e)}, \tag{6}$$

where $n_a=2.13\times10^{14}$ is the concentration of normal atoms, g_a is the statistical weight of the normal atom, g is the weight of the 6^3P atom in question, and V_e is its excitation potential. For T_e the value of 11,100°K is used, based on probe measurements made in this laboratory by M. A. Easley.[14] The populations as thus calculated are given in Table II. The last column of the table gives the ratios of the populations calculated from absorption to the Boltzmann populations.

[13] Alpert, McCoubrey, and Holstein, Phys. Rev. 76, 1257 (1949). The formula as quoted in their article inadvertently omits the factor τ.
[14] The author is indebted to Miss Easley for permission to use her unpublished values for both T_e and n_e.

TABLE II. Comparison of populations with Boltzmann populations. V_e, excitation potential; g, statistical weight; k_0, absorption coefficient of core of line (from Table I); n, calculated from the ratio of the k_0's and $n=1.9\times10^{11}$ cm^{-3} for 6^3P_1, obtained from output and diffusion of 2537; n_B, Boltzmann population for $T_e=11{,}100°$K.

State	V_e	g	Ratio k_0	$n\times10^{11}$	$n_B\times10^{11}$	n/n_B
6^3P_2	5.43	5	100	7.6	36.4	0.21
6^3P_1	4.86	3	25	1.9	40.2	0.047
6^3P_0	4.66	1	46	3.5	16.3	0.21

The use of a temperature here for the electrons is taken to be justified even though the distribution may differ from Maxwellian in being deficient in the very high speed members; for the experiments of Miss Easley indicate that such deficiency occurs only for electrons of considerably higher energy than is here involved.

Fabrikant, Butaeva, and Zirg[15] calculated absolute values for the populations of $6^3P_{2,1,0}$ directly from their absorption measurements. They deduced k_0 in each case from the measured absorption by use of the Ladenburg-Reiche formula, as was done above, and used known relations[16] connecting the k_0's with τ, the mean life of the 7^3S_1 state. For τ they used Mitchell and Murphy's value[17] of $0.8\pm0.1\times10^{-8}$ sec. They assumed Doppler broadening and that therefore (with gas atoms at substantially room temperature) the five hyperfine structure components did not overlap, so that the number of absorbing atoms was $\frac{1}{5}$th the number in the state concerned. If the same procedure is followed here, populations are obtained which are about a third those found above. Panevkin[18] following the same procedure as Fabrikant, Butaeva, and Zirg, and studying a discharge rather similar to the present one, has obtained $6^3P_{2,1,0}$ populations one-third to one-fourth as large as those found here. It is believed that the optical densities involved are too great for such application (in the absolute) of the Ladenburg-Reiche formula, the values of k_0 derived with it being too small. Such an error becomes very pronounced[19] if an attempt is made to apply this method to the case of the 1-At. Hg arc where the densities of the 6^3P atoms are about 100-fold higher. Since the populations in Fabrikant, Butaeva, and Zirg's discharge were of the same order as those found here, it is believed their estimates are too low, perhaps by a factor of 2 or 3. In accord with this is the fact that they need populations several-fold higher than they calculate, in order to explain their observed 2537 output.[20]

QUASI EQUILIBRIUM FOR THE METASTABLE STATES

It was at first thought that the flatness of the absorption curves for these states in Fig. 1 indicated a true state of thermal equilibrium with the electrons. However, Table I does not indicate this. Further, following Panevkin,[21] true thermal equilibrium in a case like this would require, not constant populations with regard to current increase, but decreasing ones due to the fact that T_e decreases with current. It is concluded therefore that the absorption curves represent a state of quasi equilibrium with the electrons in which detailed balancing is not yet complete. Thus the populations of the metastable states are determined solely by electron collisions and the balance (not yet a Boltzmann one) changes only slowly with the current. All 6^3P states are closely tied together through collisions of the first and second kinds as Yavorsky[22] has shown; as will appear below, 6^3P_2 and 6^3P_0 are held below Boltzmann populations because of the important "leakage" of 2537.

The flatness of the absorption curves, considering the falling T_e, really means a gradual approach toward true thermal equilibrium conditions in which $^3P_2$ for example would be quenched to normal by electrons as fast as

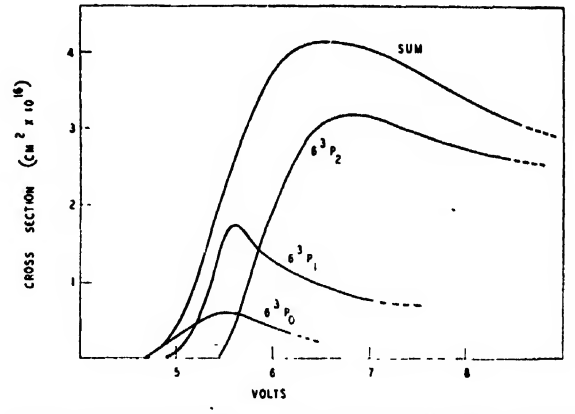

FIG. 2. Excitation function for the 6^3P states of Hg. That for 6^3P_1 is Nottingham's photoelectrically determined curve. The relative heights of the maxima of the three curves and also as far as possible their relative shapes are in accord with the quantum mechanical calculations of Penney and of Yavorsky. The scale of the three curves and some details of their shapes are chosen so that their sum reproduces the curve of Arnot and Baines, obtained from purely electrical measurements.

[16] See reference 4, p. 101 ff., where $1/\tau$ of Eq. (35) is to be replaced by the Einstein transition probability A, for the line in question and the measured τ of the 7^3S_1 state is the reciprocal of the sum of the A's for the green blue and violet lines. The relation between the A's being given by the sum rules which state that $A\propto g\nu^3$, g being the statistical weight of the lower state concerned, and ν being the frequency of the line.

[19] Using Barnes and Adams' [Phys. Rev. **53**, 545 (1937)] measurements of the absorption of 5461, 4358, and 4047 for a $\frac{1}{4}$-atmosphere pressure Hg arc, the same method has yielded populations for the 6^3P states which are at least 25-fold smaller than those calculated from Boltzmann's theorem and the temperature as determined by x-rays [C. Kenty and W. J. Karash, Phys. Rev. **78**, 625 (1950)].

[20] While the authors seem to obtain an agreement, they base it on a speed of escape of 2537 through the Hg vapor which is much faster than that allowed by the present treatment of radiation diffusion or by Fabrikant's own (presumably) later treatment (reference 11).

excited from normal and all other processes would be balanced by their opposites.

COMPUTATION OF THE RATES OF EXCITATION OF THE $6^3P_{2,1,0}$ STATES

While existing knowledge of the excitation functions for the 6^3P states of Hg leaves much to be desired, the following calculations, based on what are judged to be the best of the evidence, yield results which are in remarkably good agreement with the observed 2537 output. This agreement is believed to lend substantial support to the essential validity of the functions chosen. For 6^3P_1 Nottingham's photoelectric relative excitation function[23] has been used. For 6^3P_0 and 6^3P_2, approximate relative shapes for the functions have been taken from Penney's[24] and Yavorsky's quantum mechanical calculations.[25] The functions chosen are shown in Fig. 2. The relative heights of the three maxima are approximately also in shape with that found by Arnot and Baines[26] from purely electrical measurements of inelastic cross sections.

This procedure gives a maximum for 6^3P_1 substantially in agreement with Bricout's optically determined value of 6 cm² cm⁻³ or 1.7×10^{-16} cm² as quoted by Brode.[27,28] (The latter number is obtained from 6 cm² cm⁻³ by dividing by 3.56×10^{16}, the number of molecules in 1 cm³ of gas at 1 mm pressure and 0°C.) All cross section maxima used or deduced in the present study are assembled in Table III.

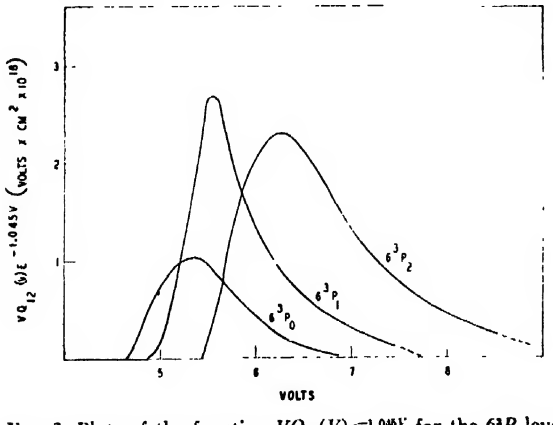

FIG. 3. Plots of the function $VQ_{12}(V)\epsilon^{-1.045V}$ for the 6^3P levels of Hg. $Q_{12}(V)$ is the cross section in cm² for the excitation of the level by electrons of energy V volts. The areas under the curves are proportional to the rates of excitation of the levels.

Assuming a Maxwellian distribution for the electrons, the rate of excitation Y per cm of length will be given by

$$Y=2.66\times10^{14}\frac{a^2n_en_a}{T_e}\int_{V_e}^{\infty}VQ_{12}(V)\epsilon^{-(eV/kT_e)}dV, \quad (7)$$

where $Q_{12}(V)$ is the excitation cross section in cm² as a function of the electron energy V in volts and n_e is the electron concentration averaged across the tube (2.1×10^{11} cm² according to Easley's[14] probe measurements). With $a=1.8$ cm and $T_e=11{,}100$°K, Eq. (7) becomes

$$Y=1.64\times10^{20}n_a\int_{V_e}^{\infty}VQ_{12}(V)\epsilon^{-1.045V}dV. \quad (8)$$

Plots of the quantity $VQ_{12}(V)\epsilon^{-1.045V}$ are given in Fig. 3. The areas under these curves were found graphically and taking $n_a=2.13\times10^{14}$ cm⁻³, the rates of excitation were found to be 1.35×10^{17}, 0.90×10^{17} and 0.40×10^{17} for the $6^3P_{2,1,0}$ states respectively.

An attempt has been made in Fig. 4 to portray the various transitions. Here the thickness of the 6^3P levels have been drawn pictorially in the ratios of the populations, i.e., calculated n values in Table II. Transitions by collisions of the first kind (excitation by electrons) are represented by straight arrows pointed upward, and collisions of the second kind (de-excitation by electrons) by straight arrows pointed downward. Radiations are represented by wavy arrows. A strength of 3×10^{16} transitions per sec. per cm length has been given to full arrows (either straight or wavy). Dotted arrows have the strengths indicated in decimals of the same unit. The relative total rate of any transition may then be visualized by adding the number of full arrows involved and the decimal part of an arrow. Thus the rates of excitation from normal of the $6^3P_{2,1,0}$ states calculated above are represented by 4.5, 3.0, and 1.33 arrows respectively, and the absolute rates may be found by multiplying these numbers by 3×10^{16}. Wavy arrows represent *measured* outputs in all cases.

QUENCHING TO THE NORMAL STATE

In complete thermal equilibrium with the electrons at their temperature T_e, quenching of any level to the normal state by electrons would, by the principle of detailed balancing, take place at the same rate as excitations to that level from the normal state. Since the rate of quenching will be proportional to the population of the upper state in question, and since the populations of the metastable states have each been estimated as 0.21 times the Boltzmann populations, their rates of quenching to normal by electrons will be 0.21 times their rates of excitation from normal, which rates have been calculated above. Likewise the rate of quenching of 6^3P_1 to normal will be 0.047 times the rate of excitation from normal. These quenching rates are shown by downward arrows in Fig. 4; 0.95 arrow for 6^3P_2, 0.14 arrow for 6^3P_1, and 0.28 arrow for 6^3P_0. The sum of these, 1.37, is 16 percent of the total excitations from normal.

Calculation of the actual quenching cross section curves[29] brings out the interesting circumstance that the maxima of these curves are all about equal (see Table III), while the Q_{12} maxima are approximately in the ratio of the g's.

The escaping 2537 has been represented in Fig. 4 as 8.3 wavy arrows to represent the measured 2537 output. The heavy wavy arrows represent the absorptions and re-emissions of 2537 before they escape; they have a strength each of the order of $\sim 70 \times 8.3$ or ~ 580 of the other full arrows. Their effect is merely to increase about 70-fold the effective lifetime of the 6^3P_1 state, a circumstance which has already been taken account of in calculating the population of this state.

TRANSFERS AMONG THE $6^3P_{2,1,0}$ STATES

The electronic excitation function for the $6^3P_1 \rightarrow 6^3P_2$ transition has been calculated from quantum mechanics by Yavorsky.[22] This is shown in Fig. 5. Again using Eq. (8) and n (in place of n_a) as 1.9×10^{11} cm^{-3} for the 6^3P_1 state, the rate of such excitations has been calculated to be 3.27×10^{16} cm^{-1} sec.$^{-1}$. This is represented by 1.09 upward arrows in Fig. 4. Figure 5 also shows the cross section $Q_{21}(V)$ for collisions of the second kind[29] quenching 6^3P_2 to 6^3P_1.

To calculate the rate of quenching transfers 6^3P_2

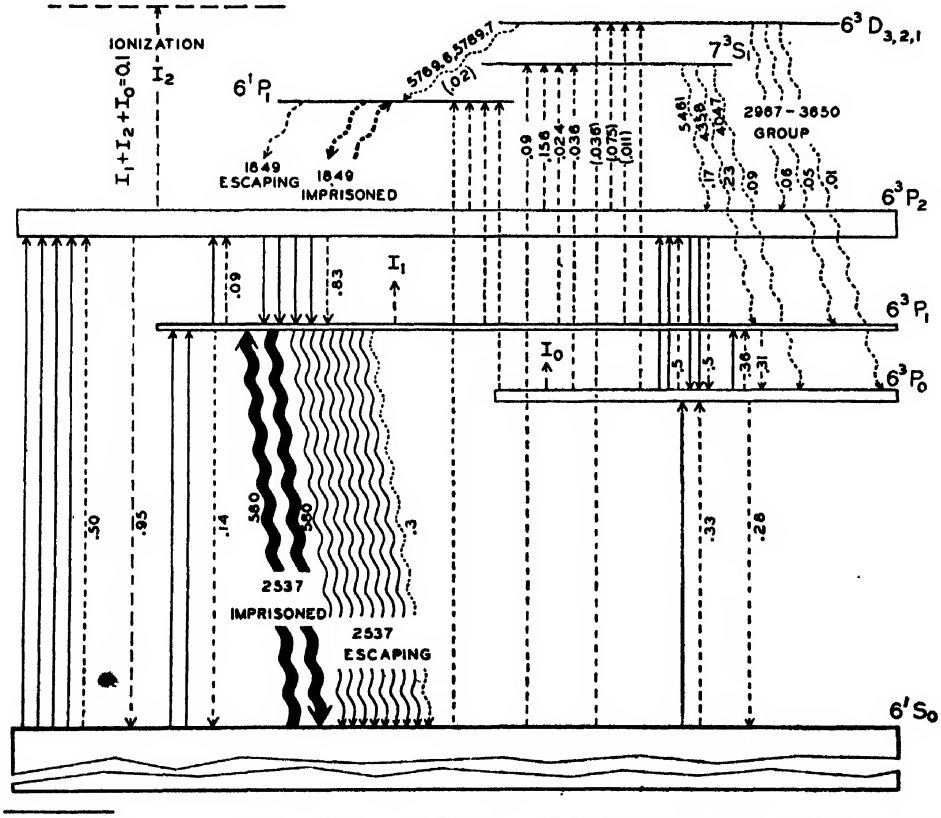

FIG. 4. Principal processes occurring in the fluorescent lamp. Straight arrows are calculated collisions of the first and second kinds. Wavy arrows are measured radiation outputs (except the heavy arrows). One full arrow, either straight or wavy represents 3×10^{16} transitions per sec. per cm of length. Decimals are fractions of full arrows. (*Correction added in proof:* There should be three full upward arrows from $6'S_0$ to 6^3P_1 instead of two as shown.)

[29] Quenching curves, $Q_{21}(V)$, have been calculated from the corresponding $Q_{12}(V)$ curves using the Klein-Rosseland relationship

$$Q_{21}(V) = \frac{g_1}{g_2} \frac{V}{V - V_e} Q_{12}(V),$$

where it is to be understood that V in $Q_{21}(V)$ on the left hand side is equal to $V - V_e$ on the right-hand side, and g_2 and g_1 are the statistical weights of the upper and lower states respectively. However, as seen above, it is not necessary to use these curves explicitly, a fact which seems not to be generally recognized.

$\rightarrow 6^3P_1$, it is first noted that if 6^3P_1 had a full Boltzmann population, the upward transition rate ($6^3P_1 \rightarrow 6^3P_2$) would be $(1/0.047) \cong 21$ times as great as it is, other things being equal, since 0.047 is the fractional Boltzmann population of 6^3P_1 (Table II). This rate of transitions (69×10^{16} sec.$^{-1}$ cm^{-1}) would also be the rate of downward ($6^3P_2 \rightarrow 6^3P_1$) transitions if 6^3P_2 had its full Boltzmann population. But since its population is actually 0.21 times this, the downward rate will be $0.21 \times 69 \times 10^{16} = 14.5 \times 10^{16}$ sec.$^{-1}$ cm^{-1}. This is shown as 4.83 downward arrows in Fig. 4. To calculate the rate of transitions in one direction from the known rate in the other direction, it is therefore only necessary to multiply by the ratio of the fractional Boltzmann populations.

Unfortunately no information exists regarding cross sections for transfers between 6^3P_0 and $6^3P_{2,1}$ states. But certain inferences may be drawn on the basis of the scheme of Fig. 4. Thus both 6^3P_2 and 6^3P_0 have, in this scheme, one quarter the Boltzmann population concerned. Transfers between the two states up and down must therefore take place at the same rate, just as they would in complete thermal equilibrium (when they would be ~five times as fast). Whatever the rate of the transfers, they will therefore not significantly change the scheme of Fig. 4 as drawn. The allotment of $2\frac{1}{2}$ arrows up and $2\frac{1}{2}$ down is arbitrary, but is compatible with a cross section for $6^3P_0 \rightarrow 6^3P_2$ of the same order as that for the $6^3P_1 \rightarrow 6^3P_2$ transfer and is in accord with evidence drawn from low current studies to be reported elsewhere. Here as elsewhere it is assumed that the number of transfers brought about by impacts of atoms or ions is negligible.[29a]

It is possible to draw more definite information regarding the transitions $6^3P_0 \rightarrow 6^3P_1$ and their reverse. Thus, in order to maintain 6^3P_0 at the constant population shown, there must be in total as many arrows leaving as ending on it. Now since a net gain of 1.05 arrows, as above defined, has already been calculated for it involving 6^1S_0, and since transfers to and from 6^3P_2 are equal and no other important losses or gains are involved, as will be seen, transfers involving $6^3P_0 \rightleftarrows 6^3P_1$ must be chosen so as to give a net gain of 1.05 arrows to 6^3P_1 from 6^3P_0. Let x be the upward rate and y the downward rate. Then $x-y=1.05$ and $x/y=0.21/0.047$ (the ratio of the fractional Boltzmann populations of Table II). Solution of these equations gives $x=1.36$, $y=0.31$. This selection of x and y would result if the cross section for $6^3P_0 \rightarrow 6^3P_1$ were 75 percent of that for 6^3P_1 and 6^3P_2. It thus appears that the cross sections for excitation from one 6^3P state to another are not greatly different from one another.

TRANSFERS INVOLVING 7^3S_1

Fabrikant, Butaeva, and Zirg[5] have concluded from their experiments that the cross sections for excitation

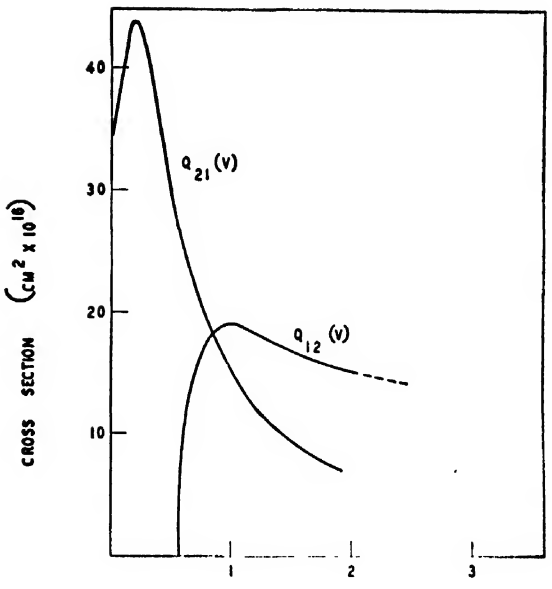

FIG. 5. $Q_{12}(V)$: Cross section for electron collisions exciting 6^3P_2 from 6^3P_1 (Yavorsky, reference 22). $Q_{21}(V)$: Cross section for collisions of the second kind with electrons returning 6^3P_2 to 6^3P_1. Yavorsky expresses his cross sections in the atomic units $10^{16}\pi a_0^2$ (=0.87 cm^2) per cm^3 at one mm pressure of the atoms concerned, where a_0 is the radius of the first Bohr orbit of the H atom (0.528×10^{-8} cm). The conversion factor is therefore $0.87/3.56 \times 10^{16} = 2.45 \times 10^{-17}$, so that his maximum of 78 in his units equals 19.4×10^{-16} cm^2.

of 7^3S_1 from $6^3P_{2,1,0}$ are an order of magnitude higher than that for excitation of 7^3S_1 from 6^1S_0. Their estimate was based on the observed faster-than-linear increase of the visible triplet lines with current in a pure Hg discharge at constant pressure. They had estimates of the concentrations of $6^3P_{2,1,0}$ from absorption measurements and knew n_e and T_e (the latter being assumed constant as the current varied). Having estimated the fraction of the visible triplet output due to cumulative excitation at any current, they then calculated excitation cross sections assuming that the shapes of the functions were similar to that for 6^1P_1 excitation from the normal state (broad maxima since no change in multiplicity is involved), and that the functions for all the 6^3P states were the same in magnitude at any given voltage above threshold. The resulting cross sections were 12.5 cm^2 per cm^3 (3.5×10^{-16} cm^2) at the maxima.

Yavorsky[30] has more recently calculated quantum mechanically $Q_{12(V)}$ for $6^3P_0 \rightarrow 7^3S_1$ and $6'S_0 \rightarrow 7^3S_1$. His curves are shown in Fig. 6. The maximum for $6^3P_0 \rightarrow 7^3S_1$ is seen to be 3.9×10^{-16} cm^2 (in rather good accord with Fabrikant, Butaeva, and Zirg's results) and that for $6^1S_0 \rightarrow 7^3S_1$ to be 0.45×10^{-16} cm^2. The latter is also in quite good accord with the value 0.64×10^{-16} cm^2 (1.2 cm^2 per cm^3) obtained earlier by Hanle and Schaffernicht.[31] The maximum in the case of $6^3P_0 \rightarrow 7^3S_1$ is seen to be relatively very broad.

[29a] Some of the evidence for this is summarized by C. Kenty, Phys. Rev. 42, 823 (1932). See especially pp. 838, 839.

[30] B. Yavorsky, Comptes Rendus U.S.S.R. 48, 175 (1945).

[31] W. Hanle and W. Schaffernicht, Ann. d. Physik 6, 905 (1930).

The upward arrows in Fig. 4 have been calculated using the curves of Fig. 6 and the concentrations of $6^3P_{2,1,0}$ given in Table II, and assuming that the cross sections for all three 6^3P states are the same. These add up to a total of 0.31 arrow or 0.93×10^{16} transitions sec.$^{-1}$ cm^{-1}. This indicates that about two thirds of the excitation of 7^3S_1 comes via the $6^3P_{2,1,0}$ states.

THE OUTPUT OF 5461, 4358 AND 4047

The 7^3S_1 state will radiate these lines in the ratio 100:117:49, i.e., in the ratio $g\nu^3$. However, these ratios will be modified somewhat by absorption. Thus 5461, being more strongly absorbed will be weakened relatively to the others and particularly with respect to 4358 which is least absorbed. It is to be noted however that the number of quanta emitted is not changed by absorption since the population of 7^3S_1 is too small for detectable quenching. The calculated excitation rate of 7^3S_1 may thus be compared with the measured rate of emission of the visible triplet.

According to Forsythe and Adams,[32] the outputs of 5461, 4358, and 4047 from the lamp under consideration (40 watt) amount to 0.6 percent, 1.05 percent, and 0.45 percent respectively, of the positive column input (about 33 watts). Converting these to quanta per sec. per cm length one obtains 0.50×10^{16}, 0.70×10^{16}, and 0.28×10^{16}, respectively (corresponding wavy arrows shown in Fig. 4). The sum of these is 1.48×10^{16} sec.$^{-1}$ cm^{-1} and it is seen that the calculated excitation rate of 7^3S_1 (0.93×10^{16} sec.$^{-1}$ cm^{-1}) falls short of this by 37 percent.

The degree of accord is considered good in view of the assumptions made. The disagreement might be accounted for if (a) Yavorsky's excitation function for $6^3P_0\rightarrow7^3S_1$ does not rise sharply enough from onset, or (b) the assumption of the equality of the excitation cross sections for all three transitions $6^3P_{2,1,0}\rightarrow7^3S_1$ is incorrect, or if (a) and (b) are both partly true. (a) seems to be a possibility since in the case of the excitation functions for the 6^3P states from normal, Yavorsky's theoretical curves[25] do not rise nearly as sharply from the onset as the experiments of Nottingham or Arnot and Baines would indicate. In regard to (b) it might be noted that if the cross section for $6^3P_2\rightarrow7^3S_1$ were increased by a factor of two, the discrepancy would be removed.

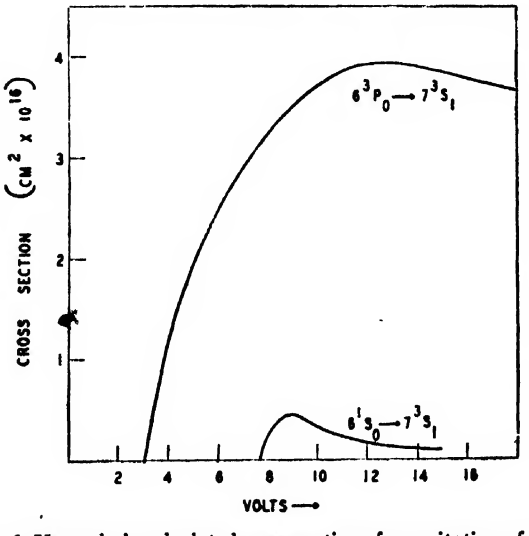

FIG. 6. Yavorsky's calculated cross sections for excitation of 7^3S_1 from 6^1S_0. Reproduced from reference 30, p. 177.

As to the experimental cross sections of Fabrikant, Butaeva, and Zirg,[5] which agree quite well with Yavorsky's[30] results, at least as to the heights of the maxima, it may be that they have, in their calculations, used a function which rises more steeply from onset than does Yavorsky's in order to account for the output. While their estimate seems to be quite good, it is believed that it involves two rather large errors which substantially neutralize each other: (1) Their estimates of 6^3P populations, based on absorption, are, according to the views mentioned above, two- or threefold too low; while (2) the fraction of the visible triplet taken by them to be due to cumulative acts is probably too small by a factor of two or more because of their assumption of the constancy of T_e as the current in their discharge in 1μ pure Hg vapor is raised. Thus their measured 2537 output per electron is markedly decreasing with rising current, showing a falling T_e, and since the direct excitation of 7^3S_1 per electron should decrease faster than that of $6^3P_{2,1,0}$ (i.e., than the 2537 output), it follows that the remainder of the 7^3S_1 excitation, namely that due to cumulative acts, must be greater than they have assumed. Their curves indicate that an error of a factor of two could thus easily have been made. In any case it seems likely that at least 67 percent of the excitation of 7^3S_1 in the fluorescent lamp under consideration comes stepwise via the 6^3P states.

TRANSFERS INVOLVING $6^3D_{3,2,1}$

Cross sections for the excitation of the $6^3D_{3,2,1}$ states (treated as one) have been roughly estimated from the data given by Forsythe and Adams.[32] These authors give as the output of the 40 watt fluorescent lamp the following: for the three lines ending on 6^3P_2 (called 3654), 0.32 percent; for the two lines ending on 6^3P_1 (called 3121), 0.37 percent; and for the yellow lines together, 0.12 percent of the positive column wattage (33 watts). A little over half of the energy of the yellow lines may be taken as coming from 6^3D, i.e., about 0.07 percent. Also the energy of the single line ending on 6^3P_0 (2967) may be taken[33] as 25 percent of that of the 3654 group or 0.08 percent. These percentages have been converted into quanta per sec. per cm length of lamp and are represented by the arrow strengths shown in Fig. 4. The total of the transitions amounts to 4.3×10^{15} sec.$^{-1}$ cm^{-1} or 0.14 arrow. It has been found

[32] W. E. Forsythe and E. Q. Adams, reference 3, Table 11, p. 86.

[33] Private information of Dr. B. T. Barnes.

that this total rate of excitation of 6^3D can be accounted for on the basis of excitation cross section curves, the same as were used for calculating 7^3S_1 transitions but increased 10 percent in magnitude. According to these curves the excitation of 6^3D is distributed as indicated by the arrows in Fig. 4, 75 percent of it coming from the 6^3P states.

TRANSFERS FROM $6^3P_{2,1,0}$ TO 6^1P_1

No data exist for estimating the transfers from the 6^3P states to 6^1P_1. If the cross sections were the same as for the transfers 6^3P to 7^3S_1, a rough calculation shows that transfers would take place about twice as fast to 6^1P_1 as to 7^3S_1. This would give such transfers an importance too small to upset the balance of Fig. 4 appreciably. That such transfers are relatively few is also indicated by the work of Butaeva and Fabrikant[34] which shows that the excitation of 1849, unlike that of 2537, is mainly directly from the normal state.

IONIZATION OF THE 6^3P STATES

The work of Klarfeld[35] has indicated that the cross sections for the ionization of the 6^3P states are an order of magnitude higher than that for ionization of 6^1S_0. Unpublished calculations made on this basis, and observations in this laboratory to be reported later, have indicated that practically all the ionization in the present lamp comes from 6^3P. The importance of such transfers for the present picture can be estimated from observed positive ion current to the wall, $\sim 50\mu$a cm^{-2}, or $\sim 500\mu$a per cm of length. This amounts to 3×10^{15} ions sec.$^{-1}$ cm^{-1}, a relatively negligible effect. It is to be noted that on account of the relative nearness of 6^3P_2 to ionization and of its relatively high population, most of the ionization will come from this state. Direct experimental evidence of this has been found in this laboratory and will be published elsewhere.

DISCUSSION

The various transitions shown in Fig. 4 have been summarized in Table IV, with a view to showing the degree of balance attained for each state. As for 6^3P_0 it is to be remembered that transitions to and from 6^3P_1 were chosen partly with a balance in view. In the other cases, no such arbitrary adjustments were made, the balances depending on 6^3P populations based on measured 2537 output; 2537 diffusion theory and relative absorption measurements; measured electron temperature and concentration and published experimental and theoretical excitation cross section curves. The degree of balance attained among all the processes is considered to be better than the accuracy of some of the data warrant. But the self-consistency shown is believed to be good evidence that the over-all picture cannot be far wrong. Possibly it can be used as evidence for the essential correctness of some of the data used, e.g., the more important cross sections.

TABLE IV. Summary of the transition rates represented in Fig. 4, showing the degree of balance attained for each of the 6^3P states and 7^3S_1 states.

State 1	State 2	Transitions* arriving at state 1 from state 2	Transitions* leaving state 1 for state 2	Net gain %

** L refers to measured radiation.

Panevkin,[18] studying a decaying plasma, initially essentially like the present discharge, observed, by absorption measurements, decay times for $6^3P_{2,1,0}$ of 4×10^{-5}, 1×10^{-5}, and 6×10^{-5} sec. respectively. The value for 6^3P_1 namely 1×10^{-5} sec. agrees fairly well with that predicted here (0.76×10^{-5} sec.), considering that in Panevkin's case this state is being replenished from $6^3P_{2,0}$ by electronic collisions (the electrons disappearing by diffusion and recombination relatively slowly on this time scale). Indeed on the present picture it would have been expected that after an initial short period of adjustment this replenishment would have caused 6^3P_1 to decay along with the metastables. It is believed that this may have been the case, but was not shown up in Panevkin's experiments because of the difficulty of making the absorption measurements on 6^3P_1, at appreciable times after cut-off, with the necessary accuracy.

The present scheme accounts rather well for the initial rates of decay of the 6^3P states, especially $6^3P_{2,1}$, found by Panevkin.

According to Fig. 4 about one third of the excitation of 2537 comes directly from 6^1S_0 and two thirds stepwise via the metastables. The same conclusion was arrived at by Panevkin[18] and earlier by Butaeva and

[34] F. Butaeva and V. Fabrikant, J. Tech. Phys. U.S.S.R. 18, 1127 (1948).
[35] B. Klarfeld, Tech. Phys. U.S.S.R. 5, 913 (1939); Comptes Rendus U.S.S.R. 24, 251 (1939).

Fabrikant.[36] These authors do not give the details of their calculations. Since as noted above Panevkin has used 6^3P populations which are one fourth to one third as great as those found here, it is to be inferred that he has used quite different values of T_e and n_e or else that his cross sections for transfers among the 6^3P states were several-fold larger than those used here. However, he quotes the same authority for these as that used here.[22]

Evidence for the essential correctness of the present scheme is found in the fact that it can be used along with the observed change in voltage to estimate with some accuracy the effect of changing Hg density and changing current on the 2537 output, and on the electron temperature and concentration.

The method consists in finding a new balance, corresponding to Fig. 4 which will satisfy the new conditions; it may be illustrated as follows. Suppose it is desired to find the effect of increasing by a certain factor the concentration n_a of Hg atoms, the current being kept constant. A consideration of the 2537 diffusion problem shows that the time of imprisonment T will increase roughly as $n_a^{1.17}$. The average concentration n_1 of 6^3P_1 atoms will as before be related to the 2537 output R quanta per cm length of the tube per sec. by the relation

$$\pi a^2 n_1 = RT.$$

The concentration n_1 will increase with T (although R may or may not, depending on the initial n_a) and this will allow the populations n_2 and n_0 of $6^3P_{2,0}$ to increase. Larger populations of the 6^3P states will, other things being equal, give a larger excitation of the visible and near ultraviolet lines and, more importantly for the discharge, a larger rate of ion production. The last result causes the observed drop in voltage and an increase in n_e (obtained with the use of the mobility equation), and a decrease in T_e.

It is now possible to find, largely by trial and error, a new T_e and a new corresponding set of 6^3P populations which will balance the excitation and de-excitation processes, and at the same time yield the needed rate of ion production (assumed proportional to n_e). It has been possible in this way, without too much labor, to predict a maximum in the 2537 output at around 40°C (6.1μ Hg pressure) as is observed.[37,38]

When the current (alone) is increased, T will not change but all processes depending on n_2 will increase. Most important is the resultant increase in n_1, which allows n_2 and n_0 to increase slightly, other things being equal. This increase in the 6^3P populations allows more efficient ion production, but it also gives a greater relative excitation of the visible and near ultraviolet lines at the expense of 2537. It has been found possible by the above method to find a new T_e, and n_e (corresponding with the observed drop in voltage) which will yield a new set of 6^3P populations, balancing all excitation and de-excitation processes and at the same time yield the needed ionization. The result predicts a decrease in the production efficiency of 2537 in good accord with the observed.

Butaeva and Fabrikant[34] have given an interesting discussion of the variation of 2537 output with Hg pressure and current but this method cannot suffice for the present case because it does not take into account the variation in T_e.

In the scheme of Fig. 4 the populations of the 6^3P states are held down to the observed small fraction of the Boltzmann populations by the "leakage" of 2537. It was seen above that about 84 percent of the total excitation of $6^3P_{2,1,0}$ is radiated as 2537, the remainder or 16 percent being returned to normal by collisions of the second kind. As the current (alone) increases, the latter percentage will increase, and when it has become all important and the 2537 leakage (and efficiency of production) negligible, the true Boltzmann populations will have been reached. In this process 6^3P_1 will increase relatively faster than 6^3P_2 and 6^3P_0, but due to falling T_e it may be that the absolute populations of $6^3P_{2,0}$ will decrease slightly as Panevkin[21] has shown (see also Fig. 1).

The writer is indebted to many of his colleagues for helpful discussions and particularly to Dr. C. G. Found, Dr. N. L. Oleson (now of the Postgraduate School, U. S. Naval Academy, Annapolis, Md.), Dr. B. T. Barnes, and Miss M. A. Easley.

Vibrational Relaxation Times in Gases*

WAYLAND GRIFFITH†
Department of Engineering Sciences and Applied Physics, Harvard University, Cambridge, Massachusetts
(Received July 17, 1950)

Relaxation times for seventeen gases have been measured using a steady flow method, the velocity field being found numerically by Southwell's Relaxation Method. Where a comparison is possible the results are found to be in good agreement with sound dispersion data. The present state of knowledge about relaxation effects is discussed and a few instances of their possible appearance are cited.

INTRODUCTION

RECENT advances in the study of high speed flows have aroused new interest in the kinetic processes of fluid mechanics. In very strong shock waves, for example, conditions required by the Rankine-Hugoniot relations may be attained only outside a region considerably thicker than that usually estimated assuming internal energy equilibrium. Historically, the fact that internal energy states of molecules fail to keep up with sufficiently fast changes in their environment was first observed experimentally in 1925. Pierce[1] was able to measure dispersion of sound which could be explained only by ascribing a relaxation time to the adjustment of vibrational energy in addition to the effects of heat conduction and viscosity. Since then measurements have been made on dispersion and absorption of sound in several pure gases and many mixtures, and suitable theories advanced for interpreting the results.[2]

In 1942 Kantrowitz[3] proposed a very clever method for finding relaxation times using a steady flow of a gas. When the total pressure in a jet is measured with a pitot tube the value will be equal to the pressure in the reservoir from which the jet issues, provided the effects of viscosity and heat conduction are negligible, and provided all changes in the flow are slow compared to the rates of energy exchange between molecules. The former are usually limited to the boundary of the flow next to the walls, outside this region their effect is small. If the gas is now imagined to stop at the nose of a pitot tube quickly compared to the time for adjustment of vibrational energy, say, the compression will take place as though the gas had no vibrational energy, the specific heat ratio γ will be altered, and the resulting pressure will be different. The relaxation time enters the calculation through the time dimension involved in the stream velocity and pitot tube diameter. Kantrowitz verified the reliability of this method with measurements on carbon dioxide.

The purpose of the present investigation is threefold; (a), to measure vibrational relaxation times for several gases, (b), to extend confidence in the results of this method by using careful techniques and an exact solution of the flow pattern, and (c), to find as nearly as possible the limits of the method, for example in detecting very fast adjustments.

In the following section a very brief presentation of the thermodynamics appropriate to these experiments will be given, along with a physical explanation which it is hoped will aid in understanding the kinetic processes involved. Also, "relaxation time" will be defined.

THERMODYNAMICS FOR A GAS WITH LAGGING INTERNAL ENERGY

In addition to the usual thermodynamic variables for a gas it is appropriate to define a new one which describes the energy of vibration in the molecules. There are fairly good reasons to suppose that the various modes are in equilibrium among themselves even though they exchange energy slowly with the external motions of translation and rotation. In the first place there is always a certain amount of anharmonic coupling. Secondly, the lifetime is found experimentally to extend over hundreds or thousands of collisions. Although no direct evidence is available for it, a mechanism by which vibrational energy is redistributed within a molecule during a collision would have ample chance to operate. Accordingly T_{vib} will be defined as the temperature in the Boltzmann formula corresponding to the population distribution among vibrational states.

Three variables are therefore needed to specify a thermodynamic state for the gas, pressure and temperature say, and T_{vib}. The specific heat will be regarded as arising from two sources, vibrational motion, and all the rest. Following the nomenclature of Kantrowitz $c_{\text{vib}} \equiv dE_{\text{vib}}/dT_{\text{vib}}$, where E_{vib} is the energy in vibrational motion. C_p' will refer to the specific heat at constant pressure not counting vibration. Thus the usual specific heat $C_p = C_p' + C_{\text{vib}}$ when $T = T_{\text{vib}}$. Similarly C_v and C_v' will be used for constant volume specific heats. The Ideal Gas equation of state is assumed throughout.

The entropy change in going from one state to another is $\Delta S = \int dQ/T$, where any reversible path may be used to evaluate ΔS. By considering such a reversible change between two states which are allowed to approach one another indefinitely, one easily arrives at a

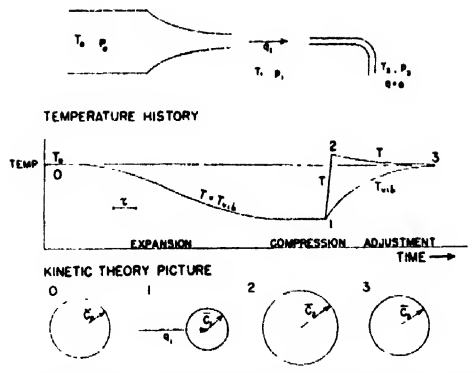

FIG. 1. Schematic drawing of the experiment, temperature history of the gas, and the variation in velocities according to kinetic theory.

formula for the entropy change as

$$dS=C_p'dT/T+C_{\text{vib}}dT_{\text{vib}}/T_{\text{vib}}-Rdp/p. \quad (1)$$

A familiar form of the Second Law results when T becomes equal to T_{vib}. We see that this is strictly applicable only when changes in temperature are slow compared to internal adjustments.

In many flow problems involving gases it is possible to neglect the viscosity, heat conductivity, and external forces in comparison to the other terms, and to assume constant specific heats without introducing serious errors. The equations for a compressible fluid with possible separate translational and vibrational temperatures are then

Continuity $$\partial\rho/\partial t+\partial\rho q_i/\partial x_i=0 \quad (2)$$

Momentum $$\rho\frac{dq_i}{dt}=-\partial p/\partial x_i \quad (3\text{–}5)$$

Energy $$\frac{\partial}{\partial x_i}\rho q_i\left(C_{\text{vib}}T_{\text{vib}}+C_v'T+\frac{p}{\rho}+\frac{q_j^2}{2}\right)$$

$$=-\frac{\partial}{\partial t}\rho\left(C_{\text{vib}}T_{\text{vib}}+C_v'T+\frac{q_j^2}{2}\right). \quad (6)$$

Eliminating the velocity from the energy and momentum equations gives

$$d/dt(C_{\text{vib}}T_{\text{vib}}+C_p'T)-(RT/p)dp/dt=0. \quad (7)$$

Combining this with (1) gives the entropy as a function of T and T_{vib};

$$dS=(1/T_{\text{vib}}-1/T)dC_{\text{vib}}T_{\text{vib}}. \quad (8)$$

This is what one might write down intuitively by considering the transfer of energy $dC_{\text{vib}}T_{\text{vib}}$ from the temperature T to T_{vib}.

A consideration of the actual collisions is required in order to find an expression for the rate at which the above exchange will take place. Using simplified models Bethe and Teller derived formulas predicting the decay function for adjustment and its dependence on pressure, vibration frequency, and temperature. Details in the steps are not included here but may be found in the papers by Bethe and Teller,[4] Landau,[5] and Landau and Teller.[6]

The variation of T_{vib} is found to be

$$dC_{\text{vib}}T_{\text{vib}}/dt=C_{\text{vib}}(T-T_{\text{vib}})/\tau, \quad (9)$$

where the relaxation time has the following functional dependence;

$$\tau\approx p^{-1}(\nu s)^{-\frac{1}{3}}\left(\frac{m}{T}\right)^{-\frac{1}{2}}\exp\left\{(\nu s)^{\frac{1}{3}}\left(\frac{m}{T}\right)^{\frac{1}{2}}\right\}. \quad (10)$$

The new quantities are ν-vibration frequency, s-molecular radius, and m-molecular mass. When changes in the temperature are small τ may be considered constant and after a time τ the temperature difference diminishes to $1/e$, or 0.368, of its original value.

With this information let us study the case mentioned earlier of a slow expansion through a nozzle to a velocity q_1 and a fast compression in front of a pitot tube. From the equations of momentum and energy

$$d/dt(C_{\text{vib}}T_{\text{vib}}+C_p'T+q^2/2)=0. \quad (11)$$

By this and Eq. (1) the ratio of reservoir pressure to pitot tube pressure will be

$$p_0/p_3=\exp\{\Delta S/R\}. \quad (12)$$

The entropy change is found from (8) and (9), the increase occurring while T and T_{vib} converge upon the stagnation value T_0. (See Fig. 1.)

$$\Delta S=\int_{T_1}^{T_0}\left(\frac{1}{T_{\text{vib}}}-\frac{1}{T}\right)dC_{\text{vib}}T_{\text{vib}}$$

$$=\int_{T_1}^{T_0}\left(\frac{1}{T_{\text{vib}}}-\frac{C_p'}{C_pT_0-C_{\text{vib}}T_{\text{vib}}}\right)dC_{\text{vib}}T_{\text{vib}}.$$

This finally gives,

$$\frac{p_0}{p_3}=\left(\frac{T_0}{T_1}\right)^{C_p/R}\left(\frac{C_p'T_0}{C_pT_0-C_{\text{vib}}T_1}\right)^{C_p'/R}. \quad (13)$$

The pressure at state 2 may also be found quite easily. Equations (9) and (1) give,

$$\frac{C_p'}{R}\frac{dT}{T}-\frac{dp}{p}+\frac{C_{\text{vib}}dt}{\tau RT}(T_{\text{vib}}-T)=0. \quad (14)$$

If τ is very long compared to other times in which changes take place in isentropic flow the last term

[4] H. A. Bethe and E. Teller, Report X-117, Ball. Res. Lab., Aberdeen Proving Ground.

[6] L. Landau and E. Teller, Physik. Zeits. Sowjetunion 10, 34 (1936).

vanishes and

$$p/p_0=(T/T_0)^{C_p'/R} \tag{15}$$

that is, the gas acts as though it had only the specific heat C_p'. For τ very short on the other hand, $T=T_{vib}$ and

$$\frac{p}{p_0}=\left(\frac{T}{T_0}\right)^{C_p/R} \tag{16}$$

in the usual fashion. From (11)

$$C_p(T_0-T_1)=\frac{q_1^2}{2}=C_p'(T_2-T_1). \tag{17}$$

Solving we find

$$\frac{p_0}{p_2}=\left(\frac{T_0}{T_1}\right)^{C_p/R}\left(\frac{C_p'T_0}{C_pT_0-C_{vib}T_1}\right)^{C_p'/R}. \tag{18}$$

The surprising result is that p_2 and p_3 are equal so that the adjustment of internal energy takes place at constant pressure. In his thesis* the author shows that $p_0>p_2$, which is consistent with the increased entropy.

Figure 1 shows a schematic drawing of the experiment, the time-history of the process, and a sort of kinetic theory picture of the situation at various stages of the flow. The acceleration from 0 to 1 is a conversion of random molecular motion with average velocity $\bar{c}_0$ into streaming motion of flow velocity q_1 and smaller average velocity $\bar{c}_1$. The compression from 1 to 2 returns all the stream energy into random motion without reexciting the vibrations immediately. The average velocity is higher than in the reservoir. The pressure is less, however, as the density is sufficiently lower to compensate for the higher temperature. The adjustment of internal energy takes place at constant pressure, decreasing temperature, and increasing density. The average molecular velocity returns to its original value but the gas is less dense.

With this qualitative idea of the effect in mind we can now develop the methods used for determining relaxation times from pressure measurements. Again we shall use a symbol introduced by Kantrowitz as a measure of the disequilibrium between vibration and translation,

$$\epsilon\equiv c_{vib}(T_{vib}-T). \tag{19}$$

In flows where changes in T are small compared to T itself (8) may be written

$$ds=-\frac{\epsilon dt}{\tau}\frac{T-T_{vib}}{TT_{vib}}\cong\frac{\epsilon^2 dt}{\tau C_{vib}\bar{T}^2}. \tag{20}$$

$\bar{T}^2$ is taken as the average of TT_{vib} over the whole process. From Fig. 1 a good value is seen to be $\bar{T}=\frac{1}{2}(T_0+T_1)$. The specific heats and relaxation time will be taken at this temperature as well.

When the difference $p_0-p_3=\Delta h$ is small compared to p_0,

$$\Delta S/R\cong\Delta h/p_0 \tag{21}$$

and

$$\Delta h/p_0=\int\frac{\epsilon^2 dt}{\tau C_{vib}\bar{T}^2} \tag{22}$$

where ϵ depends on the relaxation time and the history of the flow. The integral is to be taken over that part of the flow for which Δh is desired. An equation for ϵ is found by eliminating the temperature from (9), (11), and (19),

$$d\epsilon/dt+C_p\epsilon/C_p'\tau=C_{vib}/C_p'd(q^2/2)/dt \tag{23}$$

the integral being

$$\epsilon(t_1)=\exp\left(-\int^{t_1}\frac{C_p dt}{\tau C_p'}\right)\int^{t_1}\times\exp\left(\int^{t_1}\frac{C_p dt}{\tau C_p'}\right)\frac{C_{vib}}{C_p'}\frac{d(q^2/2)}{dt}dt \tag{24}$$

This completes the thermodynamics, for a knowledge of the velocity history of the flow and the specific heats now enable one to relate pressure differences to relaxation times.

DESIGN OF THE EQUIPMENT

A review of the literature on sound dispersion indicates that relaxation times are of the order of five microseconds. Generally diatomic molecules have longer times, polyatomic gases shorter times. Accordingly a steady flow is desired in which a gas expands slowly compared to this time and stops in about five microseconds.

Because the analytical flow solutions known are limited in number and sometimes difficult to reproduce experimentally, it was decided to use a fairly simple arrangement with axial symmetry and solve the problem numerically using R. V. Southwell's Relaxation

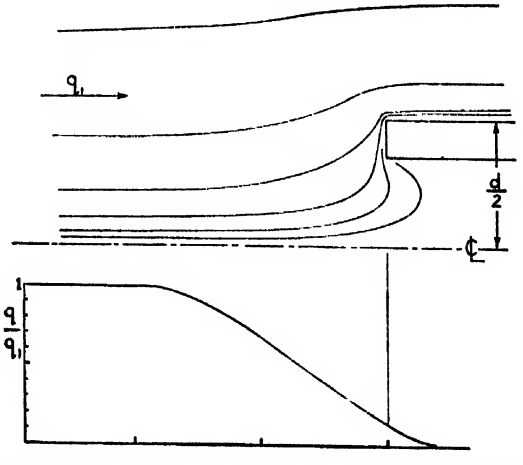

FIG. 2. Streamlines for flow past an open-ended cylinder computed numerically and the velocity along the central streamline.

Method.[7] It rests upon the accuracy with which a difference equation can be made to approximate a differential equation. An excellent discussion of the method may be found in a paper by Emmons.[8] Incompressible flow was assumed, the effect of compressibility can be found from the velocity dependence of the observations.

The solution for a plane parallel jet impinging on a flat plate was obtained first since the simplicity of this arrangement was quite attractive. The required nozzle diameter was only 0.024 in., though, so this scheme was abandoned in favor of a pitot tube to obtain sufficiently fast stopping times.

A square-ended cylinder was chosen for the shape of the tubes and the Relaxation Method used to locate streamlines. First the streamline at 2.25 d was assumed to be undisturbed; when this was moved out to 2.50 d values of the stream function were changed by less than one percent. A hollow center of diameter 0.620 d was

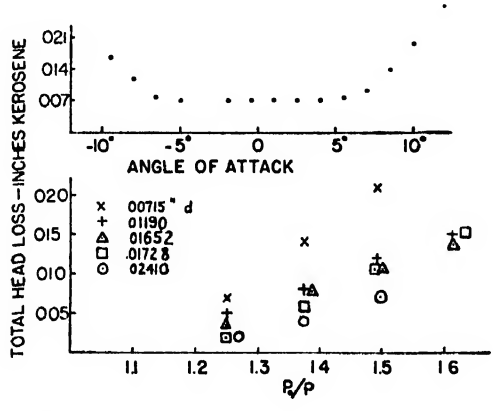

FIG. 3. The effect of angle of attack on total head loss and minimum losses for five tubes at various ratios of reservoir to stream pressure.

then included in the calculation. This made the deceleration of the flow considerably less abrupt. The streamlines and a velocity-time plot are shown in Fig. 2. For a jet velocity of 400′/sec. the diameter should then be about $400\times12\times5\times10^{-6}\times2/3=0.016$ in. It is interesting that the disturbance extends only one diameter upstream.

Glass tubes were found to be most satisfactory, being both easy to clean and relatively easy to make. With sufficient practice and patience square ends on tubes down to 0.005 in. could be ground with a fine Water of Ayr stone. Diameters of the tubes actually used in various phases of the investigation were as follows: 0.0241 in., 0.01728 in., 0.01652 in., 0.01190 in., and 0.00715 in. The respective i.d./o.d. ratios were: 0.610, 0.622, 0.590, 0.604, and 0.622.

A good design for the nozzle is important since we should like to measure only the effect due to fast stopping. Equation (23) shows that the best possible type of acceleration is one in which dq^2/dt is constant. This is the same as dT/dt constant, chosen by Kantrowitz for another reason. Two nozzles one-half inch long were made. The exit diameters were 0.070 in. and 0.040 in. The flow at 400′/sec. is 1.1 cfm through the larger nozzle and 0.36 cfm through the smaller one. A correction for the wall boundary layer was made, similar to that described in Kantrowitz's paper.

The reservoir was made from a two-foot section of three inch iron pipe. The nozzle was mounted in one end, the other having a connection for the gas supply line and a blowout diaphragm. Inside the chamber a 100-mesh screen and straightening vanes were placed twelve inches from the nozzle. The reservoir was mounted horizontally and had a thermocouple and pressure tap for measuring the stagnation conditions. Arrangements for a few experiments at elevated temperatures were made by placing a coil gas heater in the supply line and winding the reservoir with Nichrome wire and pipe insulation.

A micromanometer was devised to measure small pressure differences very accurately and quickly. A short length of glass tubing with a fine cross-hair was mounted at an angle on a frame which travelled vertically. Also mounted on the frame was an Ames dial which read distances above an arbitrary level to an accuracy of 0.0005 in. With a mirror fixed behind the cross-hair one could move the frame to align the meniscus and hairline within 0.003 in. For a slope of 1:4 in the tube, the height of the meniscus could be measured to 0.001 in. Since the meniscus is always in the same part of the tube the usual difficulties of varying wall diameter and incomplete wetting were greatly reduced. With kerosene in the manometer a change in pressure of 2×10^{-6} atmos. was detectable.

A special holder was made for the tubes which allowed independent adjustments to be made in axial and transverse positions and in direction. Once the tip of the tube was properly located in the stream the angle of attack could be changed to align it correctly. The tubing used was Seran, a transparent plastic. Reservoir pressure was measured with a mercury U-tube. All of the pressure lines were kept at one level as nearly as possible to reduce errors due to buoyancy when gases with densities quite different from air were tested. A small blower and stovepipe were used to draw off the more toxic gases.

EXPERIMENTAL METHODS AND DETERMINATION OF RESULTS

The gases used were obtained in steel cylinders from commercial supply houses. The purest form available was chosen in each case since work on sound dispersion indicated that certain impurities, especially water vapor, could cause large variations in the measured results. Preliminary runs with compressed air showed

[7] R. V. Southwell, *Relaxation Methods in Engineering Science* (Clarendon Press, Oxford, 1940).
[8] H. W. Emmons, Q. App. Math. 2, 3, 173 (1944).

that readings could be taken once a minute. Nitrogen was chosen as the best available gas for taking minimum readings because of its very small vibrational heat capacity. The effect of the angle of attack is shown in Fig. 3. The range of minimum loss extends ±5°, thus making proper alignment fairly easy. Consistent readings were found for axial positions between one and two nozzle diameters and over three-fourths of the stream. Also shown in Fig. 3 are the minimum pressure losses at various pressure ratios using the 0.040 in. nozzle. The readings were very nearly the same for the 0.070 in. nozzle. The dependence on tube size cannot necessarily be interpreted as a relaxation effect, for the smaller tubes may be less perfect, and some loss due to viscosity might also be expected. Important to the main work is the conclusion that the losses due to other than relaxation effects can be reduced to such a small value. Before each experimental run readings with nitrogen were taken and subtracted from the observed data. A qualitative idea of relative relaxation times may be formed from Fig. 4 which shows the measured pressure loss for several of the gases tested.

The method for calculating relaxation times from these data will now be developed. Equation (23) gives

$$(d\epsilon/dt)dt+(C_p\epsilon/C_p')dt/\tau = (C_{vib}/C_p')\left(d\frac{q^2}{2}\Big/dt\right)dt. \quad (25)$$

As the time required for stopping becomes shorter the second term will become small compared to the other terms, and in the limit, when $\int \epsilon dt/\tau$ becomes negligible in comparison to the other two terms, the change in ϵ is

$$\Delta\epsilon=(C_{vib}/C_p')\Delta q^2/2.$$

In the case being considered ϵ was originally zero and the velocity was q_1. A sudden stopping then produces a value of

$$\epsilon_0=(C_{vib}/C_p')q_1^2/2.$$

With $q=0$, (25) gives for the approach to equilibrium $d\epsilon/dt=-C_p\epsilon/C_p'\tau$. The pressure change for an instantaneous compression is accordingly,

$$\Delta h_{ic}/p_0=\int_{\epsilon_0}^{0}\frac{\epsilon^2 dt}{\tau RC_{vib}\bar{T}^2}=\int_{\epsilon_0}^{0}\frac{C_p'\tau\epsilon d\epsilon}{C_p\tau RC_{vib}\bar{T}^2} =\frac{C_p'}{2C_pC_{vib}R\bar{T}^2}\left(\frac{C_{vib}q_1^2}{2C_p'}\right)^2. \quad (26)$$

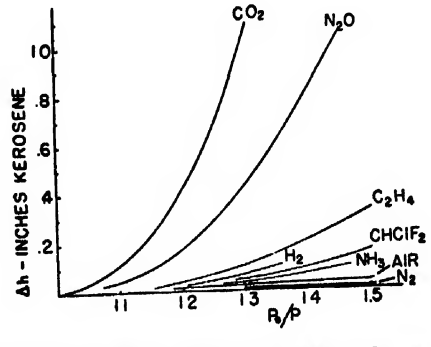

FIG. 4. Observed pressure losses for several of the gases tested.

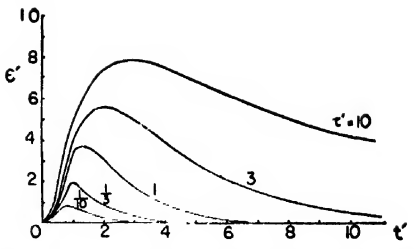

FIG. 5. The parameter ϵ' measures the disequilibrium of vibrational energy. For instantaneous stopping it would initially have the value 1; plotted are the variations in ϵ' for five values of the dimensionless relaxation time τ'.

It is more convenient at this point to substitute a set of dimensionless variables than to continue with the physical variables. Using Kantrowitz' notation again define the following dimensionless variables,

$$\tau'=\frac{C_p'}{C_p}\frac{q_1\tau}{d} \qquad t'=\frac{q_1 t}{d}$$
$$\epsilon'=\frac{\epsilon}{(C_{vib}/C_p')(q_1^2/2)} \qquad q'=q/q_1. \quad (27)$$

Using (27) and (26) in Eqs. (24) and (22) we find

$$\epsilon'=\exp\left(-\frac{1}{\tau'}\int dt'\right)\int\exp\left(\frac{1}{\tau'}\int dt'\right)\frac{dq'^2}{dt'}dt' \quad (28)$$

and

$$\frac{\Delta h}{\Delta h_{ic}}=\frac{2}{\tau'}\int\epsilon'^2 dt' \quad (29)$$

Thus we see that $\Delta h/\Delta h_{ic}$ depends only on τ' for a given flow pattern. This is the great simplification obtained by running an experiment in which only small temperature changes occur.

The integration of (28) to find ϵ' was done numerically for several values of τ'. Curves of ϵ' corresponding to these are given in Fig. 5. The mathematical difficulty of infinite stopping time on the central streamline was avoided by abandoning the integration when further contributions from the integrand became negligible. Physically the discrete nature of the gas explains the paradox.

The integration for $\Delta h/\Delta h_{ic}$ was found by counting squares in a graph of ϵ'^2 *vs.* t'. The resulting values are

τ'	1/10	1/3	1	3	10
$\Delta h/\Delta h_{ic}$	0.0828	0.226	0.480	0.723	0.908

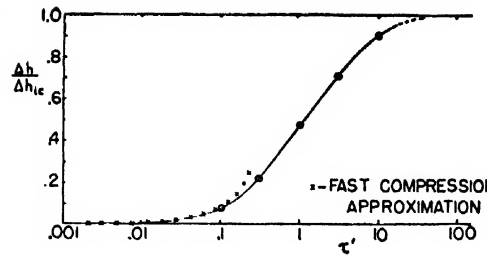

FIG. 6. Graph used to find dimensionless relaxation time τ' from observed pressure loss Δh.

For very short relaxation times an approximation method used by Kantrowitz was also applied here, the result being $\Delta h/\Delta h_{ic}=0.867\tau'$. Figure 6 shows that this is valid for $\tau'<0.08$.

The temperature T_1 was found from the pressure ratio p_1/p_0 and Eq. (16), the velocity q_1 from (17). Thus Δh_{ic} could be computed and τ' read from the graph.

EXPERIMENTAL RESULTS

The results for N_2O shown in Fig. 7 give an idea of the consistency of the method and show that no velocity dependence up to $M=0.8$ is observable. A similar test on CO_2 confirmed this result. Apparently the faster deceleration in the compression is just compensated for by the gain in collision rate. Relaxation times for the seventeen gases tested are given in Table I. The temperature dependence of τ shown in Fig. 8 was found from a few measurements; the accuracy was somewhat reduced due to difficulties in keeping the reservoir temperature equal to the gas temperature.

Hydrogen has no appreciable vibrational energy at room temperature so the observed pressure loss was ascribed to rotational lag and the same formulation assumed applicable. An upper limit for rotation of N_2 was also computed in this way. Only an upper limit could be found for four gases which showed no pressure loss greater than N_2. Two brands of CO_2 were tested, commercial CO_2 with a few percent water vapor, and a special purified lot containing 0.044 percent water vapor. This produced a large change in the result and it is felt that the time for the pure gas is somewhat longer still. This conclusion is borne out by a comparison with sound dispersion data, the most recent value for carefully purified CO_2 being about a third larger. Other impurities in other gases are not nearly as effective as this combination so the results may be considered fairly reliable. As a possible check for future work the suppliers' data on impurities are included in Table I. Also included are values from the literature on all the pure gases tested. Of the six in common beside CO_2 agreement is seen to be very good for H_2, N_2O, and C_2H_4, while agreement for SO_2, CH_4, and NH_3 extends only to the order of magnitude.

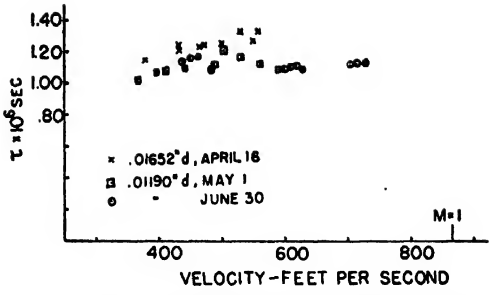

FIG. 7. Data on N_2O indicating accuracy of readings and absence of compressibility effect on results.

DISCUSSION

With the information on pure gases available from these experiments and the data already reported in the literature several conclusions may be drawn about the collisions. Relaxation times decrease for increasing temperature, supporting the theory that the fast collisions are most important. The higher the vibration frequency the longer the relaxation time; $CH_4>CH_3Cl>CHF_2Cl$; $CH_4>C_2H_6$; $C_2H_4>C_3H_6$. This indicates that the idea of resonant coupling used in deriving (10) is fairly reasonable. Since progression along the methane and ethylene series seems to give shorter relaxation times it is likely that all complicated molecules reach equilibrium quickly. Few fruitful measurements have been made on diatomic molecules, presumably because their small vibrational energy produces an exceedingly small effect. A further difficulty arises from the long times indicated; an impurity that is more effective than the molecule itself in collisions will control the adjustment.

This brings up the next important consideration, the effect of mixtures. Early experimenters were not aware of the great influence which foreign molecules with chemical affinity have. This accounts in large part for the dismaying array of values in the literature, and for the remarkable difference in the two brands of CO_2 tested here. The shift in the absorption maximum has been found linear for small amounts of impurities,[9] indicating that bimolecular collisions are responsible for energy exchange. A single exception is the case of O_2, where a quadratic dependence on water vapor content

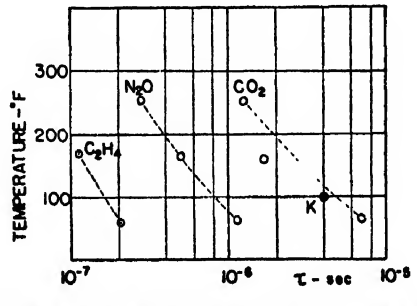

FIG. 8. Dependence of relaxation time on temperature. The point marked K is from Kantrowitz' work.

[9] V. O. Knudsen and E. F. Fricke, J. Acous. Soc. Am. 12, 255 (1940).

points to triple collisions as the mechanism.[10] In general unlike molecules exchange energy more readily than like molecules. Since the monatomic gases and N_2 are exceptions[11] one may conclude that chemical affinity is important. The small mass and high velocity of H_2 is significant since it is more effective than D_2. To explain the orders of magnitude the moments of inertia and dipole strength must also be considered.[11,12] Eucken[13] discusses the problem from the point of view that vibrational excitation is preliminary to chemical reaction; if colliding molecules are known to react exchange of vibrational energy is likely.

Limitations of the flow method of measurement can now be outlined fairly well. The size of nozzles and pitot tubes used here represent the lower practical limit of utility and construction. A sharp-nosed tube might produce half the stopping time, but would be harder to make. Operating the entire experiment at a lower pressure lengthens the adjustment period, but reduces the sensitivity even more. For testing compounds with small vapor pressures this is necessary anyway. For diatomic molecules higher pressures would give greater sensitivity, the disadvantage being the larger gas flow. The inherent inability of this method to detect more than one rate of adjustment does not seem to be serious, since no bona fide cases of this sort have been discovered in sound dispersion.

CONCLUSIONS

The results of this investigation extend considerably the available data on pure gases. Molecular energy exchange is such a complicated process that it is unfortunately still impossible to predict a relaxation time for an untested gas or mixture. Certain limits, however, may now be set on conditions where relaxation effects will appear. Calculations show that the thickness of a shock wave in CO_2 is about a tenth of an inch; at $M=2$ the initial value of $T-T_{vib}$ is 350°F so quite a strong effect in this narrow region might be expected. Experiments to look for this using a shock tube are being planned. In the usual aerodynamic problems relaxation effects are completely negligible as has always been assumed. For extreme cases of heat and velocity as are met in rocket and meteor flight studies relaxation effects are doubtless significant, but until the large-scale effects are better understood this will not be considered.

The flow method is seen to be a very satisfactory technique for measuring vibrational relaxation times, and may be used to study many other rate processes, for example dissociation and recombination.

The author would like thank Professor Howard Emmons for many valuable discussions and continued interest during the course of this research.

Numerical Determination of Fundamental Modes

DONALD A. FLANDERS AND GEORGE SHORTLEY*
Argonne National Laboratory, Chicago, Illinois
(Received July 12, 1950)

A convenient and practical method of numerical determination of the fundamental eigenfunction and eigenvalue in a class of linear eigenvalue problems has been developed and applied in two and three dimensions. The method is based on use of a network and of difference equations, but departs from previous methods in that it is not iterative. Rather, a polynomial operator is applied to a trial function just once, to accomplish a determinable degree of reduction in all eigenfunctions other than the fundamental that are contained in the trial function. In the case of the diffusion equation, the polynomial operator is a Tschebyscheff polynomial of a simple averaging operator. It is shown that this operator, when of degree m, is "better" than any other polynomial operator of this degree and much "better" than m iterations of a simple averaging operator—"better" in the sense of accomplishing to a greater degree the elimination of *all* unwanted eigenfunctions. Techniques for the use of computing equipment for application of the polynomial operator are discussed. By orthogonalization, the method can be applied to modes other than the fundamental.

INTRODUCTION

IN connection with work on complex problems occurring in certain applications of diffusion theory, a convenient and practical method of numerical determination of the fundamental eigenfunction and eigenvalue in linear eigenvalue problems has been developed and applied in two and three dimensions.[1]

While the methods we have developed are applicable to a wide class of systems of linear partial differential equations and a wide variety of linear boundary conditions, we feel that the new ideas and techniques will be most useful if they are first presented in the simplest possible setting. Hence, in this paper we shall first consider in detail the numerical determination of the lowest eigenvalue and corresponding fundamental eigenfunction of the equation

$$\Delta u+\alpha u=0, \tag{1}$$

which occurs in the theories of heat conduction, diffusion, vibration, and elsewhere. For simplicity we shall fix attention on a connected two-dimensional region bounded by straight-line segments parallel to the x- and y-coordinate axes, and shall consider the simplest boundary condition

$$u=0 \qquad \text{on the boundary.} \tag{2}$$

The methods discussed can be generalized so as to apply to more general linear differential equations of elliptic type, to systems of such equations, to more complex geometrical configurations, to more general linear boundary and interface conditions and to more dimensions. Systems of equations will be discussed briefly in the last section.

We replace the continuum by a square lattice of mesh h, and equation (1) by a difference equation, in the usual way. Again for simplicity we assume that the dimensions are such that the boundaries fall along rows of lattice points, and that a lattice point falls at the origin of coordinates. We further assume that the mesh is so small that every pair of interior points can be joined by a polygonal path consisting of segments of the network lying wholly in the interior of the region; we shall say that the *interior* points are *connected* by the net. We denote the lattice points by P_{ij} and the corresponding values of u by u_{ij}, where $i=x/h, j=y/h$.

If we use the notation ωu_{ij} to represent the average of the values of u at the four nearest neighbors of the point P_{ij}, i.e.,

$$\omega u_{ij}=\tfrac{1}{4}(u_{i+1,j}+u_{i-1,j}+u_{i,j+1}+u_{i,j-1}),$$

the second-difference approximation[2] to Δu at the point P_{ij} is

$$\Delta u_{ij}\approx\frac{\omega u_{ij}-u_{ij}}{\tfrac{1}{4}h^2}.$$

The difference equation that approximates (1) is then

$$\omega u_{ij}-u_{ij}+\tfrac{1}{4}h^2\alpha u_{ij}=0,$$

or

$$\omega u_{ij}=\lambda u_{ij}, \tag{3}$$

where

$$\lambda=1-\tfrac{1}{4}h^2\alpha. \tag{4}$$

* Operations Research Office, The Johns Hopkins University, on leave of absence from The Ohio State University; consultant at the Argonne National Laboratory.

[1] For a review of previous work on numerical methods in two and three dimensions (mostly work on boundary-value rather than eigenvalue problems) see Thomas J. Higgins, *Numerical Methods of Analysis in Engineering* (The Macmillan Company, New York, 1949), Chapter 10. This chapter contains an extensive bibliography.

[2] Nothing we say in this paper will be changed except in minor details if one chooses to use the higher-order approximation to Δu that is obtained if we define the averaging operator ω as

$$\omega u_{ij}=\tfrac{1}{5}(u_{i+1,j}+u_{i-1,j}+u_{i,j+1}+u_{i,j-1})+\tfrac{1}{20}(u_{i+1,j+1}+u_{i-1,j+1}+u_{i+1,j-1}+u_{i-1,j-1}),$$

in which case

$$\Delta u_{ij}\approx(\omega u_{ij}-u_{ij})/\tfrac{3}{10}h^2$$

and (4) becomes

$$\lambda=1-\tfrac{3}{10}h^2\alpha.$$

This expression for Δu_{ij} is valid for any seventh-order polynomial passing through the nine points, whereas the expression in the text is valid for a cubic polynomial passing through the five points. For a detailed discussion of approximations to the Laplacian, see Shortley and Weller, J. App. Phys. 9, 345 (1938).

The highest eigenvalue λ_1 of (3) will give an approximation to the lowest eigenvalue α_1 of (1) according to the relation (4), and the corresponding eigenvector of (3) will approximate to the fundamental eigenfunction of (1). We shall not discuss in this paper the accuracy of these approximations; it is well known that the solutions of the difference equation converge to solutions of the differential equation as $h \to 0$.

We shall consider the function u_{ij} to be defined only at interior points of the region. At a point adjacent to the boundary ωu_{ij} then will be taken to represent $\frac{1}{4}$ the sum of the values at the three, two, or one neighboring interior points, since one or more zero boundary values occur in the averaging process. We assume that there are N interior points, and for convenience number them from 1 to N, replacing the double index i,j by a single index k. The set of values u_k will then be denoted by a column vector $\mathbf{u}=(u_k)$. For the sake of brevity two components of $\mathbf{u}$ will be called neighboring if they represent values of u at neighboring points of the lattice.

Let $\omega_{kl}=\frac{1}{4}$ or 0 according as u_k and u_l are neighbors or not, and let ω denote the square matrix with elements ω_{kl}. The matrix equation

$$\omega\mathbf{u}=\lambda\mathbf{u} \tag{5}$$

then represents the result of incorporating the boundary conditions into the system of Eqs. (3). Thus Eq. (5) is the complete finite-difference analog of the analytic system (1), (2). It is the algebraic eigenvalue problem set by (5) with which we shall be concerned henceforth.

BASIC PROPERTIES OF THE SOLUTIONS OF THE MATRIX EQUATION

The general theory of equations such as (5) is well known. We set down here such general facts as we shall need, and we derive certain further useful properties specific to the particular equation.

The matrix ω is real and symmetric. Hence, it has N real eigenvalues and a complete orthonormal system of eigenvectors.[3] We denote the eigenvalues by

$$\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_N,$$

and the corresponding eigenvectors of an arbitrary (but fixed) complete orthonormal system by

$$\mathbf{u}^1, \mathbf{u}^2, \cdots, \mathbf{u}^N. \tag{6}$$

(Since $-\mathbf{u}$ is an eigenvector belonging to the eigenvalue λ if $\mathbf{u}$ is, and is normalized if $\mathbf{u}$ is, we shall assume throughout that whenever $\mathbf{u}$ denotes an eigenvector, the maximum of the absolute values of the components of $\mathbf{u}$ is equal to the value of some component u_k of $\mathbf{u}$.)

The averaging operation performed by ω cannot increase the maximum of the absolute values of the components of any eigenvector $\mathbf{u}$, so that every $|\lambda_n| \leq 1$. In fact one can readily see that only the inequality can hold because of the zero boundary condition. (It is clear that the $\leq$ sign will hold for more general operators than ω provided the corresponding matrix contains no negative elements and the sum of the elements in every row is ≤ 1, while the inequality may be asserted if in addition the sum of the elements of some row is <1.)

The highest eigenvalue, λ_1, is non-degenerate (i.e., $\lambda_1 > \lambda_2$ or, equivalently, there are not two linearly independent eigenvectors with eigenvalue λ_1), *and* $\mathbf{u}^1$ *is everywhere positive.* These facts may be proved by using the variational analog of the eigenvalue problem, which may be stated thus: If $\mathbf{u}^0$ is a normalized eigenvector of (5) with eigenvalue λ_0, then $\mathbf{u}^0$ is a vector that gives the quadratic form

$$(\mathbf{u}, \omega\mathbf{u}) \equiv \sum_{k,l} \omega_{kl} u_k u_l$$

the stationary value λ_0, subject to the normalization condition

$$(\mathbf{u}, \mathbf{u}) \equiv \sum_k u_k^2 = 1;$$

and conversely.

Let $\mathbf{v}$ be any normalized eigenvector belonging to λ_1 (i.e., with eigenvalue λ_1), and let $\mathbf{w}=(|v_k|)$. Then $\mathbf{w}$ is normalized, and we shall show that it is also an eigenvector belonging to λ_1. For since no $\omega_{kl}<0$ it follows that $\omega_{kl}w_k w_l \geq \omega_{kl}v_k v_l$ in every case, and hence that $(\mathbf{w}, \omega\mathbf{w}) \geq \lambda_1$. Since λ_1 is the maximum value that $(\mathbf{u}, \omega\mathbf{u})$ can assume for any normalized vector $\mathbf{u}$, we

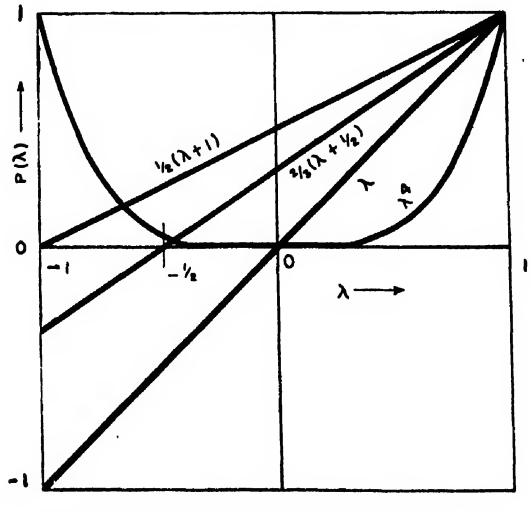

FIG. 1. The factors $P(\lambda)$ corresponding to certain polynomial operators $P(\omega)$.

[3] If ω is a real but unsymmetric matrix, and weight factors γ_i exist such that $\gamma_i\omega_{ij}=\gamma_j\omega_{ji}$, ω will have N real eigenvalues and a complete system of eigenvectors orthonormal with respect to the weight factors γ_i, the direct product being defined by

$$(\mathbf{u}, \mathbf{v}) = \Sigma_i \gamma_i u_i v_i.$$

In this case $(\mathbf{u}, \omega\mathbf{u})$ is a symmetric quadratic form that is an extremum for an eigenvector. This case is of importance when different choices of net spacing are made in different regions, the weight factor representing essentially the area of continuum associated with each net point. The weight factors for change of net spacing are given by Kimball and Shortley, Phys. Rev. 45, 815 (1934). The techniques of the present paper are readily applicable to matrix operators of this type, and in particular to the Schrödinger problem discussed by Kimball and Shortley.

must have $(\mathbf{w}, \omega\mathbf{w})=\lambda_1$, and hence $\mathbf{w}$ is an eigenvector belonging to λ_1. Thus $\omega w_k \equiv \sum_l \omega_{kl} w_l = \lambda_1 w_k$ for every k.

Now $\mathbf{v}$ (and hence $\mathbf{w}$) can have no zero component. For if $\mathbf{w}$ has any zero values, there must be at least one point P_r for which $w_r=0$ that has a neighboring point P_s for which $w_s>0$. This follows because $\mathbf{w}$ does not vanish identically and because the interior points are connected by the net. But we have arrived at a contradiction since on the one hand $\omega w_r=\lambda_1 w_r=0$, while on the other ωw_r is a sum of non-negative terms $\omega_{rl} w_l$ of which at least one, $\omega_{rs} w_s$, is not zero.

Further, no component of $\mathbf{v}$ is negative. As before one could find neighboring values $v_r<0, v_s>0$ ($v_k=0$ having been excluded). But now we have $(\mathbf{w}, \omega\mathbf{w})>(\mathbf{v}, \omega\mathbf{v})$ since $\omega_{rs} w_r w_s = -\omega_{rs} v_r v_s > 0 > \omega_{rs} v_r v_s$.

Finally, no two linearly independent eigenvectors can belong to λ_1. For if $\mathbf{v}^1$ and $\mathbf{v}^2$ were such eigenvectors, normalized and with only positive components, their difference would be an (unnormalized) eigenvector belonging to λ_1 that would have both positive and negative values, which is impossible. Thus $\mathbf{u}^1$ is unique and is everywhere positive. Since every eigenvector belonging to a different eigenvalue must be orthogonal to $\mathbf{u}^1$, $\mathbf{u}^1$ must be the only everywhere positive eigenvector in the set $\mathbf{u}^1, \cdots, \mathbf{u}^N$.

We have thus proved that

$$1>\lambda_1>\lambda_2\geq\lambda_3\geq\cdots\geq\lambda_N>-1. \tag{7}$$

An arbitrary vector $\mathbf{v}$ has a unique expansion in terms of the set (6):

$$\mathbf{v}=\sum c_n \mathbf{u}^n, \tag{8}$$

where c_n is the inner product of $\mathbf{v}$ and $\mathbf{u}^n$, that is

$$c_n=(\mathbf{v}, \mathbf{u}^n)=\sum_k v_k u^n{}_k.$$

If $\mathbf{v}$ is everywhere positive the coefficient c_1 must also be positive, and if furthermore $\mathbf{v}$ is reasonably pillow-shaped, c_1 will probably be larger than the magnitude of any other coefficient.

The effect of applying the operator ω to an arbitrary vector is to produce the vector

$$\omega\mathbf{v}=\sum_n \lambda_n c_n \mathbf{u}^n.$$

More generally, if $P(\omega)$ is any polynomial in ω,

$$P(\omega)\mathbf{v}=\sum_n P(\lambda_n) c_n \mathbf{u}^n,$$

that is to say that each coefficient c_n is multiplied by the value of the polynomial $P(\lambda)$ at $\lambda=\lambda_n$. Figure 1 shows the graphs of the factors $P(\lambda)$ corresponding to the operators ω, ω^4 and $(\omega-a)/(1-a)$ for $a=-1$ and for $a=-\frac{1}{2}$.

It is clear from Fig. 1 that the operator ω will reduce the magnitude of every coefficient c_n in proportion to the nearness of the corresponding eigenvalue to 0, but that if $|\lambda_n|$ is close to λ_1 the reduction relative to c_1 will be small, or there may even be a relative increase if $|\lambda_n|>\lambda_1$. Iteration of the operator ω, represented by the operator ω^p, is seen to have the same properties, except that the relative effect increases with increasing p. On the other hand the operator $(\omega-a)/(1-a)$ can be chosen with a negative so that every $c_n(\neq c_1)$ is reduced in magnitude, not only absolutely, but relatively to the magnitude of c_1.

TECHNIQUES FOR THE SOLUTION OF THE MATRIX EQUATION

By iterative application to a trial vector (8) of a polynomial operator $P(\omega)$ of the type shown in Fig. 1 it is possible to obtain a sequence of vectors $\mathbf{v}^0(=\mathbf{v})$, $\mathbf{v}^1, \cdots, \mathbf{v}^i, \cdots$, such that the ratios $|c_n{}^i/c_1{}^i|$ are successively reduced. Past procedures for obtaining the fundamental solution of such a matrix equation have been of this type. p iterations of a polynomial operator $P_d(\omega)$ of degree d are equivalent to the operator $[P_d(\omega)]^p$, which is of degree pd. We shall now show that for given degree m there exists a "best" polynomial operator $P_m(\omega)$. Since this polynomial is not a power of any polynomial of lower degree, it is therefore "better" than the result of p iterations of any operator of degree d such that $pd\leq m$.

The criterion for the "best" polynomial operator $P(\omega)$ of degree m may be rigorously expressed in the following form: We assume that the eigenvalues of the

problem lie in an interval $(-a, c)$ and that there is an interval $(-a, b)$, with $b<c$, within which it is desired that the maximum of $|P(\lambda)/P(c)|$ shall be a minimum. By limiting consideration to those polynomials for which $P(c)=1$ we then seek among such polynomials those for which the maximum of $|P(\lambda)|$ is a minimum throughout the interval $(-a, b)$. If such a polynomial exists for each choice of m, a, b, c, then by taking $a=-\lambda_N$, $b=\lambda_2$, $c=\lambda_1$ we can preserve the magnitude of c_1 in the expansion of an arbitrary trial vector (8), and obtain the maximum reduction in magnitude of the remaining coefficients.[4] In practice, we do not know in advance what values should be assigned to a, b, and c. In later sections we shall show how such assignments may reasonably be made.

The existence of the desired "best" polynomial is given by the following theorem, in which, for convenience, we have made the changes of variable

$$\Omega=\frac{2}{a+b}\omega+\frac{a-b}{a+b}, \qquad \mu(\lambda)=\frac{2}{a+b}\lambda+\frac{a-b}{a+b} \tag{9}$$

[so that $\mu(-a)=-1$, $\mu(b)=+1$], and have set $d=\mu(c)\equiv 2(a+c)/(a+b)-1>1$.

THEOREM: Among all polynomials of degree m in μ having the value $+1$ at $\mu=d>1$, there is just one having the minimum maximum absolute value throughout the interval $(-1, +1)$, namely the polynomial

$$S_m(\mu)=T_m(\mu)/T_m(d), \tag{10}$$

where $T_m(\mu)$ is the mth-order Tschebyscheff polynomial,[5] obtained by expanding

$$T_m(\mu)=\cos(m \arccos\mu)$$

in powers of μ.

PROOF: $T_m(\mu)$ is alternately $+1$ and -1 at the $m+1$ points $\mu_k=\cos(k\pi/m)$ $(k=0, 1, \cdots, m)$. Consequently $|S_m(\mu)|$ has $1/T_m(d)$ as its maximum at these $m+1$ values of μ. Suppose that $R(\mu)$ is a polynomial of degree m that is $=1$ at $\mu=d$ and has equal or smaller maximum absolute value in the interval $(-1, +1)$. Let $Q(\mu)=S_m(\mu)-R(\mu)$. Then $Q(\mu)$ is of degree m or less, $Q(d)=0$, and $Q(\mu_k)\geq 0$ or ≤ 0 according as k is even or odd. We proceed to show that $Q(\mu)$ has at least $m+1$ zeros in the closed interval $[-1, d]$, which is possible only if $Q\equiv 0$, i.e., if $R\equiv S_m$. Note that if $0<k<m$ and $Q(\mu_k)=0$ then μ_k is a multiple zero since both S_m and R must have natural extrema at μ_k, and hence $S_m'(\mu_k)-R'(\mu_k)=Q'(\mu_k)=0$. Now consider the interval $[\mu_k, \mu_{k+1}]$ $(k=1, \cdots, m-2)$. Either Q is positive at one end of this interval and negative at the other, in which case there is a zero in the interior of the interval; or Q is zero at one or both ends of the interval. In the latter case Q has at least two zeros in the closed interval—let us assign *one* of these zeros to the interval $[\mu_k, \mu_{k+1}]$ and one to the adjoining interval that has the double zero at its end point. In this way we see that Q has at least one zero assignable to each of the $m-2$ intervals mentioned above. The intervals $[\mu_0, \mu_1]$ and $[\mu_{m-1}, \mu_m]$ have (at least) either an interior zero, a double zero at μ_1 or μ_{m-1}, or a single zero at μ_0 or μ_m. Hence at least one zero is assignable to each of the m intervals $[\mu_k, \mu_{k+1}]$ $(k=0, \cdots, m-1)$. Q also has a zero at d. Hence it has at least $m+1$ zeros, which proves that $Q\equiv 0$ and $R\equiv S_m$.

The quantity $1/T_m(d)$ is the maximum of $|S_m(\mu)|$ in the interval $[-1, +1]$, and is therefore the measure of the reduction of the coefficients of all eigenfunctions with eigenvalue in the range $-a<\lambda<b$, relative to an eigenfunction with eigenvalue c, when $S_m(\Omega)$ is applied to a trial vector (8). Table I gives this reduction factor, and can be used to determine the degree of the polynomial required to remove unwanted eigenfunctions to any given degree of accuracy. The parameter d has been replaced by the quantity $r=(a+b)/(a+c)$, which is more directly related to the spacing of the eigenvalues.

Figure 2 illustrates the effect of the operator $S_6(\Omega)$ for the case $a=1$, $b=0.9$, $c=1$ $(r=0.95)$. All eigenfunctions with eigenvalues in the range from -1 to $+0.9$ are multiplied by a factor of 0.13 or less, as shown by the curve $S_6[(20\lambda+1)/19]$. For comparison the sixth order curve λ^6 is shown, and the range over which this is less than 0.13 is indicated. In an actual computation

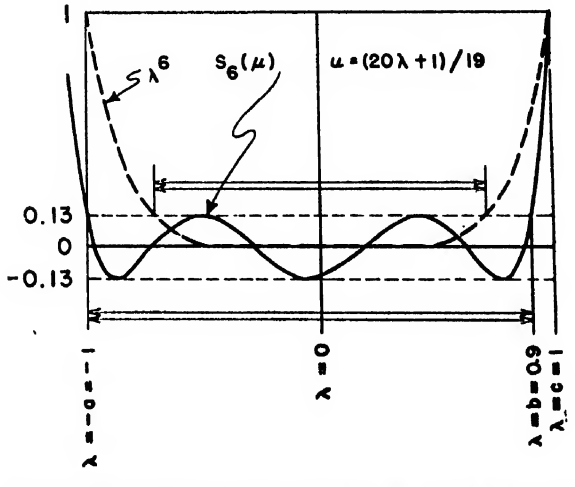

FIG. 2. As shown by the double arrows, the Tschebyscheff operator $S_6(\Omega)$ will accomplish a given reduction over a much wider range than will the operator ω^6. (In the upper right-hand corner, u should be μ.)

[4] In one sense the "best" polynomial would be $(\omega-\lambda_2)(\omega-\lambda_3)\cdots(\omega-\lambda_N)$, since this would eliminate every eigenvector except $\mathbf{u}^1$. But in any practical case such as we envisage, where the number of eigenvectors is large (in the hundreds or thousands), this would not actually be as useful (even assuming the eigenvalues known) as the polynomial we describe, since it would be of much higher degree.

[5] We are indebted to Drs. Tukey and Grosch for suggesting the possible usefulness of Tschebyscheff polynomials, in the course of a discussion of this work at the IBM Seminar on Scientific Computation held in Endicott, New York in November, 1949. We had previously used polynomials with zeros equally spaced. These were fairly efficient, but appreciably less so than the Tschebyscheff polynomials.

a polynomial of order higher than six would always be used.

In the practical application of an operator $S_m(\Omega)$ to a trial vector it is often convenient to use the following factor formula for Tschebyscheff polynomials:

$$T_{pq}(x)=\prod_{k=1}^{p}\left[T_q(x)-\cos\frac{2k-1}{p}\frac{\pi}{2}\right]. \tag{11}$$

This follows from the identity

$$\cos(pq\arccos x)\equiv\cos\{p\arccos[\cos(q\arccos x)]\},$$

which may be written

$$T_{pq}(x)=T_p[T_q(x)].$$

Since $T_p(y)$ has p zeros located at $y=\cos[(2k-1)/p](\pi/2)$ $(k=1,\cdots,p)$, (11) results from setting $y=T_q(x)$ in the factored form of $T_p(y)$.

If we have a vector v that is known to be a linear combination of just the first two eigenvectors, i.e.,

$$\mathbf{v}=c_1\mathbf{u}^1+c_2\mathbf{u}^2, \tag{12a}$$

one can determine λ_1, λ_2, $\mathbf{u}^1$, $\mathbf{u}^2$ by the following "harmonic analysis": First compute $\omega\mathbf{v}$ and $\omega^2\mathbf{v}$,

$$\omega\mathbf{v}=\lambda_1c_1\mathbf{u}^1+\lambda_2c_2\mathbf{u}^2, \tag{12b}$$

$$\omega^2\mathbf{v}=\lambda_1^2c_1\mathbf{u}^1+\lambda_2^2c_2\mathbf{u}^2. \tag{12c}$$

Next form the inner products

$$\left.\begin{aligned}(\mathbf{v},\mathbf{v})\equiv A&=c_1^2+c_2^2,\\(\mathbf{v},\omega\mathbf{v})\equiv B&=\lambda_1c_1^2+\lambda_2c_2^2,\\(\omega\mathbf{v},\omega\mathbf{v})\equiv(\mathbf{v},\omega^2\mathbf{v})\equiv C&=\lambda_1^2c_1^2+\lambda_2^2c_2^2,\\(\omega\mathbf{v},\omega^2\mathbf{v})\equiv D&=\lambda_1^3c_1^2+\lambda_2^3c_2^2.\end{aligned}\right\} \tag{13}$$

When c_1^2 and c_2^2 are eliminated from the equations (13) there result two independent equations for λ_1 and λ_2, which may be written in the form

$$\begin{vmatrix}A&1&1\\B&\lambda_1&\lambda_2\\C&\lambda_1^2&\lambda_2^2\end{vmatrix}=\begin{vmatrix}B&\lambda_1&\lambda_2\\C&\lambda_1^2&\lambda_2^2\\D&\lambda_1^3&\lambda_2^3\end{vmatrix}=0. \tag{14}$$

If these be solved for λ_1 and λ_2, and the possibilities $\lambda_1=0$, $\lambda_2=0$, $\lambda_1=\lambda_2$ (which do not concern us here) be discarded, the two λ's will be found to be the roots of the equation

$$\begin{vmatrix}A&B&1\\B&C&\lambda\\C&D&\lambda^2\end{vmatrix}=0. \tag{15}$$

$c_1\mathbf{u}^1$ and $c_2\mathbf{u}^2$ can then be determined from (12a, b) by

$$\left.\begin{aligned}c_1\mathbf{u}^1&=\frac{1}{\lambda_1-\lambda_2}\omega\mathbf{v}-\frac{\lambda_2}{\lambda_1-\lambda_2}\mathbf{v},\\c_2\mathbf{u}^2&=\frac{-1}{\lambda_1-\lambda_2}\omega\mathbf{v}+\frac{\lambda_1}{\lambda_1-\lambda_2}\mathbf{v}.\end{aligned}\right\} \tag{16}$$

If v is only approximately represented by the linear combination (12a), so that relations (13) are only approximately true, the solutions of (15) will give approximate values, λ_1' and λ_2', of λ_1 and λ_2. Since λ_1' and λ_2' $(\lambda_1'>\lambda_2')$ satisfy (13) exactly, $\lambda_1'A\equiv\lambda_1'(c_1^2+c_2^2)>\lambda_1'c_1^2+\lambda_2'c_2^2\equiv B$, $\lambda_1'>B/A\equiv(\mathbf{v},\omega\mathbf{v})/(\mathbf{v},\mathbf{v})$, i.e., λ_1' is greater than the estimate of λ_1 that would be obtained directly from the variational principle. In the examples we have tried we have always found $\lambda_1'<\lambda_1$, but we have not been able to prove that this will be true in general.

APPLICATION OF THE TECHNIQUES

In this section we shall discuss in some detail the application of the techniques developed in the preceding section. The general idea is first to do enough preliminary work to determine the rough shape of the eigenvector and approximate values of λ_1 and λ_2; then to make reasonable choices of a, b, and c, compute $r=(a+b)/(a+c)$, and choose an order m from Table I that will give adequate elimination of unwanted eigenfunctions. Then the operator $S_m(\Omega)$ given by (9) and (10) is applied to the rough eigenfunction to accomplish this elimination.

The problems for which these techniques were developed were based on relatively complicated regions that necessitated the use of hundreds or thousands of points to get even a moderately acceptable representation of the region and its boundary by the network. This has meant that the computations were possible only with the assistance of fairly high-speed computing machinery with a large memory, such as IBM punched-card equipment, particularly the 604 electronic computer. The following remarks are assumed to be concerned with such large-scale problems computed with comparable equipment.

In starting it is generally worth while to use a rather coarse net, even at the expense of considerably oversimplifying the geometry; e.g., if the region contains holes on whose boundaries the function is 0, it may be worth while to select a mesh so large that such a hole is represented by a single point at which the function is 0. The particular advantages of such a rough first approximation are that (a) the eigenvalues are much less densely spaced, so that approximate values of λ_1 and λ_2 are much more easily determined; (b) relation (4) shows that if λ' and λ'' are the eigenparameters for networks of mesh h' and h'', respectively, then λ_1'' and λ_2'' may be approximated from λ_1' and λ_2' by using $\lambda''=1-(h''/h')^2(1-\lambda')$; (c) the simplest possible interpolation in the vector derived from the coarse net will generally yield a vector that differs from the fundamental for the fine net principally by eigenvectors with eigenvalues near -1 (i.e., high-frequency oscillations), which are easy to eliminate. Thus, one may get a good starting vector for the fine network by treating the solution for the coarse network as a stepfunction in the fine network and smoothing it by a few preliminary operations with $(\omega+1)/2$, about equal in number to the ratio of h' to h''. A better starting func-

tion would be obtained by using an interpolation based on the difference equation (3) itself. Thus if 1, 2, 3, 4 are four points at the corners of a square of diagonal $2h'$, the difference equation determines the value u_0 at the center of the square as

$$u_0=(1/\lambda_1')\,\tfrac{1}{4}(u_1+u_2+u_3+u_4),$$

where λ_1' is the eigenvalue appropriate to a net of mesh h'. If we start with a net of mesh h, we can first use $h'=h/\sqrt{2}$ to fill in the center points of the meshes, then $h'=h/2$ to fill in the remaining points in a net of mesh $\frac{1}{2}h$.

The form of the starting function for the coarse network is not too important, provided the generally convex character of the function is observed. Advantage should be taken of any symmetries in the figure to reduce the number of points, which not only reduces the number of eigenfunctions but also decreases the density of the eigenvalues. It should be noted that the matrix resulting from using only a portion of a symmetrical figure is no longer symmetrical. For example, if the full figure is symmetrical along a diagonal and half the figure is used, the neighbors of a diagonal point are the neighbors on one side counted twice. The eigenvectors of the resulting matrix will not then be orthogonal in general. Their orthogonality will be restored if they are treated as eigenvectors of the matrix associated with the complete figure, which is done simply by giving to each point in the subregion actually used a weight equal to the number of points in the full region for which it stands.

In problems of the type considered here one may assume $a=1$ throughout, since $\lambda_N\approx-1$; and $c=1$ initially, since $\lambda_1\approx+1$. The first step is to pick an operator Ω and a polynomial $S_m(\Omega)$ of low degree that will enable one to compute λ_1 and λ_2 by the crude harmonic analysis of the previous section with fair accuracy. Thus, with $a=c=1$ the choice of $r=0.9$ and $m=8$ corresponds to $b=0.8$, $d=1.222$, $\Omega=(10\omega+1)/9$, $1/T_m(d)=0.0106$. This $S_m(\Omega)$ will reduce the coefficients of all eigenvectors in the expansion of v with eigenvalues lying in the range $-1\leq\lambda\leq0.8$ by at least the factor 0.01, and those with eigenvalues in the range $0.8\leq\lambda\leq1$ at least in proportion to the ratio $(\lambda-0.8)/0.2$. Ordinarily this will permit a harmonic analysis that will determine λ_1 and λ_2 with sufficient accuracy to choose a final operator for this network. However, if the number of points in the coarse network is rather large, it may be worth while to take r and m larger.

In the actual performance of an operation $S_m(\Omega)$ one is faced with a choice of methods. On the one hand $S_m(\Omega)$v may be computed by iterating with the operator Ω and then forming the polynomial as a linear combination of the results. This has the practical disadvantage that with large m the sizes of the terms are so disparate that a great deal of accuracy is lost in taking differences of large multiples of the results of the iterations. At the other extreme, $S_m(\Omega)$ may be factored into its linear factors,

$$S_m(\Omega)=\prod_{k=1}^{m}\frac{\Omega-\mu_k}{d-\mu_k},\qquad\left(\mu_k=\cos\frac{2k-1}{m}\frac{\pi}{2}\right)\tag{17}$$

and these linear operators applied successively. This method suffers from the disadvantage that the coefficients of the operator must be changed at each step, which is a dangerous source of error in machine operation. A reasonable practical compromise combines the two methods by use of the factor formula (11). Thus if we set

$$S_m(\Omega)=\prod_{k=1}^{p}\frac{T_q(\Omega)-\cos[(2k-1)/p]\pi/2}{T_q(d)-\cos[(2k-1)/p]\pi/2},\tag{18}$$

where q is about 6 or 8[6] and $p=m/q$, we may iterate q times with Ω, follow this with the computation of the first of the p polynomials, iterate on the result q times with Ω, compute the second polynomial factor, and so on. Since the cosine term in the denominator is small compared to $T_q(d)$, it may be omitted. This has the effect of changing the scale of the vector slightly, which is of no theoretical importance. If this omission is made, then the operator used in the iterations is always the same, while the coefficients used in the successive polynomials differ only in the constant term. Loss of significant figures is avoided by keeping q relatively small. When q is at least as large as 6 or 8, the change of scale produced by neglecting the cosine term in the denominator is not bothersome. (If the function does grow out of bounds, cutting it in half once will generally be sufficient. Note that this should be done *after* a polynomial factor is computed, not in the course of a set of iterations preparatory to the computation of such a polynomial.)

When a satisfactory solution for the coarse network has been obtained, a starting vector for the fine network may be constructed along the lines suggested above. At this point procedure will depend to some extent on whether the interest in the problem centers in the determination of the fundamental eigenvalue or of the fundamental eigenfunction. If the former, then b may safely be chosen somewhat less than λ_2 and we may determine λ_1 by harmonic analysis. If λ_1 and λ_2 are widely separated this method may also be used for determining the vector $c_1\mathbf{u}^1$. However, the determination of $c_1\mathbf{u}^1$ from (16) generally involves great loss of accuracy because of the nearness of λ_1 and λ_2, so if interest is centered in the eigenfunction, one is forced to choose b close to λ_2 with consequent increase in the size of m.

HIGHER MODES

While the method we have outlined is peculiarly adapted to obtaining the fundamental mode, it is pos-

[6] T_6 and T_8, which we have found most useful, are given by

$$2^{-5}T_6(\Omega)=\Omega^6-\tfrac{3}{2}\Omega^4+\tfrac{9}{16}\Omega^2-\tfrac{1}{32}$$
$$2^{-7}T_8(\Omega)=\Omega^8-2\Omega^6+\tfrac{3}{4}\Omega^4-\tfrac{1}{4}\Omega^2+\tfrac{1}{128}.$$

sibly useful for obtaining a limited number of the higher modes. Once the fundamental has been accurately obtained for the network, a trial vector for the next mode can be chosen that is accurately orthogonal to the fundamental. Application of $P(\omega)$ to such an orthogonal vector should not reintroduce (except as a result of rounding-off errors) any of the fundamental. Hence it should be possible to obtain a higher mode by orthogonalizing the trial vector to the predetermined lower modes, applying a suitable Tschebyscheff operator, and re-orthogonalizing as necessary. One useful application of this technique might be in the solution of Schrödinger's equation for diatomic molecules.

MORE GENERAL PROBLEMS

Several of the problems we have solved by a procedure similar to the above have been of a more general type than the one proposed in the introduction. Since the modifications introduced by this generalization may assist others in applying the procedure, we shall state briefly the most important features of the more general problems and their solution.

The single dependent variable u is replaced by two functions u and v that are to satisfy simultaneous equations

$$\left.\begin{aligned}(\Delta-E)u+Fv&=-\alpha u\\ Gu+(\Delta-H)v&=-\alpha v.\end{aligned}\right\} \tag{19}$$

The fundamental region is divided into subregions within each of which the coefficients E, F, G, H are constant functions of a parameter ρ. Certain homogeneous conditions are imposed across the interfaces. It is desired to determine ρ so that the fundamental eigenvalue $\alpha_1=0$, and to find the corresponding pair of eigenfunctions u, v.

The matrix equation analogous to (5) is then of the form

$$\begin{pmatrix}\omega-\frac{1}{4}h^2E & \frac{1}{4}h^2F\\ \frac{1}{4}h^2G & \omega-\frac{1}{4}h^2H\end{pmatrix}\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix}=\lambda\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix}, \tag{20}$$

where $\lambda=1-\frac{1}{4}h^2\alpha$, and consequently it is desired that $\lambda_1=1$. As in the first problem the introduction of the boundary conditions (and here of the interface conditions as well) results in modification of the interpretation of the operator ω at certain points, but ω still represents a linear combination of neighboring values with non-negative coefficients whose sum is ≤ 1. The two vectors $\mathbf{u}$, $\mathbf{v}$ are considered to form a single vector for the purposes of the computation.

Note that the matrix is no longer symmetric. This means that the eigenvectors may not be assumed to be orthogonal. Hence it is necessary ultimately to compute the adjoint solution in order to form correct inner products if a harmonic analysis is to be carried out. In the early stages this is not necessary since it can be shown that the λ_1 and λ_2 determined by the analog of (15) represent the result of fitting relations (12) by least squares. The λ's thus determined are, however, less accurate than those determined by true inner products.

In these problems h is chosen sufficiently small so that the coefficients h^2E, h^2F, h^2G, h^2H are small compared to 1. Hence the operator is nearly the operator $\begin{pmatrix}\omega 0\\ 0\omega\end{pmatrix}$. Aside from the asymmetry the principal effect of the more general matrix is to increase the range of the eigenvalues. Since it is possible to estimate ρ (on physical grounds) with fair accuracy in advance, λ_1 is still approximately $+1$. λ_N, however, may be considerably less than -1, say -3 or -4 if $\mathbf{u}$ and $\mathbf{v}$ are disparate in size. Our first problem is then to estimate λ_N. This may be done by choosing a sequence of operators of the type $(\omega-a)/(1-a)$ to replace ω in the matrix. If one takes $a=0$ and applies the resulting operator two or three times, the presence of eigenvectors with eigenvalue <-1 will be revealed by their coefficients being multiplied by negative factors of large absolute value, which thus produces oscillations of increasing amplitude in the successive vectors. (That such eigenvectors will appear, provided $\lambda_N<-1$, is practically guaranteed by the rounding-off errors introduced into the computation.) When the existence of such large negative eigenvalues has been established, similar operations may be carried out with $a=-1$, $-\frac{3}{2}$, -2, etc., until the phenomenon disappears. Thus a practical value of a for use in determining the operator Ω in the Tschebyscheff polynomial is achieved. The polynomial operator S_m is now not a function of Ω but of the matrix operator in (20) with Ω substituted for ω.

A final word about the treatment of the interface conditions. The particular conditions imposed are expressed in the difference equations by assertions of the form: the value of u at an interface point is a weighted average of certain neighboring values of u in the adjacent regions. It would be possible to eliminate all interface points from the vector in a manner similar to that in which the boundary points were eliminated. However, since λ_1 is very nearly $+1$ in these problems it is more convenient to retain the interface points, replacing their values at each stage by the weighted average specified in the interface conditions. This averaging then becomes part of the operator. Since we are doing the averaging and determining the interface values always one step late, this procedure is only exact for an eigenfunction of eigenvalue unity.

We are indebted to many of the members of the Theoretical Physics Division of the Argonne Laboratory, and in particular to Drs. Frank Hoyt and Elmer Eisner, for helpful discussions during the development of these techniques.

Determination of Eigenvalues Using a Generalized Laplace Transform*

MORRIS D. FRIEDMAN
N.A.C.A., Ames Aeronautical Laboratory, Moffett Field, California
(Received August 14, 1950)

The classical eigenvalue problems of mathematical physics are solved by means of a Laplace Transform extended, not over the interval $(0, \infty)$ but over the interval of interest for the differential equation. The method is applied to the Hermite, Laguerre and Bessel equations and to the equation for the hypergeometric polynomials which include the Legendre, Tschebyscheff, and Jacobi polynomials as special cases.

INTRODUCTION

IN many fields of mathematical physics, for example, quantum mechanics, electro-magnetics, acoustics, there occur second-order differential equations depending on a parameter λ which have satisfactory or well-behaved solutions only for particular values of λ. A solution is said to be well behaved if it is single-valued, continuous, and finite throughout the configuration space of the system (i.e., for all values of x which x may assume). In case the range of the variable x is infinite an extra condition about the behavior of the solution at infinity is needed. The values of the parameter λ for which the solutions are well behaved functions are called eigenvalues and the corresponding solutions eigenfunctions. This paper proposes a general method for finding the eigenvalues of a second-order differential equation.

The usual method of solving these second-order equations, called the Sommerfeld Polynomial Method, is to substitute a power series expansion (whose form is determined by an asymptotic solution of the differential equation) for the unknown function and then to determine the coefficients by equating like powers of x. This gives the general solution of the equation. Then the radius of convergence of the power series is investigated in order to find for which values of λ the solution is well behaved. This method is long, and it will be shown that by using a generalized Laplace transform,[1] the same results can be achieved in a more direct way and with less labor.

Those equations which can be put into the Sturm-Liouville[2] form will be treated. The Bessel, Hermite, Laguerre, Legendre, Jacobi, Tschebyscheff, and the Trigonometric equations will be special cases. These equations can be put into the following general form:

$$[P(x)U'(x)]'-[Q(x)-\lambda R(x)]U(x)=0. \quad (1)$$

Since the solutions of (1) have singularities at the zeros of $P(x)$ or at ∞, the problem is to find values of λ for which $U(x)$ is well behaved at these singular points. The method proposed is as follows.

Multiply each term of Eq. (1) by $e^{-sx}dx$ and integrate over a suitably chosen contour. In general, the contour will be a line joining the singularities of the differential equation, that is, either the real axis between two zeroes of $P(x)$, or the part of the real axis connecting a zero of $P(x)$ to ∞. The fact that $U(x)$ is well behaved at the singular points implies that the transformed function must be a regular, analytic function of s. Those values of λ for which the transform is analytic are the eigenvalues.

Consider

$$\int_C [P(x)U'(x)]'e^{-sx}dx - \int_C [Q(x)-\lambda R(x)]U(x)e^{-sx}dx=0. \quad (2)$$

When the first term on the left is integrated by parts twice, there results

$$\{P(x)U'(x)e^{-sx}+sP(x)U(x)e^{-sx}\}_C + s^2\int_C P(x)U(x)e^{-sx}dx - \int_C [sP'(x)+Q(x)-\lambda R(x)]U(x)e^{-sx}dx=0. \quad (3)$$

Now, if that contour is selected which will make the braces vanish, there results the integral equation:

$$\int_C [s^2P(x)-sP'(x)-Q(x)+\lambda R(x)]U(x)e^{-sx}dx=0, \quad (4)$$

or dividing by $R(x)$

$$\int_C \left[s^2\frac{P(x)}{R(x)}-s\frac{P'(x)}{R(x)}+\frac{Q(x)}{R(x)}+\lambda\right]U(x)R(x)e^{-sx}dx=0. \quad (5)$$

Suppose now that $P(x)/R(x)$, $P'(x)/R(x)$ and $Q(x)/R(x)$ are polynomials. This is actually the case in the standard eigenvalue problems. Put

$$U(x)R(x)=\bar{U}(x), \quad (6)$$

---

and let

$$\int_C \bar{U}(x)e^{-sx}dx = U(s), \tag{7}$$

where $U(s)$ is a generalized Laplace transform of $\bar{U}(x)$. Under certain conditions, multiplication of the integral in (7) by a power of x is equivalent to multiplying the derivative to that order by (-1) to that power; e.g.

$$\int x\bar{U}(x)e^{-sx}dx = -v'(s),$$

$$\int x^2\bar{U}(x)e^{-sx}dx = v''(s), \text{ etc.}^3$$

Therefore, Eq. (6) may be represented as the result of a function of s and the differential operator with respect to s acting on the integral of $\bar{U}(x)e^{-sx}dx$, or

$$g(s, D)\int_C \bar{U}(x)e^{-sx}dx = g(s, D)v(s) = 0, \tag{8}$$

where D is the differential operator with respect to s and $v(s)$ is the Laplace transform of $U(x)$. The result is, thus, a differential equation in $v(s)$ depending upon the parameter λ. The method consists in finding those values of λ for which $v(s)$ is an analytic function of s.

EIGENVALUES OF THE HYPERGEOMETRIC EQUATION

The method will first be applied to the particular case of the hypergeometric equation whose form is[4]

$$[(1+x)^r(1-x)^{p+q-r+1}U'(x)]' - \lambda(1+x)^{r-1}(1-x)^{p+q-r}U(x) = 0. \tag{9}$$

From this equation can be derived the Jacobi ($r=P+1$; $q=0$; $p=Q+P+1$), the Tschebyscheff ($r=\frac{1}{2}$; $p=q=0$), and the Legendre ($r=1$, $p+q=r$) equations. It will be shown that substitution of these values in the solution of λ for the hypergeometric equation will yield the corresponding solutions for the eigenvalues of the respective equations.

Since $P(x)$ in (9) has zeroes at $x=+1$ and $x=-1$, the terms of (9) are multiplied by e^{-sx} and the result is integrated between the limits of -1 and $+1$:

$$\int_{-1}^{1}[(1+x)^r(1-x)^{p+q-r+1}U'(x)]'e^{-sx}dx - \int_{-1}^{1}\lambda(1+x)^{r-1}(1-x)^{p+q-r}U(x)e^{-sx}dx = 0, \tag{10}$$

which can be written as

$$\int_{-1}^{1}[s^2(1+x)^r(1-x)^{p+q-r+1} - sr(1+x)^{r-1}(1-x)^{p+q-r+1} + s(p+q-r+1)(1+x)^r(1-x)^{p+q-r} + \lambda(1+x)^{r-1}(1-x)^{p+q-r}][U(x)e^{-sx}dx] = 0, \tag{11}$$

the same form as (5). Now, let

$$\int_{-1}^{1}(1+x)^{r-1}(1-x)^{p+q-r}U(x)e^{-sx}dx = v(s). \tag{12}$$

Recalling that multiplication of the transform by a power of x is equivalent to differentiation, (11) then becomes

$$s^2v - s^2v'' - srv - srv' + s(p+q-r+1)v - s(p+q-r+1)v' + \lambda v = 0, \tag{13}$$

where $v=v(s)$ and v' and v'' are derivatives of $v(s)$ with respect to x.

From (12) it is seen that if $U(x)$ is well behaved then $v(s)$ is an analytic function of s for all values of s. It is now necessary to find for which values of λ, (13) has analytic solutions. If $v(s)$ is analytic, then it can be written as

$$v(s) = \sum_0^\infty a_k s^k; \text{ and similarly,}$$

$$v'(s) = \sum_0^\infty k a_k s^{k-1}; \text{ and } v''(s) = \sum_0^\infty k(k-1)a_k s^{k-2}.$$

When these series are substituted in (13), there results

$$\sum a_{k-2}s^k - \sum (k^2-k)a_k s^k - r\sum a_{k-1}s^k + (p+q-r+1)\sum a_{k-1}s^k - (p+q-r+1)\sum k a_k s^k + \sum \lambda a_k s^k = 0, \tag{14}$$

or

$$(k^2+kp+kq-\lambda)a_k - a_{k-2} - (p+q-r+1)a_{k-1} = 0; \text{ for } k=0, 1, 2, \cdots. \tag{15}$$

(*Note:* $a_{-1}=a_{-2}=0$.)

Suppose, now, that a_n is the first non-zero coefficient. Then for $k=n$, (15) becomes

$$(n^2+np+nq-\lambda)a_n = 0, \tag{16}$$

so that λ must be

$$\lambda = n^2+np+nq, \tag{17}$$

and then the n-th eigenvalue is

$$\lambda_n = n(n+p+q). \quad n=1, 2, \cdots.$$

Notice that if a_n is the first non-zero coefficient then $v(0)=v'(0)=\cdots=v^{(n-1)}(0)=0$; or

$$(-1)^k v^k(0) = \int_{-1}^{1}(1+x)^{r-1}(1-x)^{p+q-r}U(x)x^k dx = 0 \qquad (k=0, 1, \cdots, n-1), \tag{18}$$

[4] E. T. Whittaker and G. N. Watson, *Modern Analysis* (Cambridge University Press, New York, 1947). (Note: In this paper, all equations were put in the self-adjoint form before solving. Differentiating the self-adjoint form and dividing by the common factor will bring the equation to the form listed in the reference.)

so that $U(x)$, the solution corresponding to the n-th eigenvalue is orthogonal to x^k $(k=0, 1, \cdots, n-1)$ with the weight function $(1+x)^{r-1}(1-x)^{p+q-r}$. This contains the well-known orthogonality property of the Jacobi, Tschebyscheff, and Legendre functions.[2,5]

If those values of p and q which were mentioned before are substituted in (17), the eigenvalues for the Jacobi, Tschebyscheff, and Legendre equations are a result.

The Legendre equation of higher order[2]

$$[(1-x^2)U'(x)]'-h^2(1-x^2)^{-1}U(x)+\lambda U(x)=0, \quad (19)$$

can be put in a more manageable form by the substitution of $Z(x)=(1-x^2)^{\frac{1}{2}h}U(x)$. The resulting equation

$$[(1-x^2)^{h+1}Z'(x)]'-[h(h+1)-\lambda](1-x^2)^hZ(x)=0, \quad (20)$$

transforms into the differential equation

$$s^2v''(s)+2s(h+1)v'(s)-(s^2+h(h+1)+\lambda)v(s)=0. \quad (21)$$

From (21), it is determined that

$$\lambda=n^2+n+2nh+h^2+h, \quad (h=0, 1, 2, \cdots).$$

THE CONFLUENT HYPERGEOMETRIC EQUATION

Another class of equations, the confluent hypergeometric, is allied to the hypergeometric mentioned above. The equations of this new class which will be treated are the Hermite, Laguerre, and Bessel.[2,4]

The Hermite equation, in self-adjoint form, is[2]

$$[e^{-x^2}U'(x)]'+\lambda e^{-x^2}U(x)=0. \quad (22)$$

Solutions are desired such that $e^{-x^2}U(x)$ is zero at $x=\pm\infty$.

$$\int_{-\infty}^{\infty}[e^{-x^2}U'(x)]'e^{-sx}dx+\int_{-\infty}^{\infty}\lambda e^{-x^2}U(x)e^{-sx}dx=0. \quad (23)$$

If the first integral on the left is integrated by parts; twice:

$$\left\{e^{-x^2-sx}U'(x)+se^{-x^2-sx}U(x)\right\}_{-\infty}^{\infty}$$
$$+s\int_{-\infty}^{\infty}(s+2x)e^{-x^2-sx}U(x)dx$$
$$+\int_{-\infty}^{\infty}\lambda e^{-x^2-sx}U(x)dx=0. \quad (24)$$

Now, around the chosen contour, if $U(x)$ is well behaved, the braces are zero and

$$v(s)=\int_{-\infty}^{\infty}e^{-x^2-sx}U(x)dx,$$

is substituted in (25), recalling that the product of a power of x and the integrand in the integral for which $v(s)$ is being substituted is a derivative of $v(s)$, then

$$s^2v(s)-2sv'(s)+\lambda v(s)=0. \quad (25)$$

This equation can be solved by separation of variables

$$v'(s)/v(s)=(s^2+\lambda)/2s-s/2+\lambda/2s, \quad (26)$$

or

$$\log v=s^2/4+(\lambda\log s)/2. \quad (27)$$

And, therefore,

$$v(s)=s^{\frac{1}{2}\lambda}\exp(\tfrac{1}{4}s^2). \quad (28)$$

It is concluded that in order for $v(s)$, determined in (27), to be analytic λ must be $2n$, where n is a positive integer.

It will now be shown that the well behaved solutions of the Hermite equation are polynomials. Assume that $\lambda=2n$ and that the corresponding solution of $U(x)$ may be written as

$$U(x)=e^{x^2}[e^{-x^2}V(x)]',$$

then (25) becomes

$$V(s)=\int_{-\infty}^{\infty}e^{-sx}[e^{-x^2}V(x)]'dx. \quad (29)$$

After an integration by parts,

$$V'(s)=e^{-sx-x^2}V(x) \quad +s\int_{-\infty}^{\infty}e^{-sx-x^2}V(x)dx, \quad (30)$$

so that from (28)

$$\int_{-\infty}^{\infty}e^{-sx-x^2}V(x)dx=s^{n-1}\exp(s^2/4). \quad (31)$$

By induction, it is seen that if

$$U(x)=e^{x^2}\frac{d^n}{dx^n}[e^{-x^2}W(x)]; \quad (32)$$

then

$$\int_{-\infty}^{\infty}e^{-sx-x^2}W(x)dx=\exp(s^2/4). \quad (33)$$

But

$$\int_{-\infty}^{\infty}e^{-sx-x^2}dx$$
$$=\int_{-\infty}^{\infty}\exp[-(x+\tfrac{1}{2}s)^2]\exp(s^2/4)dx$$
$$=\int_{-\infty}^{\infty}\exp(s^2/4)\exp(-y^2)dy=\pi^{\frac{1}{2}}\exp(\tfrac{1}{4}s^2), \quad (34)$$

so that

$$\int_{-\infty}^{\infty}e^{-sx-x^2}(dx/\pi^{\frac{1}{2}})=\exp(\tfrac{1}{4}s^2), \quad (35)$$

[5] P. Frank and R. Von-Mises, *Differentiale Gleichungen—Vol. I* (Mary S. Rosenberg, New York, 1943), second edition.

and $W(x)$ may be taken equal to $\pi^{-\frac{1}{2}}$ to satisfy Eq. (33). This shows that

$$U(x)=\frac{e^{x^2}}{\pi^{\frac{1}{2}}}\frac{d^n}{dx^n}(e^{-x^2}). \tag{36}$$

The confluent hypergeometric equation also contains, as a special case, the Laguerre equation.[2,4]

$$[xe^{-x}U'(x)]'+\lambda e^{-x}U(x)=0. \tag{37}$$

A well behaved solution of this equation is one which is regular at $x=0$ and such that $e^{-x}U(x)$ vanishes at $x=\infty$. Just as for the Legendre equation, so too, for the Laguerre there is an equation for functions of higher order. This equation

$$[x^{k+1}e^{-x}U'(x)]'+\lambda x^k e^{-x}U(x)=0, \tag{38}$$

can be solved in the same manner as the equation of first order.

Multiply (38) by e^{-sx} and integrate along C, the real axis from 0 to ∞. Then

$$\int_C [xe^{-x}U'(x)]'e^{-sx}dx+\int_C \lambda e^{-x}e^{-sx}U(x)dx=0. \tag{39}$$

This Eq. (39) is similar in form to Eq. (2) and since the contour selected will cancel all integrated terms, (40) can immediately be put in the form (5) as follows:

$$s^2\int_C xe^{-x-sx}U(x)dx+s\int_C xe^{-x-sx}U(x)dx$$

$$-s\int_C e^{-x-sx}U(x)dx+\int_C \lambda e^{-x-sx}U(x)dx=0. \tag{40}$$

Now let the transform be

$$v(s)=\int_0^\infty e^{-x(1+s)}U(x)dx, \tag{41}$$

then (41) becomes

$$-s^2v'(s)-sv'(s)-sv(s)+\lambda v(s)=0. \tag{42}$$

After collection of terms and separation of variables, there results

$$\frac{v'(s)}{v(s)}=\frac{-s}{s(s+1)}=\frac{\lambda}{s}-\frac{1+\lambda}{s+1}, \tag{43}$$

and

$$\log v=\lambda\log s-(1+\lambda)\log(s+1), \tag{44}$$

or

$$v(s)=s^\lambda/(s+1)^{1+\lambda}. \tag{45}$$

Since $U(x)$ behaves like $e^{x-\epsilon}$ at $x=\infty$, $v(s)$ must be regular at $x=0$. Were λ negative, $v(s)$ would have a pole; were λ a fraction there would be a branch point, and since both assumptions are contrary to the conditions, then $\lambda=n$, a positive integer.

(Note that the transform of x^n is $n!/(1+s)^{n+1}$; so if $v(s)$ be expanded in inverse powers of $(1+s)$, $U(x)$ can be found.)

From (45), for $\lambda=n$,

$$v(s)=(1+s-1)^n/(1+s)^{n+1}=\frac{1}{s+1}\left(1-\frac{1}{s+1}\right)^n, \tag{46}$$

and

$$v(s)=\sum_0^n \frac{(-1)^k\binom{n}{k}}{(1+s)^{k+1}}. \tag{47}$$

The inverse transform of $v(s)$ in (47) is[2]

$$U(x)=\sum_0^n (-1)^k\frac{x^k}{k!}\frac{n!}{k!(n-k)!}, \tag{48}$$

which is a solution of (37).

The Bessel equation[6]

$$x^2U''(x)+(2x+2)U'(x)-\lambda U(x)=0,$$

can also be put into the self-adjoint form with the weight function $\exp(-2/x)$. The result is

$$[\exp(-2/x)x^2U'(x)]'-\lambda\exp(-2/x)U(x)=0, \tag{49}$$

and the more general form

$$[\exp(-b/x)x^aU'(x)]'-\lambda\exp(-b/x)x^{a-2}U(x)=0, \tag{50}$$

which are also special cases of the confluent hypergeometric equation.

A solution single-valued on the unit circle $|x|=1$ is desired. Again, multiply the equation, in this case (49), by e^{-sx} and integrate around C, the unit circle, obtaining

$$\int_C [\exp(-2/x)x^2U'(x)]'e^{-sx}dx$$

$$-\int_C \lambda\exp(-2/x)e^{-sx}U(x)dx=0. \tag{51}$$

Integrating as before, yields the result in the form of (4)

$$\{\exp(-2/x)x^2e^{-sx}U'(x)+s\exp(-2/x)x^2e^{-sx}U(x)\}_C$$

$$+\int_C (s^2x^2-2sx+2s-\lambda)$$

$$\times\exp(-2/x)e^{-sx}U(x)dx=0. \tag{52}$$

Now, around this contour, because $U(x)$ is single-valued, the braces evaluate to zero. Then, putting

$$v(s)=\int_C \exp(-s/x)e^{-sx}U(x)dx, \tag{53}$$

[6] J. Kroll and O. Frink, "A new class of orthogonal polynomials," Abstract 249, Bull. Am. Math. Soc., July 1948.

the resulting equation is

$$s^2v''(s)+2sv'(s)+2sv(s)-\lambda v(s)=0. \quad (54)$$

Substituting a power series for $v(s)$, and equating coefficients of like powers of s, yields

$$n^2-n+2n=\lambda, \quad (55)$$

or

$$\lambda=n^2+n.^5$$

In Eq. (50), λ can be determined to be $n(n-a+1)$.[6]

The property of orthogonality demonstrated for the Jacobi equation can, similarly, be shown to apply to the other equations treated.

Finally, consider the special case of the Sturm-Liouville type equation, the Trigonometric[2]

$$U''(x)+\lambda^2U(x)=0, \quad (56)$$

with the conditions $U(0)=U(1)=0$.

Multiply (56) by e^{-sx} and integrate from 0 to 1. Thus

$$\int_0^1 U''(x)e^{-sx}dx+\int_0^1 \lambda^2U(x)e^{-sx}dx=0. \quad (57)$$

Integrate the first integral by parts twice:

$$\left\{U'(x)e^{-sx}+sU(x)e^{-sx}\right\}_0^1+s^2\int_0^1 U(x)e^{-sx}dx$$

$$+\int_0^1 \lambda^2U(x)e^{-sx}dx=0. \quad (58)$$

Evaluate the brace and set

$$v(s)=\int_0^1 U(x)e^{-sx}dx, \quad (59)$$

obtaining

$$U'(1)e^{-s}-U'(0)+(s^2+\lambda^2)v(s)=0. \quad (60)$$

Solving for $v(s)$

$$v(s)=\frac{U'(0)-U'(1)e^{-s}}{s^2+\lambda^2}. \quad (61)$$

Now, for $v(s)$ to be analytic, it is necessary to get rid of the poles at $s=\pm i\lambda$. Therefore the numerator of (61) must be zero when $s=\pm i\lambda$.

Inserting $\pm i\lambda$ for s and solving simultaneously

$$\begin{aligned} U'(0)-U'(1)e^{-i\lambda}&=0,\\ U'(0)-U'(1)e^{+i\lambda}&=0, \end{aligned} \quad (62)$$

$$U'(1)(e^{i\lambda}-e^{-i\lambda})=0. \quad (63)$$

Since $U'(1)$ is not zero, the parenthesis must be, and therefore

$$\sin\lambda=0,$$

or

$$\lambda=n\pi; \quad \lambda^2=n^2\pi^2.$$

SUMMARY

A method which can be used to determine the eigenvalues of equations of mathematical physics has thus been demonstrated on the equations of the Sturm-Liouville type. The method also demonstrates that the solutions have certain orthogonality properties and in the special cases of the Hermite and Laguerre equations allows the solution to be found.

Letters to the Editor

Comment on "Relationship between Gough-Joule Coefficients and Moduli of Vulcanized Rubbers"[1]

M. Mooney
United States Rubber Company, Passaic, New Jersey
August 31, 1950

In the article of the title quoted above the authors were interested in establishing by experiment the theoretical equality between the tangent shearing modulus of a rubber and the ratio of the temperature coefficient of shearing stress to the negative temperature coefficient of shearing strain. Their published data can be used also for calculating the value of an important property, the relative temperature coefficient of relative stress, σ, at constant strain, γ, or $T/\sigma(\partial\sigma/\partial T)_\gamma$. The value of this coefficient is unity if there is entropy change but no energy change in an isothermal strain, as is postulated in the kinetic theory of elasticity.

The values of the coefficient can be calculated from the data given by Conant, Hall, and Thurman for σ/γ, $1/\gamma(\partial\sigma/\partial T)_\gamma$, and T, the reference temperature.

The calculations yield the results:

Compound	$T/\sigma(\partial\sigma/\partial T)_\gamma$
Hevea *B*	0.82
GR-S	1.33
Butaprene	0.90
Butyl	1.05
Neoprene	1.04
Hevea *A*	0.81
Hevea *C*	0.67

While the values of the coefficient are correct in order of magnitude, they depart from unity in many cases by amounts which are presumably larger than the experimental error. These results are qualitatively in agreement with those published by Copeland and Mooney,[2] who also found significant departures from the theoretical value, unity, in several cases. Quantitatively, however, the results of the two groups of experimentalists are not in good agreement.

Obviously more work in the field of thermo-elasticity is called for to determine whether the differences in results are caused by the use of different compounds, different test methods, or other factors. However, it is growing more and more evident that, contrary to the kinetic theory of elasticity, the energy of an elastomer subjected to isothermal strain sometimes contributes appreciably to the stress.

Concerning the experimental method used by Conant and associates, it may be remarked, incidentally, that the constraints on the thermal expansion imposed by a sandwich type of sample involves some corrections which may be appreciable, and certainly are not easily estimated.

An Approximation Method for the Determination of the Elastic Constants of Cubic Single Crystals

J. R. Neighbours and Charles S. Smith
Case Institute of Technology, Cleveland, Ohio
Received October 5, 1950

A recent investigator[1] has shown how the elastic constants of cubic crystals may be found from measurement of the three wave velocities in an arbitrary direction in the crystal. It is the purpose of this paper to show how this approximation method may be extended to higher orders.

Materials having cubic symmetry are characterized by three elastic constants, C_{11}, C_{12}, C_{44}. These constants relate stress and strain in a particularly simple way when the reference axes, XYZ, are also the crystallographic axes. In another set of axes, $X'Y'Z'$, the relationship is more complicated.

In general, the relationship between the sets of axes is governed by the scheme of direction cosines.

	X	Y	Z
X'	l_1	m_1	n_1
Y'	l_2	m_2	n_2
Z'	l_3	m_3	n_3

(1)

If the Y' axis is arbitarily taken to lie in the $X-Y$ plane, this scheme may be written in terms of l_1, m_1, and n_1 only.

	X	Y	Z
X'	l_1	m_1	n_1
Y'	$-m_1[l_1^2+m_1^2]^{-\frac{1}{2}}$	$l_1[l_1^2+m_1^2]^{-\frac{1}{2}}$	0
Z'	$-l_1n_1[l_1^2+m_1^2]^{-\frac{1}{2}}$	$-m_1n_1[l_1^2+m_1^2]^{-\frac{1}{2}}$	$[l_1^2+m_1^2]^{\frac{1}{2}}$

(2)

It may be shown that, for irrotational plane waves traveling in the X' direction, the equations of motion are:

$$\left.\begin{aligned}\rho\frac{\partial^2u'}{\partial t^2}&=C_{11}'\frac{\partial^2u'}{\partial x'^2}+C_{16}'\frac{\partial^2v'}{\partial x'^2}+C_{15}'\frac{\partial^2w'}{\partial x'^2},\\ \rho\frac{\partial^2v'}{\partial t^2}&=C_{16}'\frac{\partial^2u'}{\partial x'^2}+C_{66}'\frac{\partial^2v'}{\partial x'^2}+C_{56}'\frac{\partial^2w'}{\partial x'^2},\\ \rho\frac{\partial^2w'}{\partial t^2}&=C_{15}'\frac{\partial^2u'}{\partial x'^2}+C_{56}'\frac{\partial^2v'}{\partial x'^2}+C_{55}'\frac{\partial^2w'}{\partial x'^2},\end{aligned}\right\} \tag{3}$$

where

$$\left.\begin{aligned}C_{11}'&=C_{11}-2[l_1^2m_1^2+l_1^2n_1^2+m_1^2n_1^2]C,\\ C_{16}'&=l_1m_1[m_1^2-l_1^2][l_1^2+m_1^2]^{-1}C,\\ C_{66}'&=C_{44}+2l_1^2m_1^2[l_1^2+m_1^2]^{-1}C,\\ C_{15}'&=-n_1[l_1^4+m_1^4-n_1^2(l_1^2+m_1^2)][l_1^2+m_1^2]^{-1}C,\\ C_{55}'&=C_{44}+2n_1^2[l_1^4+l_1^2m_1^2+m_1^4][l_1^2+m_1^2]^{-1}C,\\ C_{56}'&=l_1m_1n_1[l_1^2-m_1^2][l_1^2+m_1^2]^{-1}C,\\ C&=[C_{11}-C_{12}-2C_{44}],\end{aligned}\right\} \tag{4}$$

and u', v', w' are the displacements in the X', Y', Z' directions, respectively.

The secular equation obtained from Eq. (3) is

$$\begin{vmatrix}C_{11}'-\rho V^2 & C_{16}' & C_{15}'\\ C_{16}' & C_{66}'-\rho V^2 & C_{56}'\\ C_{15}' & C_{56}' & C_{55}'-\rho V^2\end{vmatrix}=0. \tag{5}$$

The roots of this equation may be found by the perturbation method to be

$$\left.\begin{aligned}\rho V_1^2&=C_{11}'+\left\{\left[\frac{C_{15}'^2}{C_{11}'-C_{55}'}+\frac{C_{16}'^2}{C_{11}'-C_{66}'}\right]+\left[\frac{2C_{15}'C_{16}'C_{56}'}{(C_{11}'-C_{66}')(C_{11}'-C_{55}')}\right]+\cdots\right\},\\ \rho V_2^2&=C_{66}'+\left\{\left[\frac{C_{16}'^2}{C_{66}'-C_{11}'}+\frac{C_{56}'^2}{C_{66}'-C_{55}'}\right]+\left[\frac{2C_{15}'C_{16}'C_{56}'}{(C_{66}'-C_{11}')(C_{66}'-C_{55}')}\right]+\cdots\right\},\\ \rho V_3^2&=C_{55}'+\left\{\left[\frac{C_{15}'^2}{C_{55}'-C_{11}'}+\frac{C_{56}'^2}{C_{55}'-C_{66}'}\right]+\left[\frac{2C_{15}'C_{16}'C_{56}'}{(C_{55}'-C_{11}')(C_{55}'-C_{66}')}\right]+\cdots\right\}.\end{aligned}\right\} \tag{6}$$

Combining the perturbation roots of the secular determinant with the first three of Eqs. (4) results in the set of equations:

$$\left.\begin{aligned}
C_{11}' &= C_{11}-2[l_1^2m_1^2+l_1^2n_1^2+m_1^2n_1^2]C \\
&= \rho V_1^2-\left\{\left[\frac{C_{15}'^2}{C_{11}'-C_{55}'}+\frac{C_{16}'^2}{C_{11}'-C_{66}'}\right]\right. \\
&\quad \left.+\left[\frac{2C_{15}'C_{16}'C_{56}'}{(C_{11}'-C_{55}')(C_{11}'-C_{66}')}\right]+\cdots\right\}, \\
C_{66}' &= C_{44}+2l_1^2m_1^2[l_1^2+m_1^2]^{-1}C \\
&= \rho V_2^2-\left\{\left[\frac{C_{16}'^2}{C_{66}'-C_{11}'}+\frac{C_{56}'^2}{C_{66}'-C_{55}'}\right]\right. \\
&\quad \left.+\left[\frac{2C_{15}'C_{16}'C_{56}'}{(C_{66}'-C_{11}')(C_{66}'-C_{55}')}\right]+\cdots\right\}, \\
C_{55}' &= C_{44}+2n_1^2[l_1^4+l_1^2m_1^2+m_1^4][l_1^2+m_1^2]^{-1}C \\
&= \rho V_3^2-\left\{\left[\frac{C_{15}'^2}{C_{55}'-C_{11}'}+\frac{C_{56}'^2}{C_{55}'-C_{66}'}\right]\right. \\
&\quad \left.+\left[\frac{2C_{15}'C_{16}'C_{56}'}{(C_{55}'-C_{11}')(C_{55}'-C_{66}')}\right]+\cdots\right\}.
\end{aligned}\right\} \quad (7)$$

If the three wave velocities V_1, V_2, V_3 in the X' direction are determined, then Eqs. (7) may be solved by successive approximations to yield C_{11}, C_{12}, and C_{44}. The X' direction, specified by l_1, m_1, n_1, which also must be measured, need not be a special direction in the cubic crystal. Certain exceptional directions are noted below.

The values of the perturbation terms (within braces, Eq. 6) depend in complex ways upon the elastic constants and direction in the crystal, but roughly the absolute value of the quantity $C=[C_{11}-C_{12}-2C_{44}]$ determines the magnitude of these terms. For ionic crystals such as silver chloride where the quantity $|C|$ is small, the higher order perturbation terms are quite small.[1] Much larger values for corresponding perturbation terms are found for metallic crystals such as nickel where the quantity $|C|$ is about an order of magnitude larger. In our experience, about five trials are required in making a solution of (7) for a metallic crystal.

In general, a given set of direction cosines defines any one of six crystallographically equivalent directions in the first octant, and care must be exercised to choose an advantageous order for the direction cosines. Since n_2 has been chosen equal to zero, the perturbation approximations to the roots of the secular equation will be better approximations to the actual roots for certain choices of l_1, m_1, and n_1. In practice, the better choices are those that place the X' axis near an $[h\,h\,l]$ type direction.

It should be pointed out that the directions [100] and [111] are ambiguous in that for each of these directions the two transverse wave velocities are equal. All three elastic constants, C_{11}, C_{12}, and C_{44}, cannot be determined by wave velocity measurements in these directions. Wave velocity measurements in those general directions near to these two are suitable in principle but not in practice for a determination of all three elastic constants.

The [110] direction in the cubic crystal is, on the other hand, unique in that wave velocity measurements in this direction will determine all three elastic constants, and in this direction the perturbation terms are zero. General directions near to this special direction will yield good accuracy for the constants and only small perturbation corrections will be necessary.

The elastic constants numerically computed from (7) may be checked by using the results to make a numerical solution of the secular determinant, Eq. (5). The three values for the wave velocities thus obtained from (5) should agree with the three measured wave velocities.

It is felt that the method outlined here has several advantages over that of measuring the wave velocities in crystals cut in special, simple directions. In practice, many difficulties may be experienced in attempts to grow single crystals large enough to be cut to a desired orientation. Even if crystals of adequate size are grown, use of the above perturbation method may be quicker and simpler than cutting an oriented crystal. This perturbation method has been used by the authors for determining the elastic constants of nickel, which work will be published at an early date. This work has been supported by the ONR.

Coefficient of Self-Diffusion of Copper

G. Cohen and G. C. Kuczynski
Metallurgy Department, Polytechnic Institute of Brooklyn, Brooklyn, New York
August 31, 1950

It has been shown previously[1-3] that the coefficients of self-diffusion of metals can be determined by measuring, as a function of time and temperature, the width x of the "neck" formed during sintering of a metallic wire to a cylinder of the same metal. The method was described in detail elsewhere.[3]

The specimens were prepared from OFHC copper. The annealed copper wire of 0.005-inch diameter was wound around the rods of ¼-inch diameter and heated in dry hydrogen at temperatures and for time periods indicated in Table I. After heating, the specimens were cut longitudinally, polished, etched, and measured under the microscope. The coefficients of self-diffusion D were calculated from the equation[3]

$$D=3/80\pi\ kT/\delta^3\gamma t\ x^6/a^2,$$

where k is the Boltzmann constant, a the radius of the wire, T absolute temperature, t the time of heating, δ the interatomic

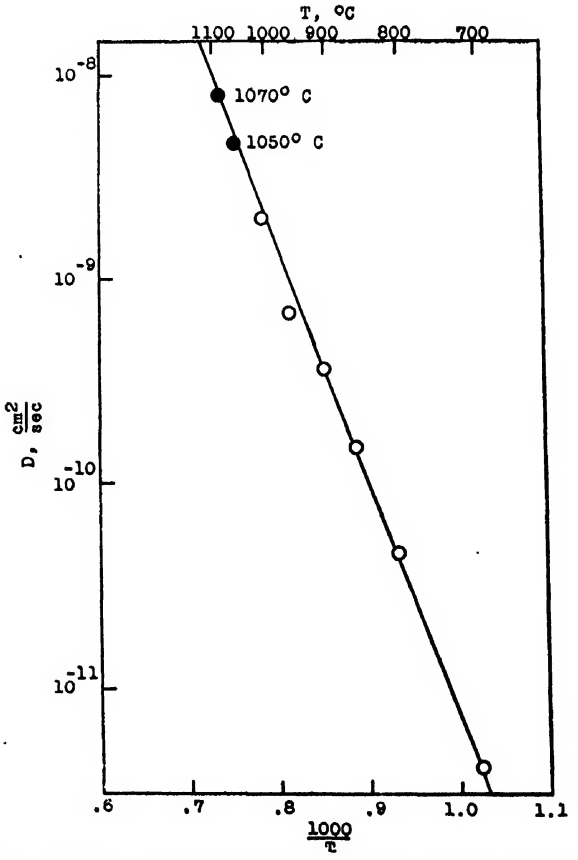

FIG. 1. Variation of self-diffusion coefficient of copper with temperature. Natural logarithm of D *versus* reciprocal of absolute temperature.

TABLE I. Self-diffusion coefficient D of copper.

Temperature, °C	Time (hrs)	$\times 10^{-4}$ cm	D cm²/sec.
700	4.0	6.1	4.06×10^{-12}
800	2.0	8.5	4.60×10^{-11}
850	1.0	9.4	1.53×10^{-10}
900	1.0	11.1	3.58×10^{-10}
950	1.0	12.2	6.80×10^{-10}
1000	0.5	13.2	1.95×10^{-9}

distance (in the present case 2.55A), and γ the surface energy of solid copper taken as 1370 ergs/cm².[4] The D-values so obtained are listed in Table I along with measured values of x. From the $\ln D/1000/T$ plot in Fig. 1, the coefficient of self-diffusion of copper was found to be expressed by the following equation: $D=4.1e^{-54,000/RT}$, which agrees fairly well with that obtained by J. Steigman, W. Shockley, and F. C. Nix,[5] which is $D=11.0e^{-57,200/RT}$. The points in Fig. 1 marked by black circles and corresponding to temperatures 1050°C and 1070°C were determined independently[6] by the same method. They fall very well on the straight line resulting from this investigation.

Erratum: Transonic Potential Flow of a Compressible Fluid

[J. App. Phys. 21, 771–778 (1950)]

W. R. SEARS
Cornell University, Ithaca, New York

SINCE the publication of the above article, Professor Y. H. Kuo has changed his analysis of the stability of mixed potential flow. His conclusions are now different from those reported in my paper.

Specifically, Dr. Kuo discovered an inconsistency in the orders of magnitude of terms resulting from his boundary condition. Upon correction of this, the term k/m disappears from the definition of σ (see my Eq. (9)), and consequently the profound effect of the local slope of the body at the sonic line disappears from the results. His final conclusions, based on the revised calculation, are that accelerating transonic flow is stable with respect to the class of disturbances considered, while decelerating flow is unstable to compression disturbances, on convex surfaces regardless of the slope m. Obviously, this brings him into agreement with other authors, who have analyzed the problem from different standpoints, and seems to eliminate the interesting possibility of stable transonic potential flow sketched in my Fig. 10.

Erratum: Separation of Gases by Fractional Permeation through Membranes

[J. App. Phys. 21, 279–283 (1950)]

SOL WELLER AND WALDO A. STEINER
Synthetic Liquid Fuels Branch, Bureau of Mines, Pittsburgh, Pennsylvania

BY an error in transcription the sign of the quantity C has been given incorrectly in some of the equations in the above paper. C should be defined by the equation

$$C=\tfrac{1}{2}[1+(\alpha-1)p/P],$$

and Eqs. (12) and (13) should read

$$x=f(i)=Ai-C+[A^2i^2+(\alpha-2AC)i+C^2]^{\frac{1}{2}}, \tag{12}$$

$$\frac{dn_B}{n_B}=\frac{di}{f(i)-i}=\frac{di}{(A-1)i-C+[A^2i^2+2Bi+C^2]^{\frac{1}{2}}}, \tag{13}$$

where $2B=\alpha-2AC$. The subsequent equations and Fig. 2 are correct.

We are grateful to Dr. T. P. Wilson for pointing out this error to us.

Deformations and Stresses in Bourdon Tubes*

R. A. CLARK** AND E. REISSNER
Department of Mathematics, Massachusetts Institute of Technology, Cambridge, Massachusetts

August 18, 1950

A BOURDON tube may be considered as a toroidal, elastic shell with thin walls, oval cross section, and with closed ends. When such a closed tube is exposed on the outside or on the inside to uniform normal wall pressure, the curvature of the center line of the tube changes proportionally with the applied wall pressure. Measurements of the resultant motion of one end of the tube with reference to the other may then be interpreted, after appropriate calibration, as pressure measurements.

The physical nature of the action of the tube may be understood by means of the following considerations. Take first a *complete* torus subject to uniform wall pressure. If the pressure is on the outside, it will produce tension in the part of the walls nearest to the axis of the torus and compression in the part of the walls furthest from the axis. This stress distribution then evidently produces an internal bending moment with axis parallel to the axis of the torus.

In the Bourdon tube *part* of the complete torus is taken and the ends are closed up. The shell is now no longer able to take the bending moment which occurred in the complete torus. Consequently one may consider the state of stress and deformation in the tube as a superposition of two states: (1) stresses and deformations in a complete torus subject to wall pressure; (2) stresses and deformations in an incomplete torus acted upon by bending moments at the ends.[1] The magnitude of the applied moment of state 2 is chosen such that it cancels the corresponding internal moment of state 1. It is the superimposed state 2 which is responsible for the change of curvature of the center line of the tube.

State 1 is treated as a problem in the theory of axi-symmetrical deformations of thin shells of revolution. State 2 is treated in the same manner after introduction into the theory of a non-axi-symmetrical component of circumferential displacement.[2]

If for the sake of discussion, the curved tube is considered as made up of two systems of curved rods, one system with circular center lines and the other system consisting of closed, oval rings, it is now understood that the action of the tube involves direct stresses and negligible bending of the circular rods and bending with negligible direct strains of the oval rings.[3–5]

There are two well-known limiting solutions both for state 1 and state 2. In the limiting solution for state 1 which concerns the complete torus under pressure the bending stresses in the oval rings are neglected and determination of the direct stresses becomes a problem of the membrane theory of thin shells.[6] In the limiting solution for state 2 the oval rings are considered rigid and the curved tube is stressed and deformed in accordance with the elementary theory of beams.

Combination of these two limiting states for a theory of the Bourdon tube has again been suggested quite recently.[7] It is, however, easy to see that joint application of the two limiting

solutions is not justified physically. The membrane solution for state 1 will be applicable only for tubes with sufficiently *thin* walls. The elementary-beam theory solution for state 2 will be applicable only for tubes with sufficiently *thick* walls. So far as is known, no results have yet been given concerning the meaning of the word "sufficiently" for the problem of state 1.

In order to gain further insight into the problem the authors have undertaken a study from the point of view of the theory of thin shells of the stresses and deformations of Bourdon tubes with elliptical cross section. In this theory the problem can be reduced to the determination of the periodic solutions of two simultaneous, linear, non-homogeneous second-order differential equations with periodic coefficients.

It is found that the solutions depend primarily on two dimensionless parameters which involve the dimensions of the tube. These parameters are of the form b/c and bc/ah, where a = radius of center line of the tube, h = wall thickness of the tube, c = major semi-axis of the elliptical cross section, and b = minor semi-axis of the elliptical cross section.

Quantitative solutions of the differential equations of the problem led to the result that the membrane solution for state 1 is adequate as soon as the parameter bc/ah is larger than about 10. On the other hand, the elementary beam-theory solution for state 2 ceases to be adequate as soon as bc/ah is larger than about 0.5.

Two different methods of solution were employed for the differential equations of the problem. For values of the parameter bc/ah up to about 5, trigonometric series were used. This led to infinite systems of simultaneous linear equations for the coefficients of the trigonometric series. These were solved approximately by retaining only a finite number of the coefficients. In this way up to ten simultaneous equations for ten unknowns were needed.

The other method of solution was an extension to *non-homogeneous* differential equations of what is often referred to as the W.K.B.J. method of asymptotic integration. This method is applicable for sufficiently large values of the parameter bc/ah. It was found that adequate results were obtained in this way as soon as bc/ah was larger than about 2. The consequent overlapping of the ranges of validity of the series solution and of the asymptotic solution permitted a check on the accuracy of either method.

Derivation of the asymptotic results proved to be very much more convenient than use of the series method. Remarkably simple explicit formulas could be obtained in the asymptotic range and these are listed below.

The sensitivity of the tube is given by the formula

$$\frac{\Delta a}{a}=\frac{p}{E}\frac{a}{b}\frac{c^2-b^2}{h^2}\left(1.63-\frac{ah}{cb}\right). \tag{1}$$

In Eq. (1) p is the applied wall pressure, E the modulus of elasticity of the tube material, and Δa the change of the radius a of the tube caused by the applied pressure. A small effect of Poisson's ratio is incorporated in the numerical coefficient 1.69 which is based on $\nu=\frac{1}{3}$. The general form of this coefficient is $[3(1-\nu^2)]^{\frac{1}{2}}$. Equation (1) is applicable as soon as cb/ah is larger than about 2. For very much larger values of cb/ah the second term inside the parenthesis becomes negligible and the result becomes still simpler.

The maximum stress in the tube is caused by bending of the elliptical rings and occurs at the ends of the major axis of the cross section. When cb/ah is larger than about 2, it is given by the formula

$$\sigma_m=1.88p(ah/cb)^{\frac{1}{2}}(c^2-b^2)/h^2. \tag{2}$$

It is further found that the stress σ_m is always smaller than the corresponding bending stress in a straight tube with the same elliptical cross section and with the same uniform wall pressure p. Denoting this stress for the straight tube by σ_{sm} it is found that, in the range of applicability of Eq. (2),

$$\frac{\sigma_m}{\sigma_{sm}}=\frac{1.87b_0}{b_0-b_1}\left(\frac{ah}{cb}\right)^{\frac{1}{2}}, \tag{3}$$

where b_0 and b_1 are expressed in terms of complete elliptic integrals in the form

$$\left.\begin{aligned} b_0&=(4/\pi)E(e), \quad e^2=1-(b/c)^2\\ b_1&=(8/3\pi e^2)[(1-e^2)K(e)-(1-\tfrac{1}{2}e^2)E(e)]\end{aligned}\right\}. \tag{4}$$

For values of bc/ah less than about 2, no simple explicit formula can be given for σ_m. An exception is the limiting relation

$$\lim_{bc/ah\to 0}\sigma_m/\sigma_{sm}=1. \tag{5}$$

Detailed derivations, together with numerical results, will be published in the near future.

Shadowgrams of Spherical Missiles Entering Water at Supersonic Speeds

J. H. McMillen, R. L. Kramer, and D. E. Allmand
Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland
October 24, 1950

While a great deal is known about the flow of water when objects are propelled through it at modest speeds, very little is known about the flow or other physical responses of the water when objects are shot into it at supersonic speeds. In order to investigate the events which accompany water entry at supersonic speeds (above 4800 ft./sec.), a shadowgraphic investigation was carried out in which spherical missiles were shot into water at speeds of 7000 ft./sec. These speeds correspond to a Mach number of 1.46 in water. Shadowgraphic records have the advantage that they indicate the simultaneous (exposure times less than a microsecond) general disposition of the transient pressure field over the entire field.

Some of the shadowgrams obtained in this investigation are reproduced in Fig. 1. The one-eighth-inch steel spheres used were not permanently deformed by the impact. These shadowgrams

Fig. 1.

are of various shots taken at increasing depths of water penetration. The first shadowgram records the spherical missile just before impact; the last one records the entry after the shock wave has advanced eighteen sphere diameters from the surface. In the early stages of entry all the light passing through the shock wave region is strongly refracted and a complete shadow silhouette is recorded. At the later stages the light passes through with less deviation and some of the features of the interior of the region, such as cavity, can be observed. In the air above the water one finds the shadow of the splash which rises with supersonic speeds in air.

Information on the pressure field in the vicinity of the missile and shock wave can be augmented by obtaining shadowgrams using narrow $\frac{1}{8}$-inch spark beams. If the region between the shock front and the water surface is regarded as half a spherical lens, then this exploratory beam method shows that the "lens" has both a diverging and a converging action. The converging lens action occurs for rays which are nearly tangential to the shock front. These rays are refracted toward the center and produce the pattern of lines found in the shadow of the cavity. The diverging action occurs for rays striking the central portion of the shock wave region. In the early penetration stages these rays diverge so strongly that the shadow region is left completely dark and in the intermediate stages the downward refraction of these rays leaves a dark band below the water surface. A study of the refraction of individual spark beams shows that the density (or pressure) increases rapidly in going from the water surface toward the nose of the missile and also that the pressure increases abruptly in approaching the shock wave from the undisturbed region in front. These pressure gradients are quite large, since the distances are small; the peak pressure or stagnation pressure is at least 20,000 atmospheres at entry.

It is also interesting to note that the missile is set into vibration at impact and secondary waves are produced throughout the missile's water flight. In the last shadowgram one can observe these secondary waves after they have been reflected in the surface.

This investigation was partially supported by the ONR.
